EVAPORATION FROM A FREE WATER SURFACE

By G. H. Hickox,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Carl Rohwer, C. W. Thornthwaite, Harry F. Blaney, Arthur A. Young, A. A. Kalinske, Adolph F. Meyer, Maurice L. Albertson, and G. H. Hickox.

Synopsis

Experiments on an evaporation pan, 1 ft in diameter, in still air and under controlled conditions, are described in this paper. An analogy is drawn between heat transfer and mass transfer as they occur in evaporation, and evaporation rates are expressed by means of appropriate dimensionless groups.

The results of the experiments are correlated by the use of these dimensionless groups, and the effects of the variables—vapor-pressure difference, wind velocity, pan diameter, water temperature, air pressure, rim height, color of pan, and depth of pan—are discussed and evaluated.

Suggestions are made for the further study of evaporation records and for obtaining field data.

Introduction

Evaporation records in the United States have been obtained by observations on small pans, the purpose being generally to provide a basis for estimating the evaporation from larger bodies of water such as lakes and reservoirs. Direct measurements on large bodies of water are extremely hard to obtain because of the difficulty of measuring inflow, outflow, and leakage with sufficient accuracy.

It is well known that evaporation from the small pans in use is not the same as the evaporation from lakes and reservoirs and considerable effort has been made to determine the relationship between pan evaporation and lake evaporation. The pans most commonly used are the exposed land pan, the buried land pan, and the floating pan (1).[2] Carl Rohwer, M. Am. Soc. C. E. (1), has assembled data comparing the evaporation from various types of pans and reservoirs, and has computed the coefficients necessary to convert pan

---

Note.—Published in October, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Senior Hydr. Engr., TVA, Hydraulic Laboratory, Norris, Tenn.

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (see Appendix I).

evaporation to reservoir evaporation. The coefficients vary with the type of pan, the locality, and the season of the year. The final report (2) of the Sub-Committee on Evaporation of the Special Committee on Irrigation Hydraulics of the Society has adopted 0.70 as the value of the coefficient to reduce annual evaporation from the U. S. Weather Bureau Standard Class A evaporation pan to reservoir evaporation. This coefficient is based largely on Mr. Rohwer's data and it is stated that a reasonable range of the coefficient is from 0.60 to 0.82. This represents a variation of 31%.

The variation can be accounted for by taking into consideration the various factors that affect the transfer of heat energy to and from the evaporation pan. The difference between the energy supplied by radiation, and the energy lost by back radiation, conduction, and convection, must be utilized either to heat the water or to evaporate it. If the differences in radiation, conduction, and convection can be established for two pans under similar conditions, it should be possible to compute the difference in evaporation. It should also be possible to apply similar calculations to determine the evaporation from a reservoir.

If such calculations can be made satisfactorily, it will be possible to utilize to much better advantage the large mass of evaporation data that have been collected and summarized (3). Robert Follansbee, M. Am. Soc. C. E. (4), has made an attempt to reduce a great many existing evaporation pan records to evaporation from reservoirs. In doing so, he has used coefficients for each pan which are average annual values and has applied them to monthly and seasonal evaporation. The application of average annual coefficients to monthly records is open to question, particularly since many of the data supporting these annual coefficients were obtained in localities where there is little evaporation in the winter months. An annual coefficient based on such data would not be expected to be quite applicable to Southern California, for example.

Until it has been established that calculations, as outlined, can be made with sufficient accuracy, considerable progress can be made by analyzing the factors that affect evaporation. An understanding of the physical occurrences of the evaporation process would lead to observations of those elements of the problem which would make the transfer of pan records to reservoirs more reliable.

The purpose of this paper is to describe the mechanism of evaporation, to draw an analogy between heat transfer and evaporation, to define the relationship between evaporation and certain basic factors, and to show how the results obtained by a number of different experimenters can be correlated.

HOW EVAPORATION OCCURS

When water changes its state from a liquid to a vapor it is said to evaporate. The transformation requires energy that is known as the latent heat of evaporation. In order for a given mass of water to evaporate and at the same time to maintain its temperature, energy must be supplied to replace that required for evaporation. If there is no loss of heat across the boundary of the mass other than that due to evaporation, the rate of supply of energy is a measure of the rate of evaporation. This is the basis of one method of calculating evaporation. The actual calculation is difficult because there are several ways in which energy may be added to and removed from a mass of water, not all of which are susceptible of easy evaluation.

From the kinetic standpoint, evaporation occurs when more molecules pass through the surface from the liquid to the surrounding gas than pass from the gas into the liquid. The molecules composing a liquid are in constant motion. Those near the surface are somewhat restrained in their motion by the fact that they are acted on more strongly by the greater number of molecules below them. Nevertheless, a few of these molecules will have energy enough to break through the surface and escape as vapor. In the space immediately above the liquid, there are molecules of the gas which are also in violent motion. A number of these molecules will strike the surface and occasionally will pass through it into the liquid. The rate at which molecules leave the surface depends on the energy with which these molecules move about in the liquid; that is, on the temperature, or the vapor pressure, of the liquid. Similarly, if the space above the liquid contains only its own vapor, the rate at which molecules enter the liquid depends on the number of molecules present and on the energy, or temperature, of the gas, or its vapor pressure. The net loss of molecules from the liquid, or rate of evaporation, thus depends on the difference between the vapor pressure of the liquid at its temperature and the vapor pressure of the gas above it. The rate of evaporation is somewhat reduced by the presence of the gases above the surface of the evaporating liquid (5).

For evaporation to continue, the molecules leaving the surface must be removed from the immediate vicinity. If they were not so removed, their number would increase to the point where the number of molecules entering the surface would equal the number leaving. The liquid then would be in equilibrium with its own vapor and evaporation would cease. The pressure of the gas immediately above the surface of the liquid would be equal to the vapor pressure of the liquid at that temperature. Ordinarily, the molecules are removed by two processes—diffusion and turbulence. The molecules leaving the surface must first pass by diffusion through a thin layer of gas, known as the boundary layer. The laws governing the diffusion of a gas are well known and if it were possible to measure the vapor concentration on both sides of the boundary layer, as well as the thickness of the layer, the rate of passage of molecules, and hence the evaporation, could be calculated easily. Unfortunately, there is no existing technique for making these measurements. After passing through the boundary layer, the vapor molecules are removed more completely by convection in which turbulence is frequently a governing factor. The laws governing transport of mass by turbulence are fairly well understood, but there are certain fundamental constants entering into the equations which have not yet been sufficiently well established for all conditions of atmospheric turbulence. However, an attempt has been made to calculate evaporation by means of the vapor concentration and wind velocity at two different levels above an evaporating surface with fair results (6).

The process of heat transfer from a solid to a gas is analogous to the removal of vapor particles from an evaporating water surface. A boundary layer of stagnant gas surrounds the solid through which heat is transferred by conduction alone. Outside the boundary layer, the heat is transferred by convection, frequently aided by turbulence. Heat transfer has been computed successfully by the use of an over-all transfer coefficient, combining the coefficients of conduction and convection, known as a film coefficient. The temperature difference used with this coefficient is the wall temperature of the solid boundary and the temperature of the surrounding gas at a considerable distance. There seems to be no reason why the rate of transfer of vapor particles cannot be calculated in an entirely similar fashion. The potential difference is the difference in vapor concentration, or vapor pressure, between the water-air interface and some far distant location. The evaporation coefficient, of course, must be determined experimentally. Heat-transfer coefficients are correlated by means of dimensionless groups. Similar groups may be used to correlate evaporation coefficients.

Evaporation as a Mass Transfer Process

Evaporation Into Still Air.—According to the kinetic theory, evaporation from a water surface is a function of the difference in water-vapor concentration at the water surface and at a distance, and of the nature of movement of the gas into which evaporation occurs. It is a process of mass transfer which is analogous to heat transfer.

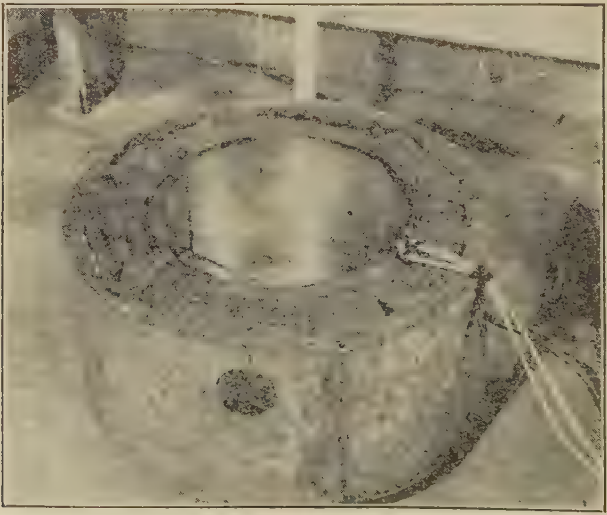

Fig. 1.—Evaporation Pan, Showing Outer Shell, Insulation, Thermocouples for Measuring Temperatures, and Heater Leads. False Floor of Quieting Chamber Removed

Experiments to study evaporation into still air from a circular water surface 1 ft in diameter were undertaken at the University of California at Berkeley. Space for conducting the experiments was made available by the Civil Engineering Department in one of its concrete curing rooms where the temperature and relative humidity were maintained during the course of the experiments at average values of 71.0° F and 53.1%, respectively. The evaporation pan was made of tin-plated copper, 12 in. in diameter and 6 in. deep. It was insulated by a 4-in. layer of hair felt. Thermocouples were placed at various points within the pan to measure water temperatures. Heat was supplied by an electric heating element immediately below the pan which was enclosed by a quieting chamber 5 ft square and 7.5 ft high in order to reduce stray air currents. A false floor was built and the pan was mounted so that the water surface was flush with it. A few tests were made with the rim of the pan projecting 0.5 in. and 1.5 in. above the false floor. All operations, including filling the pan and measuring evaporation rates and temperatures, were conducted from outside the chamber. Water and air temperatures inside the chamber were measured by thermocouples. Air temperature outside the chamber was measured with a thermometer. Relative humidity was measured with a standard sling psychrometer. The heating element was supplied with direct current power, controlled by rheostat, and measured with voltmeter and ammeter. Atmospheric pressure was measured by a recording barograph. Fig. 1 illustrates the evaporation pan (7*b*) and Fig. 2 shows the relative arrangement of apparatus.

Fig. 2.—Arrangement of Evaporation Pan, Quieting Chamber, and Instruments

The rate of evaporation was measured by an optical interferometer especially designed for the purpose. It consisted of a tilting mirror B and a glass plate A (Fig. 3). Monochromatic light from a source E was reflected toward the plate and mirror, producing interference bands which were then observed through a telescope. The tilting mirror was actuated by a float in a cylinder connected with the evaporation pan. As the water level changed, the number of interference bands visible between two lines etched on the glass plate changed. The change ΔN in the number of bands that occurred in the space a between the lines is a measure of the depth of evaporation E, which can be expressed by the equation

$$E = \frac{l}{a}\frac{\lambda}{2}\Delta N \quad \ldots\ldots (1)$$

In Eq. 1, l = length of lever arm; a = the space between two etched lines on a glass plate; and λ = the wave length of light. All letter symbols used in this paper have been collected and defined in Appendix II. Fig. 3 is a schematic diagram of the evaporimeter and Fig. 4 shows the type of interference pattern produced (7*c*). This meter was so sensitive that a determination of evaporation rate could be made in from 5 to 15 min. In fact, for high water temperatures the number of bands changed so rapidly that it was difficult to count them.

FIG. 3.—SCHEMATIC DRAWING OF EVAPORIMETER

Before making any observations, the temperatures and evaporation rate were allowed to become steady, and were maintained as nearly constant as possible throughout the test.

The basic equation for conduction of heat may be written

$$dq = k\frac{\partial t}{\partial x}\,dA \quad \ldots (2a)$$

in which: A = area in square feet; q = rate of heat transmission in British Thermal Units (Btu) per second; k = conductivity, in Btu per second-degree-foot; t = thermometric temperature; x = length along the path of heat flow; and $\frac{\partial t}{\partial x}$ = the temperature gradient in degrees per foot.

The analogous equation for mass transfer is

$$dw = D_v\frac{\partial c}{\partial x}\,dA \quad \ldots\ldots (2b)$$

in which, corresponding to Eq. 2*a*: w = rate of flow of vapor in pounds per second; D_v = diffusivity in feet^2 per second; c = unit vapor concentration, in pounds per cubic foot; and $\frac{\partial c}{\partial x}$ = unit concentration gradient in pounds per cubic foot-foot.

Experimental Data.—The results obtained have been plotted in terms of concentration difference and evaporation rate in Fig. 5. Because of the scattering of the points, they have been represented arbitrarily by two straight lines. The equations of these lines are, for $\Delta c < 4.2 \times 10^{-4}$,

$$w_A = 0.0045\,\Delta c \quad (3a)$$

and, for $\Delta c > 4.2 \times 10^{-4}$,

$$w_A = -\,0.0000059 + 0.0183\,\Delta c \quad (3b)$$

In Eqs. 3, w_A is the weight rate of evaporation in pounds per (square foot)-second and Δc is the concentration difference in pounds per cubic foot.

When water evaporates from a circular surface into still air so that the vapor is removed by diffusion alone, the rate of evaporation can be calculated with the aid of the following equation developed by H. Gröber and Sigmund Erk (8) for calculating the transmission of heat q through a circular area of radius r into a semi-infinite solid:

$$q = 4\,k\,\Delta t\,r \quad (4)$$

Applying the analogy between heat transfer and diffusion, the evaporation w_A may be written as

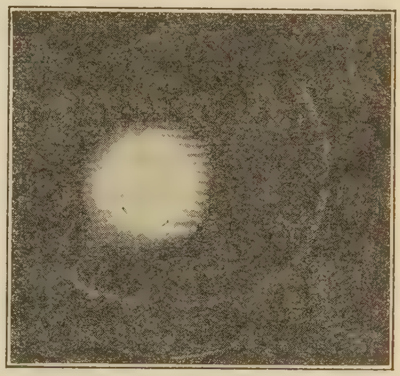

Fig. 4.—Typical Interference Bands Produced by Interferometer

$$w_A = \frac{4\,D_v\,\Delta c}{\pi\,r} \quad (5)$$

This equation is represented in Fig. 5 by the dashed line. The difference between this equation and the experimental values needs explanation. Eq. 5 applies only when the diffusing gas is moving through another stationary gas, which was not the case in these experiments. The movement of water vapor was aided materially by convection currents caused by the heated air next to the water surface, thus increasing the rate of evaporation considerably over that governed by diffusion alone. It is not necessary for the water surface to be warmer than the air, however, in order for convection currents to exist. Since water vapor is lighter than air, convection currents may be set up due to differences in density even when the temperatures of the water and the air at a distance are the same.

For this series of experiments there was a critical temperature of the water surface at which the layer of the air and water vapor immediately above it had the same density as at a distance. When these densities were equal, there should be no convection currents, and evaporation should be governed by diffusion alone. Below this critical temperature, the layer next to the water surface is cooler than the air above and does not rise. It probably increases in thickness until a slow movement occurs toward the edges of the pan. The evaporation rate for this condition should be slightly greater than that for diffusion due to the movement of the air in removing saturated vapor. Fig. 5 shows that a break in the curve, with a change in the rate of evaporation, actually occurs at a concentration difference of about 4.2 × 10^{-4} lb per cu ft. Under the conditions of these tests, the weight of a cubic foot of air and water vapor at a distance was 0.0743 lb per cu ft. Calculation shows that a mixture of saturated water vapor and air has the same unit weight at a temperature of 67.7° F and the unit weight of the water vapor will be 10.7 × 10^{-4} lb per cu ft. An average of test data for eight runs in the immediate vicinity of the break in the curve of Fig. 5 gave the water temperature as 68.2° F and the unit weight of water vapor at the water surface as 10.77 × 10^{-4} lb per cu ft. This is excellent agreement.

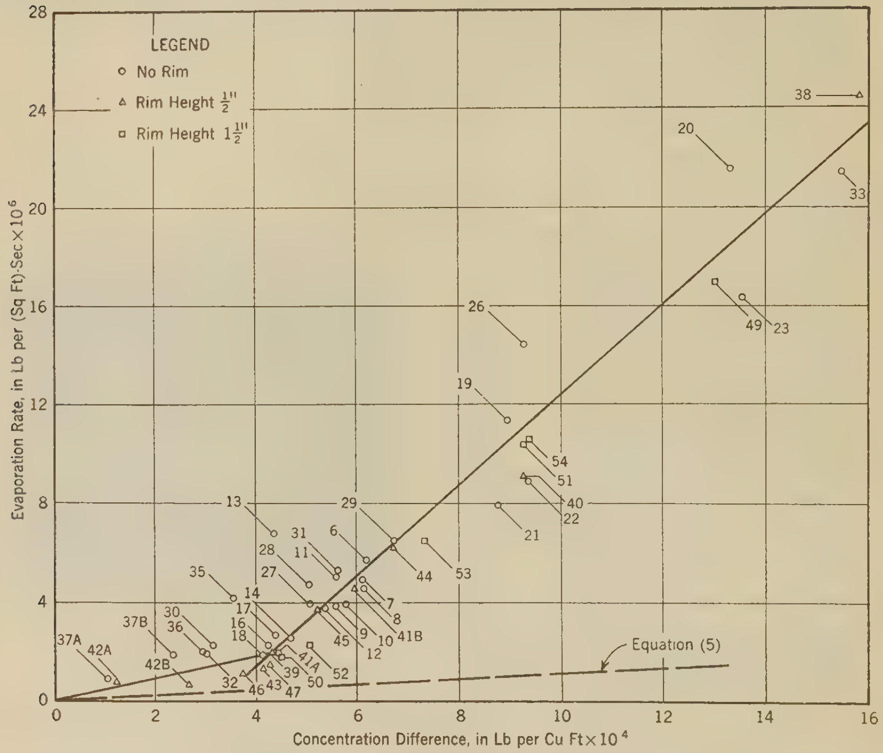

Fig. 5.—Evaporation Rate Versus Concentration Difference

Examination of Fig. 5 shows that Eq. 5 does not apply even when there seems to be no convection. This is probably due to the fact that it is practically impossible to bring the air absolutely to rest. Under the conditions given, the rate of evaporation given by Eq. 5 is 0.278 × 10^{-6} lb per (sq ft)-sec, and the corresponding velocity of the saturated vapor diffusing through air at rest is $V = \frac{0.278 \times 10^{-6}}{10.7 \times 10^{-4}} = 0.00026$ ft per sec. It is evident that a slight movement of air over the water surface would increase the removal of water vapor materially.

Dimensionless Representation.—The data of Fig. 5 for vapor transfer can be represented by dimensionless moduli in a manner similar to that for heat transfer by convection. In general, for heat transfer by free convection, experimental data may be represented by

$$N_{Nu} = f\,(N_{Gr}, N_{St}) \qquad \text{(6a)}$$

in which (see Eqs. 22*a*, 21*a*, and 24*a*, Appendix II): N_{Nu} = Nusselt's number; N_{Gr} = Grashof's number; and N_{St} = Stanton's number. Following the analogy between heat transfer and mass transfer, experimental data on evaporation in free convection may be represented by

$$(N_{Nu})' = f\,[(N_{Gr})', (N_{St})'] \qquad \text{(6b)}$$

in which (see Eqs. 22*b*, 21*b*, and 24*b*, Appendix II): $(N_{Nu})'$ = Nusselt's number primed; $(N_{Gr})'$ = Grashof's number primed; and $(N_{St})'$ = Stanton's number primed. Eq. 6*b* is commonly written in the form

$$(N_{Nu})' = K' \left[\frac{(N_{Gr})'}{(N_{St})'} \right]^{n} \qquad \text{(6c)}$$

in which K' = a coefficient and n = an exponent. Values of Nusselt's number primed, Grashof's number primed, and Stanton's number primed, and values of the Grashof-prime Stanton-prime ratio were computed from the experimental results for all the tests shown in Fig. 5. Nusselt's number primed has been plotted against the Grashof-prime Stanton-prime ratio in Fig. 6. The best straight line through the points can be represented by the

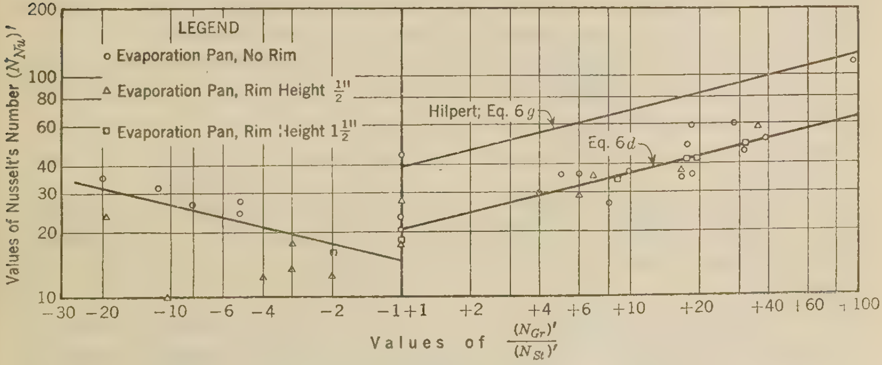

FIG. 6.—NUSSELT'S NUMBER $(N_{Nu})'$ VERSUS THE RATIO $\frac{(N_{Gr})'}{(N_{St})'}$

equation

$$(N_{Nu})' = 0.645 \left[\frac{(N_{Gr})'}{(N_{St})'} \right]^{0.25} \qquad \text{(6d)}$$

Here K' and n of Eq. 6*c* have values of 0.645 and 0.25, respectively.

The only experimental data available for comparison are those of R. Hilpert (9) on moist vertical plates which have been expressed by V. H. Cherry (10) as

$$(N_{Nu})' = 0.94\, (N_{Gr})' f\, (N_{St})' \qquad \text{(6e)}$$

If it be assumed that this can be written as

$$(N_{Nu})' = 0.94 \left[\frac{(N_{Gr})'}{(N_{St})'} \right]^{0.25} \qquad \text{(6f)}$$

and that $(N_{Nu})'$ should be increased 30% for the upper face of a horizontal surface as suggested by W. J. King (11),

$$(N_{Nu})' = 1.22 \left[\frac{(N_{Gr})'}{(N_{St})'} \right]^{0.25} \qquad \text{(6g)}$$

This equation has been plotted in Fig. 6.

Evaporation Into Air in Motion.—The general equations for diffusion of one gas through another gas in motion have not as yet yielded a direct solution to the problem of evaporation into atmosphere. F. Graham Millar (12) has succeeded in approximating actual evaporation records by calculations based on turbulence and eddy diffusivity, but is able to correlate Mr. Rohwer's work only by assuming Mr. Rohwer's anemometer to be in error. However, the diffusion equations have pointed the way to a correlation of experimental results by means of dimensionless moduli. The analogy between mass transfer and heat transfer by free convection has already been shown. A similar analogy for air in motion has been shown by T. K. Sherwood (13).

No experiments were performed to measure the evaporation into moving air, but it is possible to utilize the data of other experimenters. A satisfactory relationship can be expressed by an equation of the form

$$(N_{Nu})' = K\, (N_{Re})^{n} \qquad \text{(7a)}$$

n which N_{Re} = Reynolds' number. Eq. 7*a* can be valid only for values of $(N_{Nu})'$ greater than those for diffusion into still air since, for a given concentration difference, there is a minimum rate of evaporation which is governed by diffusion.

B. C. Shepherd, C. Hadlock, and R. C. Brewer (14) made experiments on evaporation from a free water surface and from saturated sand in pans 1 ft square in a wind tunnel. Water temperatures ranged from 86.4 to 132.8° F, vapor-concentration differences from 0.5×10^{-4} to 16.5×10^{-4} lb per cu ft, and wind velocities from 2.08 to 22.0 ft per sec. Although the data are slightly scattered, they may be represented by the equation

$$(N_{Nu})' = 0.103\, (N_{Re})^{0.75} \qquad \text{(7b)}$$

This equation is plotted in Fig. 7.

The inclusion of the data on evaporation from saturated sand is justified because no significant difference from evaporation from a water surface is evident. This is further substantiated by R. W. Powell (15), who performed experiments on evaporation from a free water surface and water retained by linen, filter paper, and gelatin.

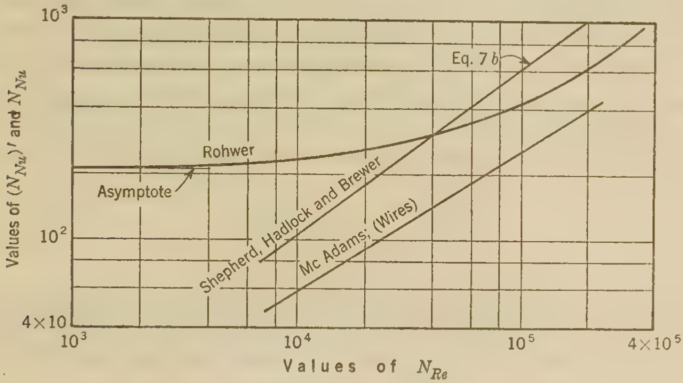

FIG. 7.—NUSSELT'S NUMBERS N_{Nu} AND $(N_{Nu})'$ VERSUS N_{Re}

Mr. Rohwer (16) made experiments on the rate of evaporation E from a 3-ft square pan in a tunnel with controlled wind velocities up to 17.5 ft per sec. He expressed his results in the equation

$$E = C\,(p_S - p_H) \qquad (8)$$

in which C is a constant coefficient and p_S and p_H, respectively, are the pressures of saturated vapor at the temperature of the water surface and the dewpoint. With an assumed average temperature for his experiments, it was possible to compute Nusselt's number primed and Reynolds' number. A curve based on Mr. Rohwer's experiments is plotted in Fig. 7.

These data, although not in sufficient detail to permit an accurate estimate of evaporation, tend to substantiate the analogy between heat and mass transfer. Further experimentation is needed in order to define the curve of $(N_{Nu})'$ versus N_{Re}. At present it may be assumed that $(N_{Nu})'$ varies approximately as the 0.75 power of N_{Re}, with a coefficient of about 0.1 or (compare Eq. 7b):

$$(N_{Nu})' = 0.10\,(N_{Re})^{0.75} \qquad (9)$$

CORRELATION OF RESULTS OF OTHER EXPERIMENTERS

Evaporation Into Still Air.—It has been shown that evaporation into still air probably can be expressed in the form

$$(N_{Nu})' = C\left[\frac{(N_{Gr})'}{(N_{St})'}\right]^{0.25} \qquad (10)$$

which is analogous to the equation used for heat transfer. For atmospheric conditions, $(N_{St})'$ is nearly constant, and may be neglected. Eq. 10 may then be written

$$\frac{h' L}{D_v} = C \left(\frac{L^3 \gamma \, \Delta\gamma}{g \, \mu^3} \right)^{0.25} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which h' = coefficient of mass (vapor) transfer; L = a characteristic dimension of the surface; γ = unit weight of water vapor and air; g = acceleration of gravity; and μ = coefficient of absolute viscosity. Eq. 11 may be transformed by a number of substitutions and assumptions. The evaporation E is proportional to $h' \, \Delta c$. Also, $(N_{St})' = \frac{D_v \gamma}{g \mu}$ = constant, and g is constant. It may be assumed, furthermore, that $\Delta\gamma$ is proportional to Δc. Hence

$$E \propto \Delta c \left(\frac{\mu \, \Delta c}{\gamma^3 L} \right)^{0.25} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

The viscosity varies approximately as $T^{0.50}$ and the unit weight as $\frac{p}{T}$, so that Eq. 12*a* can be written in terms of unit pressure p and temperature,

$$E \propto \Delta c^{1.25} \frac{T^{0.875}}{L^{0.25} \, p^{0.75}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12b)$$

The most important variable affecting the rate of evaporation is the difference in vapor concentration. This variable enters to the 1.25 power because of its effect on convection. The experiments on the 1-ft pan described in this paper showed that evaporation into still air varies as the 1.72 power of the concentration difference. J. W. Hinchley (17) found that the exponent was 1.2. J. R. Griffin (18) reports that his experiments combined with those of B. F. Sharpley (7) indicate an exponent of 1.25. Mr. Rohwer's data (16) give an exponent between 1.4 and 2.0. His apparatus was not completely shielded. Also he determined relative humidity at a distance from air which was drawn across the water surface before passing the psychrometer. Undoubtedly, the effect was a reduction in the apparent concentration difference. It also seems probable that the exponent is not constant because of the assumption made in deriving the equation. It was assumed that the difference in vapor concentration was proportional to the difference in unit weight. This would be true if the system were at one temperature throughout It was stated previously, however, that a vapor-concentration difference could exist without any difference in the unit weights because of the temperature difference. The vapor-concentration difference for which the difference in unit weight is zero depends on both the vapor concentration and the temperature of the air. This may explain the different results obtained by the various experimenters.

According to Eq. 12*b* the evaporation into still air may be expected to increase with the 0.875 power of the air temperature, and inversely as the 0.75 power of the air pressure. There are very few data available, however, on evaporation into still air and it is not possible to check these conclusions.

Most experimenters have developed formulas which express the evaporation in terms of vapor-concentration difference and wind movement in such a way that, for zero wind velocity, the evaporation is directly proportional to the concentration difference. The evaporation rate may be expected to vary inversely as the 0.25 power of the pan diameter. This effect is discussed in the next section. Because of the difficulty of producing absolutely quiet air, and the effect of even slight air movement, as shown previously, the discussion probably has more academic than real value.

Evaporation Into Air in Motion.—Following the analogy between heat transfer and mass transfer by free convection, if it is assumed that evaporation into wind can be expressed by

$$(N_{Nu})' = K\,(N_{Re})^{0.75} \qquad (13)$$

then

$$\frac{h'\,d}{D_v} = K\left(\frac{V\,\rho\,L}{\mu}\right)^{0.75} \qquad (14)$$

Making the same substitutions as before,

$$E \propto \Delta c\left(\frac{V^3\,\mu}{\gamma\,L}\right)^{0.25} \qquad (15a)$$

In terms of temperature and pressure,

$$E \propto \Delta c\,\frac{V^{0.75}\,T^{0.375}}{L^{0.25}\,p^{0.25}} \qquad (15b)$$

It will be noted that the effects of temperature and pressure are different in still and moving air. For high velocities, the exponents given by Eq. 15*b* may be expected to govern, and, for low velocities, they will tend to the value of Eq. 12*b*. It is interesting to examine the results of various experimenters in the light of Eq. 15*b*.

Practically all recent investigators find that evaporation is directly proportional to the difference in vapor concentration at the water surface and at a distance. This is the conclusion reached by Messrs. Rohwer (16), Shepherd, Hadlock, and Brewer (14), G. W. Himus (19), and Millar (12) among recent investigators and by the late D. FitzGerald, Hon. M. Am. Soc. C. E. (20), and J. A. Folse (21) earlier. The later experiments were conducted in wind tunnels with controlled velocities. For any velocity, it was found that evaporation was proportional to the vapor-concentration difference.

Recent investigators who disagree with this conclusion are H. C. Hickman, Assoc. M. Am. Soc. C. E. (22), G. N. Cox, M. Am. Soc. C. E. (23), and C. W. Thornthwaite and B. Holzman (6). Mr. Hickman found evaporation on the Great Lakes for zero vapor-concentration difference. His determination of vapor-pressure difference was based on but one observation of relative humidity per day which he applied to the average of the maximum and minimum air temperatures to obtain the average vapor concentration in the atmosphere. This is entirely in error since the relative humidity varies widely throughout the day and no single observation can be considered representative. It is quite probable that a vapor-concentration difference existed at the time the evaporation occurred. A more detailed discussion of Mr. Hickman's work, by the writer, has been published elsewhere (24).

Mr. Cox assumed "that the evaporation is a function of the difference between the vapor pressure as determined by the relative humidity and that which would exist for saturated vapor." This conclusion does not seem to be supported by other experimenters or to be justified by the kinetic theory. In fact, for a floating pan, Mr. Cox finds it necessary to introduce the difference of temperature between air and water in order to account for the variable effect of the vapor pressure at the water surface.

Messrs. Thornthwaite and Holzman point out that the movement of water vapor from water surface to air at a distance takes place by means of two entirely different processes—namely, by diffusion through a laminar boundary layer for a short distance and then by turbulence through the overlying atmosphere. They claim that no over-all transfer coefficient can account for the variations that occur in the boundary layer and the turbulent mass because of the varying degrees of roughness which are encountered and which affect both the thickness of the boundary layer and the degree of turbulence. They propose to measure evaporation by means of simultaneous readings of vapor-pressure concentration and wind velocity V at two different elevations H above the laminar layer. The roughness coefficient may be determined from the relationship

$$\log_e Z = \frac{V_2 \log_e H_1 - V_1 \log_e H_2}{V_2 - V_1} \quad \ldots\ldots\ldots\ldots\ldots (16)$$

Subscripts denote location of observation, 1 being the lower and 2 the upper location. The rate of vapor transfer, which is assumed to be equal to the rate of evaporation or condensation, is given by

$$E = \frac{(K_0)^2 (c_1 - c_2) V_2}{\log_e \frac{H_2}{H_1} \log_e \frac{H_2}{Z}} \quad \ldots\ldots\ldots\ldots\ldots (17)$$

This method is correct only for an adiabatic atmosphere and is subject to difficulties in the way of determination of constants; but it offers promise as a possible means of determining transpiration and evaporation from soils.

Effect of Wind Velocity.—According to Eq. 15*b*, the evaporation should vary as the 0.75 power of the wind velocity, other things being equal. Mr. Millar (12) found this to be the case for his experiments, and the data of Messrs. Shepherd, Hadlock, and Brewer (14) also conform to this criterion. Mr. Himus (19) found that evaporation varied approximately as the 0.77 power, and Mr. Powell and E. Griffiths' work (25) indicates a variation with the 0.85 power. The conclusions of Mr. Hickman (22) on this point are influenced by his erroneous determination of vapor concentration.

A number of investigators have used wind correction factors of the form $a + b\,V$, in which a and b are constants. A few are listed as follows:

Authority	Factor F
F. H. Bigelow (26)	$1 + 0.07\,V$
D. FitzGerald (20)	$1 + 0.5\,V$
A. F. Meyer (27)	$1 + 0.1\,V$
Carl Rohwer (16)	$1 + 0.268\,V$

Mr. Folse (21) proposed the following correction:

$$F = 0.358\,(V - 10.8) \qquad (18)$$

and R. E. Horton, M. Am. Soc. C. E. (28), gave a curve for velocities as great as 30 miles per hr. All these expressions except that of Mr. Folse are in a form which permits computation of evaporation at zero wind. Mr. Rohwer's experiments, however, indicated that evaporation into still air followed a different law. This is in accordance with the present analysis. Furthermore, zero wind does not mean the same for Mr. Rohwer's work as for that of the other investigators. Mr. Rohwer took considerable pains to see that the air surrounding his pan was quiet, whereas the other experiments were made outdoors where zero wind is that movement which is not recorded by an anemometer. The effect of even a slight air movement on evaporation has been discussed previously. For practical purposes, however, absolutely still air seldom exists and the form of the correction is suitable over an appropriate range of wind

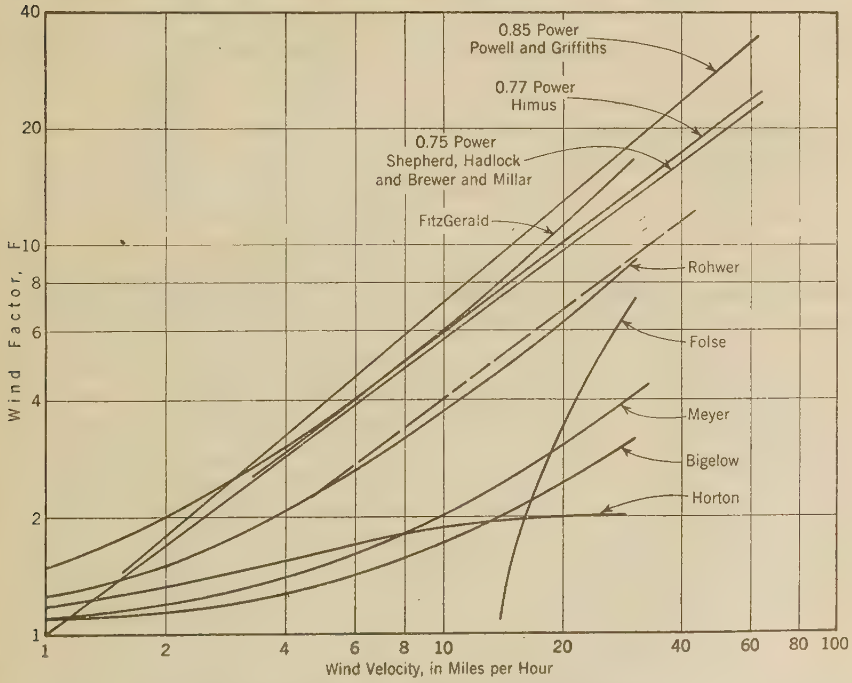

FIG. 8.—RELATION OF EVAPORATION TO WIND VELOCITY

velocity. Mr. Rohwer's correction, for example, conforms closely to the 0.75 power law between 5 and 30 miles per hr, whereas Mr. Bigelow's curve has the same slope between about 20 and 100 miles per hr. The exponential law has better theoretical and experimental support for velocities above about 2 miles per hr but cannot be used for extrapolation to zero wind. It can be very useful, however, in correlating results and in moderate extrapolation. The various correction factors are plotted in Fig. 8. The exponential forms have arbitrarily been given a value of unity at 1 mile per hr. For the purposes of this paper, the dashed line of Fig. 8 has been adopted as the best available wind correction factor.

Effect of Pan Diameter.—The effect of pan size has been studied by a number of investigators and the results are summarized herein.

TABLE 1.—EFFECT OF PAN SIZE ON EVAPORATION

No.	Description	Square pan	Circular pan	Reservoir
	Dimension	3 ft by 3 ft	Diameter, 4 ft	1,800 acres
1	Difference in vapor pressure (inches of mercury)	0.640	0.639	0.672
2	Wind velocity (miles per hour)	1.94	1.90	1.68
	Relative Evaporation:			
3	Observed	1.33	1.28	1.00
4	Corrected	1.32	1.29	1.00

Mr. Rohwer (1) compared evaporation from a 3-ft square pan and a 4-ft circular pan with that from a 1,800-acre reservoir with the results given in lines 1, 2, and 3, Table 1. Correcting the evaporation from the pans to the same vapor-pressure difference and wind velocity as that for the reservoir on the assumption that the evaporation varies directly with the vapor-pressure difference and with the wind as shown by the dashed curve in Fig. 8, the

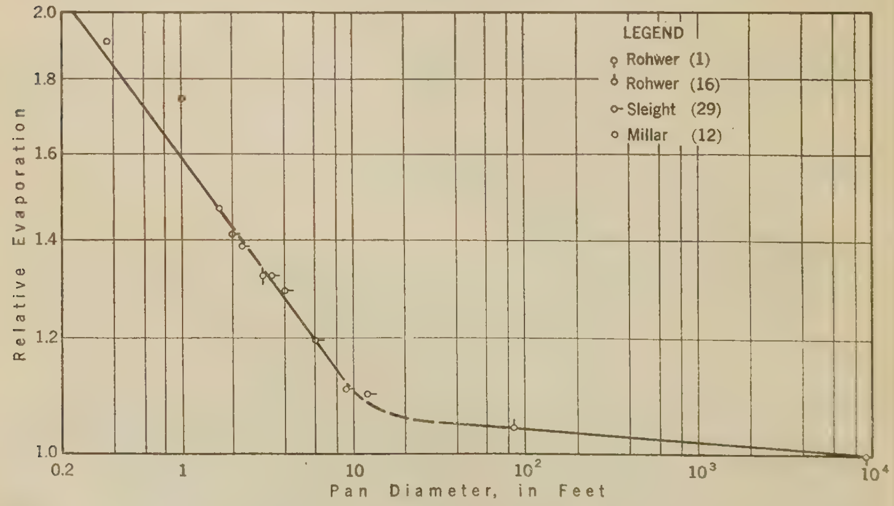

FIG. 9.—RELATION OF EVAPORATION TO DIAMETER OF SURFACE

relative evaporation rates are as shown in line 4, Table 1. The shape of the reservoir is not known, but if it is circular, its diameter is approximately 9,000 ft. These points are plotted in Fig. 9.

Mr. Rohwer (16) also compared evaporation from three different types of pans with that from an 85-ft reservoir. Only one of the pans was comparable, however, the others having different exposure. He found that evaporation from a 3-ft square pan was 26.6% greater than from the reservoir. Assigning the previous value of 1.32 to the 3-ft pan, the relative evaporation from the 85-ft reservoir is 1.043. This value is plotted in Fig. 9.

The late R. B. Sleight, Assoc. M. Am. Soc. C. E. (29), gave the relative rates of evaporation from circular pans of different diameters as indicated in Table 2. The last line of Table 2 gives the rate of evaporation relative to the 1,800-acre reservoir, assuming that the 4-ft pans of Messrs. Sleight and Rohwer were comparable. These data are also plotted in Fig. 9.

Compared with 1,800-acre reservoir as unity	1.099	1.108	1.196	1.290	1.320	1.383	1.410	1.745

Mr. Millar (12) found that the evaporation from a 50.8-cm pan was only 0.77 as great as from an 11.2-cm pan. Fig. 9 shows that the evaporation from a 50.8-cm (1.67-ft) pan relative to a large reservoir is about 1.47. The corresponding evaporation from the 11.2-cm (0.37-ft) pan is 1.91. This point is also plotted in Fig. 9. Two straight lines have been drawn through the points to represent the effect of pan size on evaporation. For pans smaller than, say, 10 ft, the evaporation varies as the − 0.16 power of the diameter, and for areas larger than 50 ft in diameter about as the − 0.01 power. It is doubtful if the transition occurs abruptly; it may be more gradual, as indicated by the dashed line.

The results are not in excellent agreement with Eq. 15*b*, but are close enough to indicate that the derivation of the equation may be valid.

Effect of Water Temperature.—According to Eq. 15*b*, the rate of evaporation should vary approximately with the 0.375 power of the absolute water temperature. The effect is difficult to find as a variation of 30° at a temperature of 70° F indicates a change in evaporation rate of only 2.1%. This is probably negligible in view of the other uncertainties.

Effect of Air Pressure.—A number of investigators have included a pressure term in their expression for evaporation. T. Russell (30) decided that evaporation varied inversely as the pressure, and Mr. Millar (12) decided it varied as the − 0.25 power. On the basis of scanty data, Mr. Sleight (29) gave values which indicated that the evaporation varied inversely as the square of the pressure. Mr. Rohwer corrected the evaporation computed for Fort Collins, Colo., to other elevations by use of the factor

$$G = 1.465 - 0.0186\,B \qquad (19)$$

in which B is the barometric pressure in inches of mercury. Mr. Millar found that Mr. Rohwer's data were consistent with the -0.25 power of the pressure.

[a] All mean values, with units as follows: Col. 3, inches of mercury; Col. 4, miles per hour; Col. 5, degrees Fahrenheit; Col. 6, inches; and Col. 7, vapor-pressure differences in inches of mercury. [b] Estimated from altitude.

This may be confirmed by a brief analysis of Mr. Rohwer's data on the basis of the previous discussion. His results are summarized in Cols. 3 to 7, Table 3. In accordance with the conclusions drawn regarding the variation of evaporation with vapor-concentration (vapor-pressure) difference, wind velocity, and temperature (neglected), the rate of evaporation can be expressed as

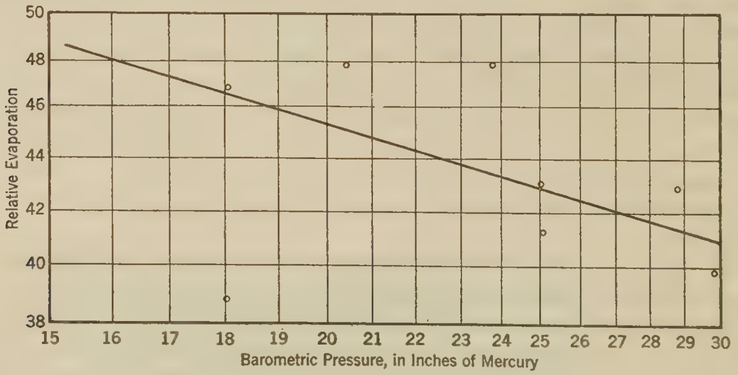

FIG. 10.—RELATION OF EVAPORATION TO BAROMETRIC PRESSURE

$$E \propto \Delta c\, f(V)\, f(B) \qquad (20)$$

in which $f(V)$ is a wind factor taken from Fig. 8. Values of $f(V)$ are given in Col. 8, Table 3.

Values of $f(B)$ obtained by dividing the observed evaporation by the vapor-pressure difference and the wind factor are given in Col. 9, Table 3. They are plotted against the pressure in Fig. 10. The line on this plate has been drawn arbitrarily with a slope of -0.25 and seems to represent the data as well as any other line that could be drawn through the points.

Eq. 15*b* is seen to be justified for representation of the effects on evaporation of vapor-pressure concentration difference, temperature, size of pan, air pressure, and wind velocities greater than about 5 miles per hr. It may be used for the correlation of experimental results and for moderate extrapolation.

Effect of Rim Height.—Three other variables have been observed to have an effect on evaporation from a pan although they have not been included in Eq. 15*b*. These are the height of rim above the water surface and the color and depth of the pan. R. W. Revell, Jun. Am. C. E. (31), attempted to evaluate the effect of rim height on evaporation from a Class A pan. He made experiments on pans having rim heights of 2 in. and 3 in. and found that more evaporation occurred into a wind from the pan with the 3-in. rim height during periods of moderate to high winds, but that less evaporation occurred from this pan during periods of low wind velocity. He suggested that the explanation of this difference in behavior lay in the difference in the size of the turbulent eddies caused by the passage of air over the rim of the pan. His data are so scattered that it is difficult to determine the effect quantitatively. He noted a higher water temperature in the pan with the 3-in. rim height, however, and attributed it in part to the lesser mass of water in the shallower pan. This assumption seems to be reasonable and is consistent with greater evaporation from this pan.

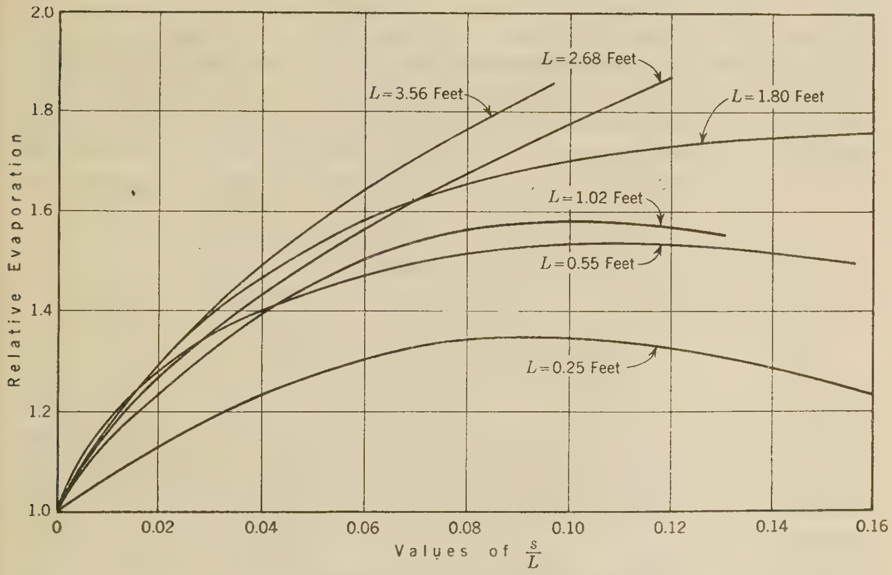

Fig. 11.—Effect of Rim Height on Evaporation

Mr. Powell (15) measured the evaporation from a cylindrical saturated surface in an air stream parallel to its axis. He found that the rate of evaporation was increased when a collar was placed around the cylinder at its leading end. He attributed the increase in evaporation to the increased turbulence of the air stream caused by the projecting collar. In Fig. 11, prepared from his data, the relative evaporation rate has been plotted against the ratio of height of collar to length of evaporating surface. It may be seen that the data for lengths greater than 2 ft and ratios of s/L less than about 0.08 may be represented with fair accuracy by a single curve. This is the range in which the Weather Bureau Standard Class A pan operates. The data by Mr. Powell are probably not strictly applicable to flat surfaces but the curve indicates that, if the rim height of a standard 4-ft pan be increased from 2 in. to 3 in. by evaporation or other loss, the relative evaporation rate in a wind of 6.7 miles per hr increases from 1.47 to 1.61, an increase of about 10%.

Effect of Pan Color.—The color of an evaporation pan has been observed to have an effect on the evaporation rate. This is undoubtedly due to the difference in absorption of solar and sky radiation which affects the water temperature and consequently the evaporation. A series of observations was made by the writer for one year, at Berkeley, on four pans of identical size, shape, and exposure. The pans were of galvanized steel, 1 ft square and 0.5 ft deep, and were buried in the ground so that the upper edge was just above the ground surface. They differed only in their color. Three were painted white, gray, and black, respectively, using lead base paint, and the fourth was left unpainted. Table 4(*a*) shows the results obtained. The

[a] Sixteen days only.

[b] Twenty-three days only.

black pan which should have had the greatest absorptivity showed 10.8% more evaporation for the year than the white pan and 5.8% more than the gray pan. The gray and galvanized pans showed almost the same results. The differences were not constant throughout the year, however, and, in some months, the annual trend was reversed. For example, from November to February, the evaporation from the white pan was greater than that from the gray pan. Significantly, the greatest differences were found during the months of maximum solar radiation. Similar effects have been noted by other investigators. Mr. Cox (23) found that, when a galvanized pan was painted with an asphaltic paint, the evaporation rate was increased about 10%. Mr. Rohwer (16) found a difference of 4% between two different brands of asphaltic paint.

Effect of Pan Depth.—The depth of an evaporation pan also has an effect on the evaporation rate. Very few data are available for exposed land pans but a few comparisons have been made for buried pans. The writer measured evaporation from four galvanized pans 1 ft square with depths of 3, 6, 12, and 24 in., respectively. The data summarized in Table 4(*b*) indicate that evaporation increased as the pan depth increased. This is not borne out by Mr. Sleight's results (29), which are as follows:

Depth of pan (ft)	Relative evaporation
0.25	127.9
0.75	126.8
1.25	127.9
1.75	127.9
2.75	128.4
5.75	127.4

The lack of agreement may be explained in part by the fact that Mr. Sleight's observations, with the exception of those on the 2.75-ft pan, were made during the period, May to September, whereas the Berkeley tests extended throughout the year.

Inspection of Table 4(*b*) shows that the relative evaporation for the Berkeley tests varies with the season. The totals for the shorter period are more nearly in agreement with Mr. Sleight's results in that the evaporation from the 3-in. pan is seen to be greater than that from either the 6-in. or the 9-in. pan. The temperature of the deeper pans appeared to be less affected by radiation than that of the shallowest pan because their masses were proportionately greater relative to the surface which received and emitted radiant energy. This led to higher temperature in summer and lower in winter, with a corresponding effect on the relative evaporation rates. Also, the deeper pans remained at a more nearly constant temperature because of the stabilizing effect of the earth with which they were in contact.

Correlation by Other Investigators.—Other investigators have also attempted to correlate their own results with those of others. Mr. Millar (12) was able to explain Mr. Rohwer's results with a fair degree of satisfaction, although he found what seemed to be a discrepancy in the wind velocities observed by Mr. Rohwer.

Mr. Powell (15) plotted $\frac{E\,L}{p_S - p_H}$ against $V\,L$ and was able to obtain a fair correlation of the results reported by Messrs. Millar (12), S. K. Banerji and H. M. Wadia (32), FitzGerald (20), T. B. Hine (33), Rohwer (16), H. Thiesenhusen (34), M. Lurie and N. Michailoff (35), and Shepherd, Hadlock, and Brewer (14). This excellent contribution should be read by all who are interested in this phase of the subject.

The Energy Balance Method of Calculating Evaporation.—Evaporation has been computed by several investigators by means of an energy balance. In this method, the total energy input (solar radiation), less the energy losses (back radiation, conduction, convection, increase of water temperature, and evaporation) must equal zero. If all quantities are known except the evaporation, this is determinable as a residual. The method has been described by Wilhelm Schmidt (36) and A. Angstrom (37) and later by N. W. Cummings (38)(39), Burt Richardson (39)(40), and others. These writers applied the method to lakes and oceans so that conduction through the walls was not a problem as with a pan. Messrs. Richardson and Cummings also used insulated pans.

In all cases the heat lost by convection has been an uncertain quantity. It was assumed by Mr. Schmidt that there was a ratio between the heat lost by convection and that used in evaporation since the processes of heat transfer by convection are analogous. I. S. Bowen (41) made the same assumption later and wrote at length to substantiate it, although in the meantime Mr. Angstrom (37) had shown the impossibility of such a ratio, pointing out that, if it existed, there would be, for a temperature gradient of zero, either no convection and no evaporation, or convection and a corresponding evaporation. It is obvious that both conditions are absurd. The first condition might be satisfied if the atmosphere were saturated with water vapor, but the second condition is impossible. Furthermore, Mr. Bowen assumed equilibrium conditions which seldom exist. Water temperatures are constantly rising and falling, so that the storage of heat is a considerable item in the energy balance, at times amounting to many times the energy used for evaporation. Under these conditions, the ratio varies considerably and, in fact, loses its significance entirely. Mr. Bowen's ratio can be significant only if applied to average conditions over a period of time long enough so that storage of heat is not a factor.

EVAPORATION MEASUREMENT IN THE FIELD

Instrumental Observation.—The factors entering Eq. 15*b* are the evaporation rate, the vapor-pressure difference, the wind velocity, the air temperature, the pan diameter, and the barometric pressure. The determination of these factors and their relationships requires field measurements of water surface temperature, air temperature, relative humidity, wind velocity, pan diameter, and barometric pressure. The methods of making these measurements depend somewhat on the purpose for which they are desired. Daily averages may be suitable for comparing evaporation at two stations which have similar climatic conditions, but are valueless for purposes of careful investigation. The distribution and range of temperature and humidity, for example, throughout the day, have a marked effect on the total evaporation. Most of the day's evaporation occurs when the water temperature is higher than the average, and the vapor pressure at the water surface is high. If the temperature were uniform throughout the day, the higher vapor pressure causing evaporation would not exist. Hence the average temperature has no particular significance with respect to daily evaporation, unless the range of temperature is also specified. Similar considerations apply to the measurement of air temperature and relative humidity since they govern the vapor pressure of the atmosphere. Probably much of the difficulty that is experienced in correlating field observations of evaporation lies in the indiscriminate use of daily averages for temperature and humidity.

A suitable method of measuring the evaporation rate depends on the purpose for which the information is desired. A careful study of evaporation requires that its rate be determined over short periods while the accompanying conditions are sensibly constant. For field data, daily totals will often be sufficient. The optical interferometer described in this paper is sensitive to half the wave length of the light used (about 0.00001 in. for green light), and is quite satisfactory where evaporation rates are desired over very short periods and where the instrument can be set on a very rigid support. It is suitable for experimentation under controlled conditions. Mr. Rohwer (1) described an optical lever arrangement that gave good results in the laboratory. The Tennessee Valley Authority secures a continuous record of evaporation from a standard Class A pan by mounting it on a balance with an attached device that prints the total weight of platform, pan, and water every 15 min. The standard hook gage is quite suitable for measuring daily totals, but is not accurate enough for short-period measurements.

The most important variable in Eq. 15*b*, after the evaporation rate, is the vapor-concentration difference. Its evaluation requires measurement of water temperature, air temperature, and relative humidity. The mechanics of the kinetic theory indicates that the water temperature should be measured as close to the surface as possible. The vapor concentration immediately above the water surface is dependent on the activity (temperature) of the molecules which pass through the surface. The temperature of a layer of water having a thickness equal to the mean free length of path of the molecules next to the surface is the temperature which governs the vapor concentration immediately above the water surface, and the rate of evaporation. This layer is very thin, probably only a fraction of a millimeter. Normally the water temperature increases from sunrise until about 2 p.m. by reason of solar radiation. During this period, the water temperature is highest at the surface. This is explained by Fig. 12, which shows that about 18% of the solar energy incident on the water surface is absorbed in the first millimeter of depth, causing a localized heating at the surface. The surface water, being warmer, does not sink, but remains on top. Typical measurements made in the middle vertical of a standard Class A evaporation pan with a mercury thermometer showed a temperature of 69° F with the bulb just under the surface, 67° one inch down, $65\frac{1}{2}$° at mid-depth, and $64\frac{1}{2}$° at the bottom. Since the bulb of the thermometer was about 4 mm in diameter, the temperature in the top millimeter was undoubtedly still higher. A small thermocouple placed just under the surface will give good results in laboratory work if properly shielded. It is not convenient for most installations since suitable potentiometers and recording equipment are expensive. Measurement of temperature with a copper-constantan thermocouple to the nearest tenth degree Fahrenheit requires measurement of potential with an accuracy of 2 microvolts. Satisfactory correlation of field observations probably can be obtained by the use of a thermometer with a cylindrical bulb placed horizontally in the upper quarter inch of water. It may be necessary to support it by means of a float where evaporation exceeds 0.1 in. per day to insure that the bulb is always submerged. Of course, the instrument should be shielded.

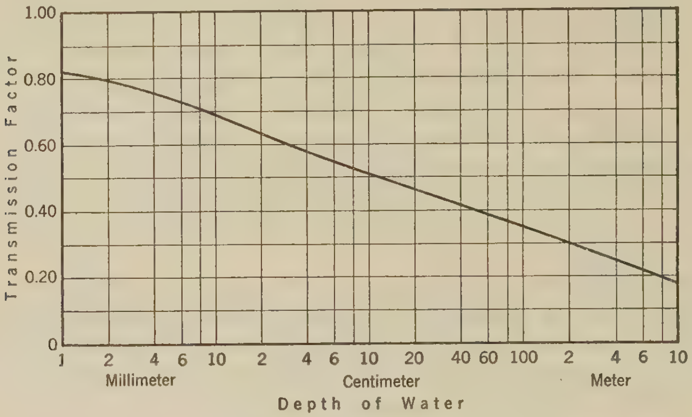

FIG. 12.—TRANSMISSIVITY OF WATER FOR SOLAR RADIATION

The most consistent correlation of evaporation rate with vapor-concentration difference has been found in the work of those experimenters who used pans heated from beneath rather than pans heated at the surface by solar radiation. Undoubtedly this is due largely to the fact that the experimenters on outdoor pans used average daily temperature, but may also be due, in part at least, to the difficulty of measuring the actual surface temperature.

Measurement of air temperature and relative humidity offers no particular difficulty. Suitable recording instruments are standard meteorological equipment. Care should be taken, however, that the measurements are made at a sufficient distance from the pan to be representative of conditions at a distance.

It is desirable to measure the wind velocity close to the surface of the pan, since practically all field installations as well as experimental laboratory tests have been made this way. The standard Weather Bureau anemometer as installed at Class A evaporation pans should be satisfactory.

The daily fluctuations of barometric pressure have a very slight effect on the evaporation rate. Barometric pressure needs to be considered only when comparing results obtained from installations at different altitudes. For this purpose, the average pressure corresponding to the altitude is sufficiently accurate.

Type of Evaporation Pan.—The pan itself has considerable effect on the evaporation and it should be standardized more carefully than has been common in past practice. It should be as large as can be handled conveniently since the change of evaporation rate with change of diameter becomes less as the diameter increases, making the results more reliable. The evaporation from a large pan also approaches more closely the evaporation from a lake, although this is not necessarily an advantage.

Mr. Powell's experiments show that the ratio of rim height to diameter has considerable effect on the evaporation rate. Fig. 11 indicates that a change in rim height for a given diameter has least effect on the evaporation rate when the ratio of rim height to diameter is about 0.1. Greater evaporation with an increased height of rim has been noted but has been variously attributed to the greater amount of solar radiation intercepted, and to evaporation from the water film drawn up the side of the pan by capillarity. The effect of rim height for a floating pan may be different from that for an exposed land pan. Further experimentation on this subject appears to be required. Until better information is available, it would seem desirable to maintain the rim height, or the depth of water in the pan, as nearly constant as possible.

The color and surface characteristics of the pan walls have an effect on the evaporation rate because of the variation in the absorptivity. The effect is not constant, but varies seasonally, although over a year's time a black pan will evaporate more water than a white one. For comparable results, pans should have similar surfaces which should be carefully maintained. The natural oxidation of a galvanized surface changes its absorptivity. Failure to clean pans frequently results in the growth of algae and a change in the characteristics of the surface.

Considerable amounts of heat are transferred through the sides and bottom of an uninsulated evaporation pan. It is evident that the ratio of wall area to surface area will affect the evaporation rate. Similar pans exposed under identical atmospheric conditions, but at different latitudes, will show differences in evaporation rate caused by the change in the angle of incidence of solar radiation on water surface and pan walls. The differences found between floating and buried pans as compared with an exposed pan can be accounted for by the difference in the amount of heat transferred through the pan walls. The amount of heat transferred can be calculated with approximate accuracy for the exposed and floating pans where the air and water temperatures, respectively, are known. It is much more difficult for the buried pan where the thermal conductivity of the soil is uncertain, varying with the moisture content, and the soil temperature is constantly fluctuating. The evaporation from a uninsulated pan is also affected by changes in the absorptivity of the outer wall of the pan. These difficulties can be most easily avoided by the use of an insulated pan. Further, the insulated pan has characteristics similar in many ways to a large body of water. Since heat transfer through the walls and bottom is minimized, the boundary or edge effect from this cause is made very small and the evaporation from the pan area approaches that from the larger body. The corrections depend largely on the pan geometry rather than on the meteorological conditions, which vary both locally and seasonally.

There seems to be no argument in favor of an uninsulated pan except cheapness. The cost of insulating a pan is not great. It may be argued that records from the standard Class A pan have the advantage of being comparable with each other. In view of the manner in which the data accompanying evaporation are obtained and recorded, it is doubtful if comparisons of results from Class A pans have much value.

In this connection, the writer wishes to call attention to an admirable discussion by Charles H. Lee, M. Am. Soc. C. E. (42), of the most important factors affecting evaporation, the shortcomings of the Class A pan, and the general confusion attending the subject of evaporation. Although first published in August, 1926, it appears not to have attracted the attention it deserves. Two quotations may not be out of place:

> "The writer's experience has led to the conclusion that in order to use data obtained from the Class A land pan it is necessary to determine a convection factor, which will differ for every locality or meteorological condition."
>
> "* * * much of the confusion and uncertainty which exists regarding evaporation rates is due to a failure to consider the fundamental factors in choosing observational methods."

Suggestions for Further Study

It is suggested that further study of the subject of evaporation from the standpoint of practical use be along the following lines:

1. The establishment of a standard evaporation station with accompanying measuring instruments designed to recognize the fundamental principle of evaporation and to measure the significant variable factors in such a way that they may be useful in correlating the observational results.
2. A study of the probable heat-transfer losses through the walls of uninsulated pans for an average day for each month of the year at all stations where there are significant changes in air temperature, humidity, or insolation. Such a study would make it possible to recompute the recorded evaporation in terms of that from an insulated pan. Although the original data are not in the best form, it is possible that a much better correlation of existing data could be obtained in this manner than is now available.
3. A study of the relationships between the existing data and those obtained from the new standard pan with the purpose of correlating all records as far as possible.

Acknowledgment

This paper is a condensation and revision of a dissertation by the writer entitled "Evaporation from a Limited Free Water Surface." It was submitted in July, 1939, in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Mechanical Engineering in the Graduate Division of the University of California.

The writer wishes particularly to acknowledge the interest, encouragement, and advice offered during the study by Professors L. M. K. Boelter, M. P. O'Brien, M. Am. Soc. C. E., and L. B. Loeb of the University of California, and the cooperation of the Tennessee Valley Authority through A. S. Fry, M. Am. Soc. C. E., Head Hydraulic Engineer, in the use of its experimental evaporation apparatus.

A copy of the dissertation, containing observational data, details of calculation, and additional technical discussions, has been placed on file in the Engineering Societies Library for further reference.

APPENDIX II

NOMENCLATURE

In dealing with material drawn from many sources, the meanings of symbols inevitably become confused necessitating changes in the notation used by the original authors. The following symbols, defined where they first appear, conform essentially with American Standard Letter Symbols for Heat and Thermodynamics Including Heat Flow,[3] prepared by a Committee of the American Standards Association, with Society participation, and approved by the Association in 1943:

A = area of water surface;
a = spacing of etched reference lines on a glass plate (see also b);
B = barometric pressure;
b = a constant expressing the form of a wind correction factor; as $a + b\,V$;
C = coefficient in Eqs. 10 and 11;
C_R = coefficient;
c = unit vapor concentration; Δc = concentration difference;
c_p = specific heat at constant pressure;
D_v = diffusivity;
E = depth of evaporation;
e = base of natural logarithms;
F = a wind correction factor (Eq. 18);
G = a barometric pressure correction factor (Eq. 19);
g = acceleration of gravity;
H = elevation above ground surface (Eq. 16);
h = coefficient of heat transfer;
h' = coefficient of mass (vapor) transfer;
K = coefficient in Eqs. 7, 13, and 14;
K' = coefficient in Eq. 6c;
K_0 = von Kármán's universal roughness coefficient;
k = thermal conductivity;
L = characteristic dimension of a surface; diameter of an evaporation pan; length of a cylinder;
l = length of lever arm of interferometer evaporimeter;
N = number of interference bands; also a dimensionless number (Eqs. 6); when primed, these dimensionless numbers characterize mass transfer;
ΔN = change in number of interference bands (Eq. 1);
N_{Nu} = Nusselt's number;
N_{Gr} = Grashof's number;
N_{Re} = Reynolds' number;
N_{St} = Stanton's number;
n = exponent in Eqs. 6 and 7;
p = unit pressure;
p_S = pressure of saturated vapor at the temperature of the water surface;
p_H = pressure of saturated vapor at the temperature of the dewpoint;
q = rate of heat transmission;
r = radius;
s = height of a collar on a cylinder;
T = absolute temperature;
t = thermometric temperature;

---

[3] ASA — Z10.4 — 1943.

V = wind velocity;
w = flow rate of vapor;
w_A = flow rate of vapor per unit area;
x = length along path of heat flow or vapor transfer;
Z = coefficient of roughness in Eq. 16;
β = coefficient of expansion;
γ = unit weight of mixture of air and water vapor; $\Delta\gamma$ = difference in unit weights;
λ = wave length of light;
μ = coefficient of absolute viscosity;
ρ = mass density.

Dimensionless Moduli.—Dimensionless groups have been used freely throughout the paper. Because of their usefulness in classifying physical phenomena and their independence of dimensions, they are widely used for correlation of experimental data. In applying these dimensionless groups, physical properties were evaluated at the arithmetic mean temperature of the fluid.

Grashof's number—

$$N_{Gr} = \frac{L^3 \, \Delta t \, \beta \, \gamma^2}{g \, \mu^3} \quad \text{(21a)}$$

—characterizes the movement of a gas or liquid under the influence of inertia forces and the buoyancy caused by temperature differences. It is associated with heat transfer by convection. Grashof primed—

$$(N_{Gr})' = \frac{L^3 \, \gamma \, \Delta\gamma}{g \, \mu^3} \quad \text{(21b)}$$

—is similar to the Grashof number but characterizes convection associated with mass transfer.

Nusselt's number—

$$N_{Nu} = \frac{h \, L}{k} \quad \text{(22a)}$$

—characterizes the phenomenon of heat conduction between a solid and a gas or liquid. Nusselt primed—

$$(N_{Nu})' = \frac{h' \, L}{k} \quad \text{(22b)}$$

—is similar to Nusselt's number but characterizes mass transfer between a solid and a gas, as in evaporation.

Reynolds' number—

$$N_{Re} = \frac{V \, \rho \, L}{\mu} \quad \text{(23)}$$

—characterizes the movement of a gas or liquid under the influence of inertia and viscous forces.

Stanton's number—

$$N_{St} = \frac{k}{\mu\, c_p\, g} \quad \text{(24a)}$$

—characterizes the conduction of heat into a viscous fluid which is in motion. Stanton primed—

$$(N_{St})' = \frac{D_v \gamma}{\mu\, g} \quad \text{(24b)}$$

—is similar to Stanton's number but is applicable to mass transfer into a moving viscous fluid, as evaporation into air.

DISCUSSION

Carl Rohwer,[4] M. Am. Soc. C. E.—Observations on the evaporation from free water surfaces in pans are usually made either to discover the fundamental laws showing the relation between the meteorological data and evaporation or to make available information from which it will be possible to estimate the loss by evaporation from large bodies of water such as lakes, reservoirs, and streams.

Because of the complex nature of evaporation phenomena and the many dependent variables involved, investigators have resorted to various expedients when developing evaporation formulas to simplify the analysis of the effect of the influencing factors. Since the laws governing certain similar physical phenomena such as turbulence, heat conduction, and mass transfer have been fairly well established, the analogies between these phenomena and evaporation are sometimes used as a basis for attacking the problem of determining the laws of evaporation. This is the method adopted by the author. However, evaporation laws cannot be developed by analogy alone because there are certain constants involved which must be determined experimentally, and for which carefully controlled evaporation observations are necessary.

The evaporation formula (Eq. 5) based on analogy between heat transfer and diffusion developed by the author is represented by the dashed line in Fig. 5. Evaporation data obtained by the author, by means of the optical interferometer designed by him, when plotted on the same figure, result in the two full lines that meet at the point where the vapor-concentration difference is 4.2×10^{-4} lb per cu ft. Since the line representing Eq. 5 and the lower part of the line representing the experimental data both pass through the origin, Eq. 5 could be made to conform to the experimental data by multiplying by a constant. However, Eq. 5 cannot be made to conform to the remainder of the experimental data by a simple transformation. The fact that there is a break in the line indicates that a different law applies beyond this point.

As stated by the author, Eq. 5 applies only to still air conditions which probably are never obtained when conducting evaporation experiments even under controlled laboratory conditions. Although all external disturbances are excluded, any difference in temperature or density will cause the air to move. This is confirmed by the experience of the writer in conducting evaporation experiments under controlled conditions in the laboratory at Fort Collins (16*a*), although the exact significance of the phenomenon was not recognized at the time. The evaporation was at a maximum when the water was warmer than the air. When this occurred, the air in contact with the water would be warmer than the surrounding air and would rise, carrying with it a certain amount of water vapor which would have had to be removed by diffusion if the air were absolutely still. When the water was colder than the air, the density gradient was reversed and the air would remain in contact with the water surface because it was held there by the rim of the tank. When this occurred the water vapor could escape only by diffusion, which is a slow process. These explanations, however, do not account for the fact that the observed evaporation below the break in the curve (Fig. 5) is about four times that computed by Eq. 5. In fact, the discrepancy beyond the break in the curve is so great that it seems doubtful whether the analogy of mass transfer is valid.

---

[4] Irrig. Engr., Div. of Irrig., SCS, U. S. Dept. of Agriculture, Colorado Experiment Station, Fort Collins, Colo.

According to the author's analysis the evaporation should vary as the 0.75 power of the wind velocity. The results obtained by several investigators are shown plotted in Fig. 8. Although the total effect of wind found by these investigators varies considerably, with one exception the results conform to the 0.75 power at the higher velocities. Whether this is a fundamental difference or whether it is due to the uncertainty of wind measurements at low velocities is not known. The author states that F. Graham Millar was able to approximate actual evaporation records on the basis of turbulence and eddy diffusivity, but could correlate the writer's data only on the assumption that the anemometer was in error. Cup anemometers probably are not the most accurate devices for measuring wind velocity, but they are almost universally used and for this reason they were adopted for the experiments at Fort Collins. Although the indicated velocities differ from the true velocities, particularly at high velocities, similar differences would occur whenever the anemometers were used and consequently comparable results would be obtained.

The effect of pan diameter on evaporation has been plotted by the author in Fig. 9, showing that beyond 10 ft the diameter has very little effect on the evaporation. This is the generally accepted conclusion. However, the author's formula for evaporation into air in motion, Eq. 15*b*, indicates that the evaporation is inversely proportional to the fourth root of the diameter of the pan. According to this formula, the evaporation from a 10-ft pan would be more than five times as great as that from a pan 9,000 ft in diameter under similar conditions instead of about 10% greater as indicated in Fig. 9.

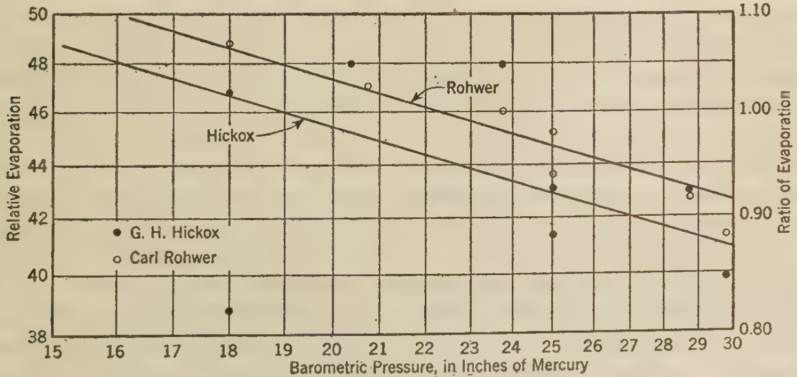

FIG. 13.—RELATION OF EVAPORATION TO BAROMETRIC PRESSURE BASED ON DIFFERENT ANALYSES OF THE SAME DATA

Fig. 10 shows the relation between the barometric pressure and the relative evaporation at different altitudes based on data obtained by the writer, recomputed in accordance with Eq. 20. Fig. 13 shows the same data and in addition the relative evaporation as computed by the writer (16*b*). It will be observed that the points fall much closer to a line with a slope of −0.25 than do those computed by the author. This indicates that the empirical analysis used by the writer gives results that are more nearly in accord with the facts than the analysis based on the analogy between evaporation and other physical phenomena.

The Sub-Committee on Evaporation of the Special Committee on Irrigation Hydraulics of the Society (2) adopted 0.70 as the ratio of the annual evaporation from a Weather Bureau pan to that from a reservoir. The author states (see heading, "Introduction") that the ratio is probably not constant throughout the year. Although this view is proved by the writer's experiments at Fort Collins (16*c*), it is doubtful whether it is worth while to use a different ratio for each month because conditions vary from year to year on account of seasonal differences. Table 5 (computed by the writer from data collected by A. A. Young, Assoc. M. Am. Soc. C. E. (43)(44), for the Division of Irrigation, Soil Conservation Service, U. S. Department of Agriculture) shows that the ratio reached a maximum during the cold months in the fall and winter at Elsinore, Calif., whereas at Fullerton, Calif., the maximum ratio occurred during the warm months of the year. The mean values for these two ratios for the entire year are, respectively, 0.77 and 0.78 instead of 0.70 as recommended by the writer and by the Sub-Committee on Evaporation of the Special Committee on Irrigation Hydraulics of the Society. There was little change in the ratios from year to year. These results support the author's contention that the ratios would not be the same under Southern California conditions as they would be in areas where the evaporation is very small during the winter months.

TABLE 5.—MONTHLY RATIOS FOR THE CONVERSION OF THE EVAPORATION FROM A WEATHER BUREAU PAN TO THE EVAPORATION FROM OTHER WATER BODIES

Month	(*a*) LAKE ELSINORE, CALIFORNIA				(*b*) 12-FT SUNKEN PAN AT FULLERTON, CALIF.

The optical interferometer developed by the author is an ingenious device for measuring very small rates of evaporation with precision. It is unfortunate that the experiments with this device were limited to a narrow range of conditions. A series of observations under controlled conditions in the laboratory on the evaporation from pans of different sizes into air moving at definite velocities would have made it possible for Mr. Hickox to check the accuracy of Eq. 15*b* without making assumptions as to the conditions under which the tests were made.

A study of the device raises the questions of whether the plate glass reflector F, in Fig. 3, would not reflect the beam of light from both surfaces of the plate glass and of whether, as a result, two sets of interference bands would appear to the observer. The one from the interior face of the glass plate would be less distinct, but, when the dark bands of one set were superimposed over the light band of the other, the difficulty of counting the bands would be increased. This possibility is mentioned because of a similar difficulty experienced by the writer in making evaporation observations by the use of the optical lever. Until the plate glass mirror first used was replaced by a metal mirror with only one reflecting surface, two distinct images of the scale on which the evaporation was read appeared in the telescope. The use of a metal mirror completely eliminated the second image.

After studying the paper the reader cannot help but feel that there is considerable doubt as to whether the analogy used is suitable for interpreting evaporation phenomena. At least the available data do not fit the theory very well. The writer does not wish to leave the impression that he is attempting to discredit Mr. Hickox's work even though the results are not conclusive. Much of the work on evaporation has been on an empirical basis and any attempt at a rational analysis of the problem should be commended.

C. W. Thornthwaite,[5] Esq. —Although the author is reporting original observations of evaporation, the most valuable contribution of his paper is probably in showing the possibility of developing an evaporation equation in terms of mass transfer of moisture through a layer of the atmosphere. For more than two decades meteorologists have been investigating turbulence in the lower atmosphere for the purpose of determining the mechanism of mass transfer of momentum, heat, moisture, and dust. The literature on the subject is already very extensive; but few engineers have given much attention to this development.

The author compares the transfer of moisture from an evaporating water surface to the process of heat transfer from a solid to a gas. He states (see heading, "How Evaporation Occurs"):

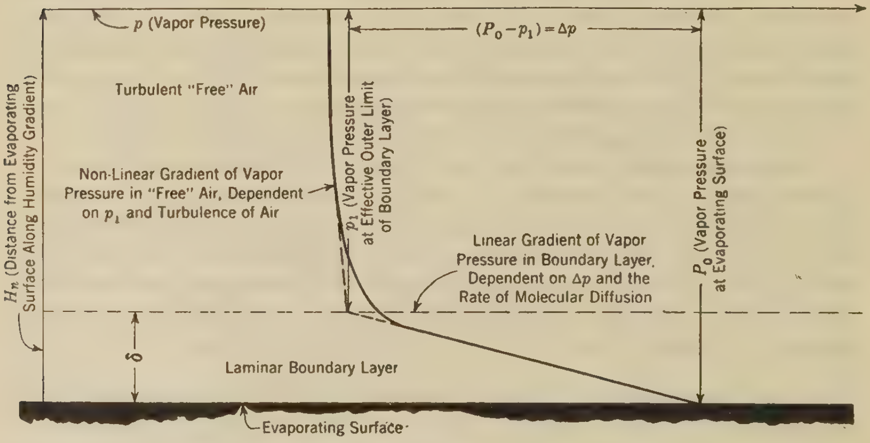
> "* * * A boundary layer of stagnant gas surrounds the solid through which heat is transferred by conduction alone. Outside the boundary layer, the heat is transferred by convection, frequently aided by turbulence. Heat transfer has been computed successfully by the use of an over-all transfer coefficient, combining the coefficients of conduction and convection, known as a film coefficient."

The temperature difference used is that between the wall temperature of the solid boundary and the temperature of the gas at a considerable distance. The author believes that the rate of transfer of water vapor through the atmosphere could be calculated in a similar manner. Whether or not it has been possible to combine the coefficients of conduction and convection in the computation of heat transfer need not be considered at this time. It is important to understand, however, that the successful determination of the flow of heat through a layer would not mean that moisture transfer could be computed similarly.

---

[5] Principal Climatologist, SCS, U. S. Dept. of Agriculture, Washington, D. C.

John Leighly (45) has outlined clearly the difficulty of computing evaporation in this way, and the discussion immediately following is adapted from his paper. Conditions for the transfer of matter or energy within the boundary layer are totally different from those which prevail in the zone of turbulence above that layer (see Fig. 14). When air is turbulent, its properties are transported rapidly between layers by the actual exchange of bodies or masses of air, and except under special conditions steep gradients of velocity, temperature, or admixtures cannot exist. In the laminar boundary layer, however, where no mixing by movement normal to the boundary surface takes place, heat may be transferred only by molecular conduction; momentum may be transferred only by molecular friction; and gaseous admixtures, such as water vapor, may be transferred only by molecular diffusion. Therefore, gradients are characteristically steeper in the boundary layer than in turbulent air. Rates of molecular transfer—coefficients of heat conduction, molecular friction, and diffusion—are nearly constant within the thickness of the boundary layer, and this constancy of rate of transfer produces sensibly linear gradients of temperature, velocity, and humidity from the bounding surface out to the limit of the boundary layer. Outside the boundary layer, in the region of turbulent mixing, molecular transfer is negligible in comparison with molar transfer through turbulence. The intensity of turbulent mixing varies greatly with distance from the bounding surface. Hence, gradients are variable in



p (Vapor Pressure)
$(P_0 - p_1) = \Delta p$
Turbulent "Free" Air

p_1 (Vapor Pressure at Effective Outer Limit of Boundary Layer)
P_0 (Vapor Pressure at Evaporating Surface)
Linear Gradient of Vapor Pressure in Boundary Layer, Dependent on Δp and the Rate of Molecular Diffusion
H_n (Distance from Evaporating Surface Along Humidity Gradient)
δ
Laminar Boundary Layer
Evaporating Surface

FIG. 14.—CHARACTERISTIC DISTRIBUTION OF HUMIDITY IN THE LAMINAR BOUNDARY LAYER NEXT TO AN EVAPORATING SURFACE AND IN THE ADJACENT PARTS OF THE OVERLYING TURBULENT LAYER

the turbulent parts of the air, normally decreasing with increasing distance from a bounding surface, as the intensity of turbulent interchange increases.

When considering the proportionality of rate of evaporation to the difference in vapor concentration at the water surface and at a distance, Mr. Leighly showed that the simplest expression of such proportionality is

$$E = C\,(P_o - p_1) \qquad (25)$$

in which E denotes mass of water lost (or gained) by unit area in unit time; C is a proportionality coefficient; P denotes vapor pressure at saturation; p denotes actual vapor pressure; and the subscripts o and 1 denote location at an evaporating surface and in the air, respectively. The equation would be complete if humidity difference were the only variable. This simple equation for E has the familiar form of many equations that express rate of transfer of matter or energy through space—conduction of heat, diffusion of solutes, etc.—along a gradient; but the difference $(P_o - p_1)$ can define a gradient only when it is divided by a term defining the distance between the points of observation of moisture concentration. If this distance is designated z, and the change in moisture concentration along it is linear, the gradient is defined by $(P_o - p_1)/z$. Therefore, the vapor-pressure difference alone can be used as the basis of an evaporation formula only if z is constant for all evaporating surfaces. Since z cannot be constant, it must be included in any evaporation formula that uses the difference $(P_o - p_1)$. Even then, the expression $(P_o - p_1)/z$ accurately describes the gradient only if change in vapor pressure normal to the evaporating surface is linear. Within the turbulent layer and thus for unlimited distances from the evaporating surface, the gradient is not constant. The only satisfactory general expression of the gradient is therefore dp/dz, which is the change in moisture concentration with respect to height.

To determine the rate of flow of heat through unit cross section of a window pane, not only must one know the coefficient of thermal conductivity of the glass and the difference in temperature between the inner and outer surfaces, but also the thickness of the glass. This is easily understood; yet from the time of John Dalton, evaporation formulas have given the rate of flow of water vapor in terms of a difference in vapor concentration at the water surface and at an undetermined distance.

One of the finest investigations of evaporation ever conducted in the United States was that by Carl Rohwer, M. Am. Soc. C. E., reported in 1931 (16). All observations used in the derivation of his formula were carefully made under rigorously controlled conditions. He used an aspiration psychrometer to determine the vapor pressure of the air within an inch of the water surface. His laboratory experiments were conducted in still air and with controlled wind. The general form of his evaporation formula is given in Eq. 25. He found that the coefficient C increased linearly with increasing wind velocity according to the relation,

$$C = (0.44 + 0.118\,V) \qquad (26)$$

in which V = wind velocity, in miles per hour. Actually the coefficient C contains both the coefficient of moisture transfer and the distance term that must be associated with difference of moisture concentration in order to define the moisture gradient. Mr. Rohwer's measurements of moisture concentration in the air, although made within an inch of the water surface, were well within the turbulent layer; but, since they were made under controlled conditions, the fact that two layers with very different transfer coefficients were involved does not vitiate the results. With increased wind velocity the coefficient of turbulent exchange becomes larger and the laminar layer decreases in thickness. Thus both factors work together to increase the value of the coefficient of proportionality *C*.

With outdoor observations of evaporation made under uncontrolled conditions, Mr. Rohwer found his formula to be less satisfactory. He recognized that both wind velocity and atmospheric moisture are highly variable in the free air and he rightly attributed some of the inconsistencies in the data to this variability.

The author presented a general formula (Eq. 2*b*) for mass transfer of water vapor which uses a gradient of vapor concentration rather than a difference. Nevertheless, there is no indication that he measured a gradient in the course of his experiments. He refers to vapor concentration "at a distance" (see heading, "Evaporation as a Mass Transfer Process: Experimental Data"). He measured the relative humidity of the air with a standard sling psychrometer. When using this instrument, the height of the observation cannot be specified nor the moisture gradient determined with any degree of accuracy. Furthermore, it is not possible to use a sling psychrometer without disturbing still air and profoundly modifying its moisture structure. Apparently all other measurements were made with great care. Considering the crudeness of the one, such accuracy in the others was scarcely justified.

The author has stated in the paragraphs following Eq. 15 that the writer and his associates do not feel that it is possible to develop a satisfactory equation for evaporation in terms of the "difference in vapor concentration at the water surface and at a distance." As a matter of fact, the evaporation equation introduced by the writer and his associates does employ a difference (46*a*). Both observations of moisture concentration were made within the turbulent layer, and the distance element of the moisture gradient was incorporated into a coefficient of proportionality.

The author greatly underestimates the difficulty of the problem when he states (see heading, "How Evaporation Occurs") that the rate of moisture transport can be determined by use of an over-all transfer coefficient, combining the coefficients of conduction and convection. In the first place, the coefficient of turbulent exchange increases with height in the free air and varies not only with wind velocity but also with its stability structure. In the second place, the thickness of the laminar layer, in which the coefficient of molecular diffusion applies, becomes less as the intensity of turbulence in the turbulent layer above it increases.

The most difficult problem is to obtain the turbulent transfer coefficient in terms of some measurable quantity such as wind velocity or temperature. This has been accomplished for atmospheric conditions when the wind velocity varies as the logarithm of height (46*b*). The writer and his associates (47)(48)(49), however, have presented measurements of wind velocity at different heights to show that the logarithmic law of wind distribution is of restricted validity. The data show that the law applies very well when the temperature lapse rate is adiabatic (or, within a shallow layer, isothermal), but that it fails when the lapse rate is either superadiabatic or stable. When plotted on a semilogarithmic scale, only the late morning and early evening observations fall along a straight line. The daytime observations plot along lines having concave curvature; those made at night show convex curvature.

The writer concluded that when the thermal lapse rate is adiabatic, as for brief periods in the morning and again in the evening, the logarithmic law is fulfilled and the coefficient of turbulent mixing derived from it is valid. At this time turbulent mixing is mechanical only.

In the middle of the day, when the ground becomes heated and superadiabatic lapse rates may become very large and thermal convection is actively induced, convective turbulence is superimposed upon mechanical turbulence and the turbulent exchange coefficient becomes greater, perhaps much greater, than the logarithmic law would indicate. The concave curvature of the wind gradients is a consequence of this increase in the coefficient of turbulent mixing. As momentum is transported downward more actively, the tendency for differences in velocity in adjacent layers to be equalized increases, and the wind profile becomes more nearly vertical except very close to the ground surface.

At night when the ground, having been cooled by radiation, cools the adjacent air, the lowest layer of air becomes cooler than that above it and a stable lapse rate is created. The air next to the ground, being cooler, is denser than that above and, if moved mechanically upward into a faster moving layer, would tend to move down again instead of mixing with the air in the new environment. In this instance the coefficient of turbulent transfer is less than that specified by the logarithmic law. Momentum is transported downward less actively; the tendency for velocity differences in adjacent layers to be equalized diminishes; and the velocity profile departs more than ever from the vertical except within a foot or two of the ground.

The fact that the logarithmic law of wind structure is valid only when an adiabatic temperature structure prevails means that the problem of determining the coefficient of turbulent transfer is much more complicated than had been anticipated. First, the wind velocity gradients themselves must be determined more accurately than is possible with ordinary anemometers. In addition, it will probably be necessary to make measurements of temperature at various heights in order to establish the degree of stability of the atmospheric layer through which the water vapor is moving.

The writer has not seen the literature referred to by the author in his statement (see heading, "How Evaporation Occurs"), "Heat transfer has been computed successfully by the use of an over-all transfer coefficient, combining the coefficients of conduction and convection * * *." He does not share the author's view, however, that "There seems to be no reason why the rate of transfer of vapor particles cannot be calculated in an entirely similar fashion." If it is possible to determine an over-all coefficient of heat transfer through both laminar and turbulent layers, it is only because the temperature structure directly controls the intensity of turbulent transfer and indirectly the thickness of the laminar layer. The temperature difference term of the equation of heat transfer, therefore, may contain a part of the transfer coefficient. Atmospheric moisture concentration does not share with heat the property of controlling the magnitude of the coefficient of turbulent transfer, however. Consequently, it appears to the writer that it will not be possible to integrate across the boundary layer. In computing the rate of transfer of water vapor from a natural surface there seem to be only two possibilities that are scientifically defensible—either determine the moisture gradient wholly within the laminar layer where the coefficient of diffusion applies, or wholly within the turbulent layer, where it will be necessary to utilize a coefficient of turbulent transfer (50*a*).

HARRY F. BLANEY,[6] M. AM. SOC. C. E.—Experiments on evaporation, described in this paper, are opportune since they afford engineers, physicists, and hydrologists another opportunity to discuss the long-standing controversy as to which is the best device for measuring evaporation from a free water surface.

When estimating evaporation from lakes or reservoirs, engineers usually cannot wait years or even months for the results of experiments. Thus, they use the best data available. Engineers will continue to use evaporation pan records and empirical formulas until the time when research workers can demonstrate the practicability of estimating evaporation from large bodies of water by the energy balance, by the vapor-pressure gradient, or by other methods discussed by the author. When long-period evaporation pan records are not available, then, from necessity, the engineer may base his estimates on climatological data.

The author has mentioned some of the many formulas developed for determining evaporation from meteorological observations. For the most part, such formulas are based on short-period observations and require data that are not usually available in many localities. In such instances, these formulas are of little practical use to engineers in estimating average annual lake evaporation.

Several years ago, in connection with water supply and irrigation investigations made by the Division of Irrigation, Soil Conservation Service, the writer was confronted with the problem of determining, within a limited time, probable past and future evaporation and evapo-transpiration losses in valley areas along the Pecos River in New Mexico and Texas (51). Formulas were developed for this purpose. Long-period records of evaporation, temperature, and humidity were available for a few sections of the Pecos River basin and adjacent watersheds. These data, together with the records published by the Texas Agricultural Experiment Station (52) in College Station were used to develop an empirical formula for computing annual evaporation from a lake surface, where temperature and humidity data are available. The relation between temperature, humidity, and evaporation was found by plotting average annual observed data for some fifteen stations having records varying from 14 to 24 years (53). A formula was developed as

---

[6] Senior Irrig. Engr., Div. of Irrig., SCS, U. S. Dept. of Agriculture, Los Angeles, Calif.

$$E_L = 0.0167\,T\,(114 - H) \qquad (27)$$

in which E_L = annual lake evaporation, in inches; T = annual mean temperature, in degrees Fahrenheit; and H = annual average percentage of relative humidity. Eq. 27 has proved useful in estimating evaporation losses from water surfaces in the Lower Pecos River basin, California coastal valleys, and other areas within the limits of the temperature, humidity, and evaporation pan records from which the formula was evolved. For example, using the average mean annual temperature and humidity for a 10-yr period (1932 to 1941), the evaporation from a lake surface in San Francisco, Calif., is computed as 41.2 in., and the evaporation for San Diego, Calif., is computed as 45.7 in. These estimates compare favorably with estimates made from nearest Weather Bureau Standard Class A pan evaporation records at Alvarado and Chula Vista, Calif., respectively, when the appropriate conversion coefficient is used.

The writer agrees with the author that the annual conversion coefficient for a Weather Bureau Standard Class A pan of 0.70, adopted by the Sub-Committee on Evaporation of the Special Committee on Irrigation Hydraulics of the Society, is not applicable to all areas. Experiments (43) by A. A. Young, Assoc. M. Am. Soc. C. E., indicate that the coefficient for Southern California is 0.77. The writer is inclined to believe that 0.75 would be a better average annual value for areas where pan records are available for the entire year.

There are many types of pans and evaporimeters used in the United States to measure evaporation. There is a great need for standardization, particularly in Southern California where at least six types of pans—Weather Bureau Standard Class A, Colorado land, Los Angeles County Flood Control District, Bureau of Plant Industry, and insulated pans—are being used and sponsored by various agencies.

The author suggests the establishment of a standard evaporation station and (see "Suggestions for Further Study") "3. A study of the relationships between the existing data and those obtained from the new standard pan with the purpose of correlating all records as far as possible." This is an excellent proposal and it is hoped that detailed specifications for such a station will be submitted by the author in the closing discussion.

ARTHUR A. YOUNG,[7] ASSOC. M. AM. SOC. C. E.—Theoretical and practical aspects of evaporation from pans, and the relation of this evaporation to evaporation from lakes and reservoirs, are presented in this paper. The results are particularly valuable to the student of evaporation and are of practical use to those men who determine evaporation losses from water in storage. The following considerations, usually not considered in evaporation measurements, will add to the general knowledge of the subject and should result in a better evaluation of evaporation rates.

Effect of Rim Height.—For most evaporation studies, pan exposure and limitations of water surface variations have been standardized in the interest of comparable results although such precautions are not always followed. Any departure from a standard method of obtaining data will be reflected in the results. Rim height varies with evaporation and replenishment, and the rate of evaporation is affected by each changing level. The immediate effect will be small but the ultimate total effect may be considerable. Investigations generally have neglected to determine, quantitatively, evaporation totals as affected by changes in the level of water surfaces.

---

[7] Irrig. Engr., Div. of Irrig., SCS, U. S. Dept. of Agriculture, Pomona, Calif.

In the attempt to show the effect of rim height on evaporation, the author has been handicapped by a lack of data directly related to evaporation pans. The data compiled by R. W. Revell, Jun. Am. Soc. C. E. (31), for a Weather Bureau Standard Class A pan were limited to a change in water surface only from 2 in. to 3 in. below the rim—the standard variation between replenishments of this pan. This study shows an increase in evaporation with increased rim height. Further information would be desirable for other levels since carelessness of observers often permits greater variations.

The study of evaporation from a saturated cylinder having a collar on the leading edge (15) showed increased evaporation with an increase in the height of the collar. The collar on the cylinder may be compared with the leading edge of the pan rim at which wind turbulence occurs. However, turbulence must also occur at the rim on the opposite side after the wind has passed over the water surface. Whatever the effect of turbulence, it would seem to be greater within the boundary of the water surface in a pan than within a cylinder with a single collar. These examples show an increase in evaporation due to greater rim heights. The following example shows the opposite effect.

In 1935 the writer made some tests to determine the effect of rim height on evaporation for the Division of Irrigation, Soil Conservation Service, at the Fullerton station near Los Angeles, Calif., using three pans, each 2 ft in diameter by 10 in. deep, set about 2 in. above the ground surface. Measurements were made continuously for five months under outdoor conditions, thus providing data for average temperature, wind, and humidity. The results are shown in Table 6. Water levels in each pan were as follows:

Pan No.	Depth of water surface below the rim (in.)	Depth of water in the pan (in.)
1	8	2
2	4	6
3	2	8

Water temperatures were obtained only at the time of observation in midmorning, and no maximum, minimum, or mean water temperatures are available. Wind movement was recorded a few inches above the top of the pans.

Least evaporation occurred from the pan having the greatest rim height, and most evaporation occurred from the pan having the least rim height. These data are contrary to findings reported by the author (15) (31), but the variations possibly are due to the different conditions under which the experiments were conducted—particularly to length of observations, variations between laboratory and outdoor conditions, size of pans, and differences in the evaporating surfaces. As depth to water increased, more of the water was shaded, greater wind protection was afforded by the sides of the pan, and there should have been greater moisture content in the air at the water surface. Each of these conditions tends to reduce the evaporation. Under such influences, water temperatures increase, and, between the 4-in. and 8-in. rim, there was an average monthly difference of 5.2° F, which was insufficient to overcome the decrease in evaporation caused by other factors.

[a] Depth of water surface below the rim. [b] Spot readings of water temperature made only at the time of observations; daily maximum and minimum temperatures were not obtained. [c] Mean values are shown in parentheses; thus: (76.2).

The Division of Irrigation also has records of a 2-ft ground pan, 3 ft deep, in which, for several years, the index point for the water surface was 1 in. higher than that for the ground. However, the index point later was lowered to ground level, thus increasing the rim height above the water surface from 2 in. to 3 in. During the first period evaporation from the ground pan exceeded that from an adjacent Weather Bureau pan by 3.90 in. annually, and the coefficient for conversion of evaporation from the ground pan to evaporation from Weather Bureau pan was 0.94. For the second period, loss from both pans was practically the same, and the corresponding coefficient was 1.01. The decrease in evaporation in the ground pan was due to increased rim height as well as to lowering the water to ground surface level. Practically, water in a ground pan should not stand above the ground level as, in so doing, it has less protection than when the water volume is entirely below ground.

Effect of Pan Color.—The effect of the color of evaporation pans depends upon the reflective and absorptive capacities of the color to light and heat. Dark pans absorb more heat than galvanized pans and their evaporation rate is greater. White pans, or those painted with aluminum paint, absorb less heat than standard galvanized pans and their evaporation loss is less.

Several tests made by the writer for the Division of Irrigation show the effect of color on evaporation pans. Evaporation for one year from a pan painted inside, below the water surface, with flat black paint was 99.2% of that from an unpainted galvanized pan of the same size and with the same exposure. For a similar pan, completely painted inside and outside with the same kind of paint, evaporation was 5% greater than that from the untreated pan. This value agrees closely with the author's data. The darkened surface beneath the water had practically no effect on evaporation, but, with the entire surface painted, evaporation increased.

Further tests were made at the Fullerton station, using nine new pans, 2 ft in diameter by 10 in. deep, set just above the ground surface to allow ventilation below. Depth of water varied from 7 in. to 8 in. A check pan retained its initial galvanized surface; the other pans were painted inside and outside with automobile enamel in various colors, with the exception that one pan was coated with aluminum paint and another was made of copper. The tests were continued from February through December, 1939. The paint below the water surface eventually became stained with lime, and, on the outside, the pans lost some of their initial brightness although not sufficiently to change the rate of evaporation materially. Results of the test are shown in Table 7. The difference in relative evaporation of 0.83 for the pan painted with white enamel (see last line of Table 7) and a value of 0.96 for the pan with white, lead-base paint, computed from Table 4, may be due to the kind of paint applied. Enamel, with its smooth surface, seems to have lower heat-absorptive qualities, which would account for some difference in evaporation. It is not claimed that the relative evaporation values as recorded for enamel paint will hold for other brands; but these values show, in general, that different colors affect evaporation in different degrees. In other tests by the writer, using the same kinds of pans at different times, but with different brands of aluminum paint, reduction in evaporation varied from 2% to 9%. This result agrees with the findings of Carl Rohwer, M. Am. Soc. C. E. (16), that different brands give different results. Evaporation pans should not be painted, as coloration always affects the rate of evaporation. This point is recognized by most operators but a few instances have appeared in the literature on evaporation where black or copper pans have been used. More often, pans are painted with one of the brands of aluminum paint to prevent discoloration or rusting of the gal-

vanized surface. Standard galvanized pans darken with age, and, if similar surfaces are maintained, comparable records are more likely to be obtained.

Evaporation from Screened Pans.—At the Fullerton station and elsewhere in Southern California, efforts have been made to obtain a pan that would have an annual loss sufficiently close to reservoir evaporation so that a reduction coefficient would be unnecessary. This result was obtained by using a ground pan shaded by a 0.25-in. mesh galvanized iron screen suspended horizontally midway between the top of the pan and the water surface. The pan was 2 ft in diameter by 3 ft deep, set 33 in. in the ground. The mean annual coefficient for eleven pan-years was 0.98 within ranges varying from 0.95 to 1.00 at the Fullerton station and from 0.97 to 1.00 at the Lake Elsinore (California) station of the Division of Irrigation. The method used in screening the water surface is shown in Fig. 15.

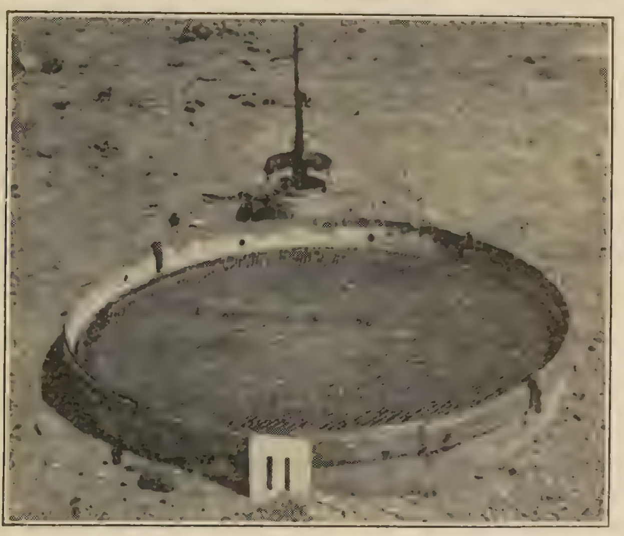

Fig. 15.—Method Used in Screening the Water Surface

Temperatures of water in the screened pan are more uniform than those in most other pans, holding up well during the night and maintaining a reasonably uniform rate of evaporation that is less than the rate from other known types. Monthly coefficients are variables. Comparison of evaporation from a screened pan with that from a 12-ft pan at the Fullerton station resulted in high coefficients during the early part of the year; but, when compared with evaporation from Lake Elsinore, coefficients were highest during the fall months. The screened pan has had a limited use in Texas where the same coefficients appear to hold true.

Evaporation Coefficients.—Coefficients for the conversion of evaporation from a pan to equivalent evaporation from a lake or a reservoir, as discussed in the paper, refer to the Weather Bureau pan for which an annual coefficient of 0.70 has been recommended (2), based upon separate experiments in Colorado by the late R. B. Sleight, Assoc. M. Am. Soc. C. E. (54), and by Mr. Rohwer (16). Both these men concluded that evaporation from a lake or a reservoir was substantially the same as that from either a ground pan, 12 ft in diameter, or a shallow reservoir, 85 ft in diameter. The coefficient of 0.70 is applicable to the general climatic region of Colorado where evaporation is limited to a part of the year because of freezing weather, but does not apply exactly to the lower altitudes of the Southwest where evaporation occurs throughout the year.

Monthly coefficients vary according to temperature; they are higher than the annual mean in summer and lower in winter. Usually, the annual coefficient is used in estimating reservoir evaporation. At times, however, monthly coefficients would be convenient for use by reservoir operators—particularly in estimating evaporation losses for snow survey forecasts (in cases where the losses are proportioned between interested users during the months of the irrigation season) and for reservoirs that contain water only during a part of the year.

Evaporation experiments by the Division of Irrigation in Southern California indicate an average annual coefficient of 0.77 for the Weather Bureau pan, based on evaporation from a 12-ft diameter pan, 36 in. deep. The coefficients were consistent from year to year, varying only from 0.76 to 0.78, and the average may be used safely for similar climates in southwestern states.

The value of 0.77 also has been obtained by a similar study in which measured evaporation from a Weather Bureau pan was compared with computed evaporation from Lake Elsinore, which has an area of 5,500 acres and is some 30 miles from the Fullerton station. The maximum depth of the lake was about 30 ft, but large areas were less than 10 ft deep. In this respect, the lake was more like a large evaporation pan than a deep reservoir. Inflow to the lake was from the San Jacinto River, which is subject to brief floods and to long-continued periods of no flow. Since 1917 there has been little or no outflow from the lake because of a deficiency in water supply. The only change in water levels has been caused by loss through evaporation since the lake bed is composed of silt through which seepage does not occur in sufficient quantities to change the values of computed evaporation.

The Lake Elsinore study was for a 3-yr period during which a Weather Bureau pan was placed immediately above the shore line, and lake evaporation was computed from inflow, rainfall on the lake surface, and change in water levels. Because of small uncertainties in computed evaporation, there were slightly greater differences in annual coefficients—from 0.76 to 0.80—than at the Fullerton station, but the average annual coefficient was 0.77 for both the Lake Elsinore and Fullerton stations.

Effect of Heat Storage in Water.—Because of the small volume of water in evaporation pans, heat storage available for the process of evaporation varies during the day, and much of the heat gained in the daytime is lost at night. Temperatures of large volumes of water are more uniform; they change little daily and their seasonal changes are slow. A part of the heat received by the reservoirs in spring and summer is used in creating evaporation, and another part is absorbed in warming the water to a considerable depth. Later in the year heat storage becomes available for evaporation during cooler months when pan evaporation is approaching a minimum. During spring and summer, pan evaporation may exceed lake or reservoir evaporation; but, because of heat in storage, evaporation from larger volumes of water in the fall may equal or exceed evaporation from a near-by pan. The annual heat energy received from the sun may be the same for pan and reservoir alike; hence, actual annual reservoir evaporation should be substantially the same as that computed by means of annual coefficients.

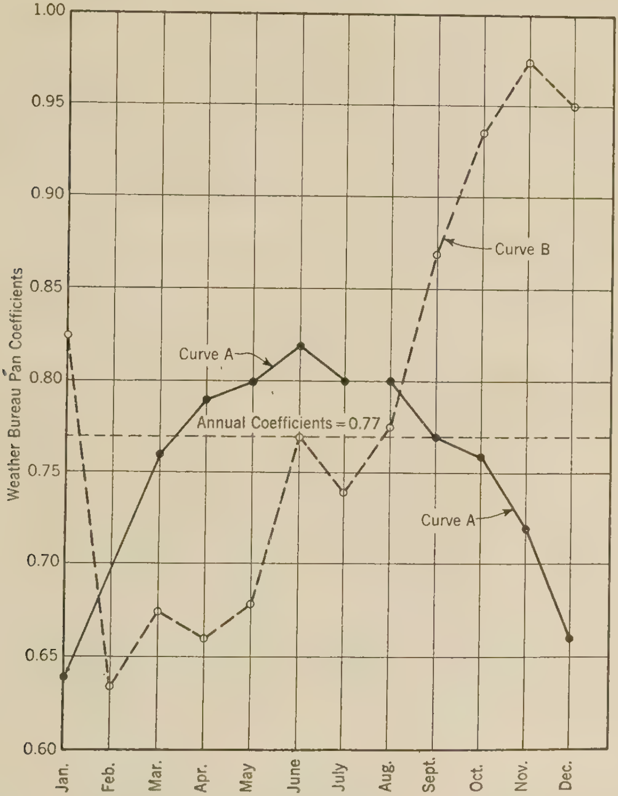

FIG. 16.—VARIATIONS IN MONTHLY WEATHER BUREAU PAN COEFFICIENTS

Actual monthly reservoir evaporation, however, differs from that computed from pan evaporation by reduction coefficients. In Fig. 16, two curves are shown in which plotted coefficients indicate the different effects of heat storage capacity. Both are for a Weather Bureau pan—one at the Fullerton station (curve A) where coefficients were based on comparison with a 12-ft diameter pan, the other at Lake Elsinore (curve B) where comparison was made with evaporation from the lake. Between the two the relation is not constant. The Fullerton coefficients rose to a maximum during the warmest months because pan temperatures change according to air temperatures. The lake coefficients were minimum during the early part of the year when the lake was storing heat, and maximum during fall months when for much of the time mean water temperatures were greater than mean air temperatures. The annual coefficient is 0.77 for each condition. Since evaporation is small during spring and fall months, the difference in computed evaporation, regardless of which set of coefficients is used, will be less important than is indicated by Fig. 16.

A. A. Kalinske,[8] Assoc. M. Am. Soc. C. E.—Evaporation from water surfaces, and also from land areas, is an important hydrological problem on which fundamental investigative work is very scarce indeed. The author reviews, quite completely, past theoretical and experimental studies, and presents some laboratory data of his own which he correlates by use of dimensionless parameters—a method that has been quite successful in analyzing heat-transfer data. Since the analogy between heat transfer and vapor transfer in gases is very apt, the author is undoubtedly on safe ground in using this analogy in his studies.

Although mentioned by the author in connection with his discussion of the influence of pan diameter on evaporation rate, a fact that many engineers sometimes overlook is that, for evaporation from a finite area into a moving air stream, the rate of evaporation varies with down-wind distance from the windward edge. Certain theoretical analyses have been made by H. Jeffreys (55), M. A. Giblett (56), O. G. Sutton (57), and F. Graham Millar (12) which indicate how the rate of evaporation varies with down-wind distance; however, the mathematical formulations are somewhat complex and not very convenient for practical use. Since this particular phenomenon is of considerable importance in connection with measuring and predicting evaporation from various areas, it might be of interest to present briefly the results of the theoretical analyses showing at least the approximate variation of evaporation with down-wind distance. The writer does not recall any such analyses in engineering literature. The analyses are based on the turbulence-diffusion theory and several simplifying assumptions must, of necessity, be made.

For the steady, two-dimensional case the general differential equation for diffusion is:

$$\frac{V\,\partial c}{\partial x} = \frac{\partial}{\partial x}\left(D_x \frac{\partial c}{\partial x}\right) + \frac{\partial}{\partial y}\left(D_y \frac{\partial c}{\partial y}\right) \ldots\ldots\ldots\ldots\ldots (28)$$

in which, corresponding to the notation of the paper, V is the wind speed in the x-direction (horizontal wind); D_y and D_x are the eddy diffusion coefficients in the y-direction and x-direction, respectively; and c is the vapor concentration per unit volume. The change in the value of $\partial c/\partial x$ with x is negligible compared with $\partial^2 c/\partial y^2$; so the first term on the right side of Eq. 28 will be dropped. The simplest possible solution of Eq. 28 is obtained when V and D_y are assumed independent of y—that is, when they are constant. The diffusion equation then becomes:

$$\frac{\partial c}{\partial x} = \frac{D_y}{V}\frac{\partial^2 c}{\partial y^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

---

[8] Associate Prof., Univ. of Iowa, Iowa Inst. for Hydr. Research, Iowa City, Iowa.

The solution of Eq. 29 is:

$$c = c_0 \left(1 - \phi_e \frac{V\, y}{2\, D_y \sqrt{x}} \right) \qquad (30)$$

in which c_0 = vapor concentration at $y = 0$, and

$$\phi_e = \frac{2}{\sqrt{\pi}} \int_0^s e^{-s^2}\, ds \qquad (31a)$$

and

$$s = \frac{V\, y}{2\, D_y \sqrt{x}} \qquad (31b)$$

The normal error function ϕ_e can be obtained by reference to statistical tables. The rate at which water vapor is transferred upward is then equal to $D_y\,(dc/dy)$, according to the diffusion theory, and therefore the rate of evaporation per unit area E at any point can be found by evaluating dc/dy at $y = 0$ from Eq. 30; thus:

$$E = c_0 \sqrt{\frac{D_y\, V}{\pi\, x}} \qquad (32)$$

The rate of evaporation from 0 to x from a strip Δz wide is:

$$E_x = 2\, c_0 \left(\frac{D_y\, V\, x}{\pi} \right)^{0.5} \Delta z \qquad (33a)$$

or, in general, over a strip L feet long:

$$E_L = 2\, c_0 \left(\frac{D_y\, V}{\pi} \right)^{0.5} \int L^{0.5}\, dz \qquad (33b)$$

For a circular area of radius r, Eq. 33b becomes:

$$E_r = 3.95\, c_0\, (D_y\, V\, r^3)^{0.5} \qquad (33c)$$

This analysis indicates that the unit rate of evaporation varies inversely as the downward distance, x, to the 0.5 power, and directly as the square root of the wind speed. The total rate of evaporation, over the entire area, varies as the area to the 0.75 power.

Mr. Sutton derived expressions such as Eqs. 33, taking into account the variation of V and D_y upward from the evaporating surface. He assumed a velocity distribution such that:

$$V = V_1 \left(\frac{y}{y_1} \right)^{n/(2-n)} \qquad (34)$$

in which V_1 is the velocity at same height y_1 and in which n can vary from 0 to 1.0, its value being somewhat dependent on the turbulence present. Mr. Sutton's expressions were quite complex. He found, nevertheless, that the total mean evaporation rate, E_L, was related to velocity and area dimensions as follows:

$$E_L \propto V_1^{(2-n)/(2+n)}\, L^{2/(2+n)}\, b \qquad (35)$$

in which b is the area width. Experiments have shown that the quantity $n/(2 - n)$, for fully developed turbulent flow, is about 1/7, from which $n = 1/4$. From Eq. 35, it is apparent that E_L varies as the down-wind linear dimension of the area to the 0.89 power, and as the air velocity to the 0.78 power. The average evaporation per unit area would then be proportional to the $-$ 0.11 power of L. Mr. Sutton states that data reported by G. W. Himus (19) seem to verify these results. Mr. Millar's derivations for finite areas indicated that the average unit rate of evaporation would be proportional to $V^{0.75}$ and $L^{-0.14}$. Since Mr. Millar's method of attacking the problem was somewhat different from that of Mr. Sutton, it is significant that there is such good agreement.

The foregoing analyses indicate that the rate of evaporation from any area into a moving air stream is dependent on the distance down wind from the windward edge of that area. This item should be kept in mind when measurements of evaporation are made at some point on an area, either with pans or by the Thornthwaite-Holzman method (6). The writer believes that, in the derivation and use of the latter method, C. W. Thornthwaite and B. Holzman did not emphasize strongly enough the fact that their equation and data did not necessarily indicate the evaporation rate over the entirety of any particular area, but rather the value of this rate at some particular point.

The theory of evaporation as based on the turbulence-diffusivity-coefficient concept has advanced to a point where there is need for some extensive and carefully controlled experiments, both in the laboratory and field—to verify directly certain assumptions made in developing this theory and to evaluate certain constants present in the equations. It was with this idea in mind that, several years ago, the Iowa Institute of Hydraulic Research, at Iowa City, Iowa, with hopes of obtaining the cooperation of the U. S. Weather Bureau, became interested in an experimental program on evaporation. The writer at that time outlined the direction to be taken by the proposed laboratory and field experiments in order that direct confirmation might be obtained as to whether or not the Thornthwaite-Holzman method of evaporation measurement actually gave values of evaporation from water surfaces. So far as the writer is aware, no such direct confirmation exists; at least he has not come across any in the literature on evaporation. It is important that direct evidence be made available before this particular method of evaporation measurement (which can have such extensive usefulness) is used too widely and confidently for obtaining evaporation data from water and land areas. The laboratory data were to be obtained in a wind tunnel some 90 ft long with a cross section 4 ft by 2 ft. In the design of this tunnel, provision was made for varying and controlling the temperature and humidity of the approaching air, temperature of evaporating water, and air velocity. Air velocity, vapor concentration, and air temperature were to be measured at various points above the evaporating surface. Turbulence measurements were to be made with a hot-wire anemometer. Field studies were planned to check and supplement the laboratory observations. It was proposed to make these studies on Spirit Lake in Iowa, which has many desirable features for conducting such a study. Actual evaporation at various points on the lake in the wind direction was to be measured with floating pans, and data were to be compared with evaporation calculations made from wind speed and humidity determinations above the lake surface.

The experiments indicated should make it possible to determine the following items definitely: (*a*) Feasibility of using the turbulence-diffusion-theory equations for computing actual evaporation, and the accuracy to be obtained from this approach; (*b*) accuracy and limitations of the method of computing evaporation from wind speed and humidity measurements at two points above a surface; and (*c*) data necessary for making predictions of evaporation from nonexistent water areas, such as proposed reservoirs.

An experimental program like the one outlined would help to provide some very important missing links between evaporation theories and actual evaporation determinations such as are needed in hydrological studies.

Because evaporation phenomena are of interest to so many different groups of scientists, the literature on evaporation is very widely scattered. In addition to the papers previously mentioned by the author and writer, some papers by R. B. Montgomery (58), H. V. Sverdrup (59), and Mr. Holzman (60) might be added to the "Bibliography." Mr. Montgomery gives extensive data on humidity distribution above an ocean surface, and in his analyses indicates that Mr. Millar (12) made some errors in his derivations. Mr. Sverdrup discusses the so-called "Bowen ratio" and indicates that, since this ratio is only approximately correct for atmospheric conditions, meteorologists are reluctant to use it. Mr. Holzman analyzes the influence of stability in the atmosphere on evaporation, and concludes that it is significant only for cold, smooth surfaces, such as snow or ice, or for low air speeds.

ADOLPH F. MEYER,[9] M. AM. SOC. C. E.—In the "Introduction," the author states,

> "An understanding of the physical occurrences of the evaporation process would lead to observations of those elements of the problem which would make the transfer of pan records to reservoirs more reliable."

Although the writer has read the paper with considerable care and has reread many parts of it, he has no definite recollection of emphasis being placed on what observations are needed and on how the transfer from pan records to reservoirs is to be made. Perhaps in the closing discussion this matter will be amplified.

From the practicing engineer's viewpoint, the following useful information developed by Mr. Hickox may well be further emphasized:

1. The color of the evaporation pan is important as it affects heat absorption, which is one of the elements influencing evaporation. The black evaporation pan used by the author consistently showed higher evaporation than the white pan. As would be expected, the difference was small during the winter months. On an average, the black pan showed 10% more evaporation than the white pan. All pans were buried in the ground.

2. Another important fact evidenced by the author's records is the higher evaporation from the deeper pan. The pan 2 ft deep showed about 10%

---

[9] Cons. Hydr. Engr., Minneapolis, Minn.

greater evaporation than the pans 3 in. and 6 in. deep and about 7% greater evaporation than the pan 1 ft deep. Heat absorption by the water during the daytime and less radiation at night appear to be the causes. Is it fair to conclude, in consequence, that a Weather Bureau Standard Class A evaporation pan, if 2 ft deep, would give substantially greater evaporation when similarly exposed than the present standard Class A pan?

The writer has frequently warned against the acceptance, without reservation, of a coefficient of 0.70 for reducing Class A evaporation to reservoir evaporation. In California, Arthur A. Young, Assoc. M. Am. Soc. C. E., found that a coefficient of 0.77 or 0.78 should be applied to the records of Class A evaporation pans to reduce them to reservoir evaporation. Most of the data on which the coefficient of 0.70 is based were limited to summer evaporation. However, it is a well-known fact that the difference between pan evaporation and reservoir evaporation is less during the winter months. It is also a well-known fact that reservoir evaporation is relatively much higher in fall and lower in spring. An average coefficient is meaningless in the solution of many problems faced by the practicing engineer.

The author also calls attention to the fact, not always recognized, that evaporation occurs even when air and water temperatures, some distance apart in elevation, are equal, because water vapor is lighter than the dry gases of the atmosphere and not only diffuses but sets up convection currents of its own accord.

Mr. Hickox tabulates the wind correction factors (see heading, "Correlation of Results of Other Experimenters: Effect of Wind Velocity") proposed by five different investigators. In most instances, the correction factor is to be applied to the wind velocity observed near the water level whereas the writer's factor, $1 + 0.1\ V$, refers to wind velocity measured about 25 ft to 30 ft above the ground or water surface. When that factor was first published in 1915 (61), the writer stated that the wind velocity at 25 ft or 30 ft above the ground was two and one-half to three times the velocity at about 1 ft above the ground. When this correction is applied, the writer's factor for wind effect becomes practically identical with that used by Carl Rohwer, M. Am. Soc. C. E., and stated by Mr. Hickox in the list preceding Eq. 18, namely, "$1 + 0.268\ V$."

Studies like those of Mr. Hickox are valuable and deserve encouragement. The practicing engineer, however, is sorely in need of records of air temperatures above lakes and reservoirs and of the temperature of the water in lakes and reservoirs about 1 ft below the surface, under the diverse climatic conditions that exist even within the borders of the United States. The equations for evaporation available to the practicing engineer are better than the basic data which he is forced to use in those equations. Little is known about relative air and water temperatures in the arid regions where evaporation losses are extremely high. Available records for northern lakes indicate that those of ordinary depth have summer water temperatures in excess of air temperatures. Some scattered records for the arid southwestern states indicate that lakes and reservoirs of ordinary depth in that region (probably because of the high heat loss during the night by radiation and through high daily evaporation) reach temperatures relatively lower in comparison with air temperatures than do lakes and reservoirs in the northern states where the heat received from the sun is relatively greater during the summer months than it is in the south. Water is a good absorber of heat.

The rather comprehensive study directed by the writer and published in 1942 (62) would have been more reliable in regions where unusual climatic conditions prevail if satisfactory records of comparative air and water temperatures of such regions had been available. After the work was nearly completed and it was apparent from the scattered records available that the estimated water temperatures for stations in the arid region were a little too high, corrections were made for Yuma and Phoenix, Ariz.; El Paso, Tex.; Roswell, N. Mex.; and Fresno, Calif.; but neither time nor available staff permitted corrections at other stations somewhat similarly located at which the computed evaporation appeared to be somewhat high when compared with pan evaporation records. No data are available on the basis of which a gradual reduction from about 10% in the regions of highest evaporation to zero in about the central portion of western United States can be made. The writer again cautions, however, against the use of 70% of Class A evaporation records in estimating the evaporation from lakes and reservoirs of ordinary depth. Lakes like Lake Superior obviously must be excepted. They constitute a problem in themselves. Evaporation from Lake Superior is probably not greater than 18 in. per yr (62).

MAURICE L. ALBERTSON,[10] JUN. AM. SOC. C. E.—Many civil engineers think of the theory of evaporation as applying only to water and of interest to the hydrologist alone. The chemical engineer, however, must understand the vaporization of liquids in drying and evaporating processes and, consequently, has conducted considerable research using other liquids as well as water. Moreover, the phenomenon of turbulence, which plays such an important rôle as the prime mover in the process of evaporation, has been studied in detail by the aeronautical engineer and the meteorologist.

In the section, "How Evaporation Occurs," the author describes briefly the kinetic interpretation of evaporation as used by the chemist. Any molecule that is to leave the surface by overcoming the attraction of the surrounding liquid must possess a minimum upward velocity component, v_o. It follows, therefore, that, as a molecule escapes, the over-all kinetic energy is diminished by $\frac{m\,(v_o)^2}{2}$ so that, when n molecules have departed, the loss of kinetic energy of the system is

$$E_k = \frac{n\,m\,(v_o)^2}{2} \qquad (36)$$

in which m is the mass of one molecule. This loss is equivalent to the heat of vaporization. The rate n_E at which these molecules are leaving the surface may be determined when the system is in equilibrium, because at that time the rate of return of the molecules n_R (max) is equal to the rate of exit n_E—that is, $n_E = n_R$ (max). According to the kinetic theory (63), the number of molecules striking a square centimeter of surface per second is

---

[10] Research Associate, Iowa Inst. of Hydr. Research, Hydr. Laboratory, Iowa City, Iowa.

$$n_R = \frac{p_v}{(2\,\pi\,m\,N_{Bo}\,T)^{0.5}} \qquad (37)$$

in which p_v is the partial pressure of the water vapor above the surface in dynes per square centimeter at absolute temperature T in degrees centigrade; n_R is the rate of return of molecules per square centimeter per second; n_R (max) is the limit of n_R when p_v is numerically equal to the vapor pressure p_S of the water; and N_{Bo} is the Boltsmann constant. Therefore, when the system is not in equilibrium—while evaporation is occurring—the net loss of molecules n_L becomes

$$n_L = n_E - n_R = \frac{p_S - p_v}{(2\,\pi\,m\,N_{Bo}\,T)^{0.5}} \qquad (38)$$

in which p_S is the vapor pressure of the water at its surface in dynes per square centimeter; and the temperature of the water surface and that of the boundary layer immediately above it are assumed to be the same. It is possible, from Eq. 38, to determine the actual weight rate of evaporation E_w in grams per second per square centimeter by multiplying by m so that

$$E_w = m\,n_L = m\,\frac{p_S - p_v}{(2\,\pi\,m\,N_{Bo}\,T)^{0.5}} \qquad (39)$$

Upon applying this relationship specifically to water, cubic centimeters may be conveniently substituted for grams, making E_w numerically equal to centimeters per second. This, in turn, may be converted into inches per day giving

$$E = 2.88 \times 10^5\,\frac{p_S - p_v}{T^{0.5}} \qquad (40a)$$

in which T is now in degrees Fahrenheit, E is evaporation in inches per day, and p_S and p_v are in inches of mercury. Eq. 40*a* demonstrates that the net rate of water transport through the boundary layer varies directly with the difference between the vapor pressure of the water and the partial pressure of the water vapor above it and inversely with the square root of the absolute temperature. As the author has shown, the change in $T^{0.5}$ is relatively small over the temperature range of interest to the hydrologist and, therefore, has little effect on the evaporation rate except as it changes the vapor pressure and partial pressure. One of the limits of Eq. 40*a* (the case of equilibrium) exists when $p_v = p_S$. Furthermore, were it possible to sweep away all water molecules as they leave the surface, allowing none to return, $p_v = 0$ and Eq. 40*a* would reduce to

$$E = 2.88 \times 10^5\,\frac{p_S}{T^{0.5}} \qquad (40b)$$

which is the limit of Eq. 40*a*, giving the greatest rate of evaporation possible at a given temperature. Evaporation as determined by this relation (see Fig. 17)

is many times as great as any actually observed. Furthermore, it is much greater than the evaporation computed with the largest wind coefficient given by Carl Rohwer, M. Am. Soc. C. E. (16*d*). Although this tremendous difference is in part caused by the existence of water vapor in the ambient air, it is primarily explained by assuming, as the author does, that the molecules travel through the boundary layer by molecular diffusion and, therefore, that only a very small percentage of them escape to the turbulent air above without returning to the liquid. Evidently, the natural turbulence over the water surface is never sufficiently great even to approach the elimination of this boundary layer.

There is little doubt that the processes of heat transfer and evaporation have many similarities as described by the author. However, it is well to remember that, as ∂x approaches zero for a constant value of ∂t in Eq. 2*a*, the rate of heat flow will approach infinity; but, according to the kinetic theory as discussed herein, the rate of evaporation can only approach some maximum finite value which is a function of the temperature of the water surface. This discrepancy, on the other hand, is explained by the fact that another form of the heat transfer equation must be used when the heat flow from a surface is being considered. If H is the rate of heat transmission per unit area and T_s and T_v are, respectively, the absolute temperatures of the surface and the air immediately above it, then the equation

$$H = k' (T_s - T_v) \dots\dots\dots\dots (41)$$

shows that, as T_v approaches zero, H approaches a maximum finite value, thereby completing the heat transfer analogy to follow Eq. 40*a*.

In the foregoing paragraphs consideration has been given to the mechanics of molecular movement from the liquid into, and through, the boundary layer. Of equal importance, although much less understood, is the transfer of vapor from the boundary layer to the air immediately above it. On the one hand, if absolutely stagnant conditions prevail, the boundary layer is infinitely high, and the resultant mixing is by molecular diffusion only. On the other hand, if conditions arise to make the flow unstable, turbulence will develop and the degree of mixing will increase tremendously. At any given point unstable conditions may be obtained by decreasing the viscosity or by increasing the velocity gradient through increasing the ambient velocity or the boundary roughness.

Although the foregoing conditions lead to the perpetual formation of turbulence, there are factors, such as viscosity, that lead to its decay. If the turbulence is being damped (that is, decaying) as rapidly as it is being created, a state of equilibrium prevails. However, if the creative forces increase, the turbulence becomes greater and the damping forces must then become equally large to reestablish equilibrium. If, instead, the creative forces diminish, the damping forces will decrease the prevailing turbulence to a magnitude that the creative forces are able to support.

Consideration of the terms in Eq. 40*a* reveals that p_s and T are dependent only upon the temperature of the water, whereas p_v is a function of the overhead turbulence and the vapor concentration and temperature of the ambient air. The turbulence is dependent upon the wind velocity, the viscosity of the air, and the surrounding roughness, such as, for example, the geometry of the evaporation pan, and is therefore dependent upon a characteristic Reynolds number of the flow over the pan. Hence, $p_v = \phi(\mathbf{R}, c_A)$ and Eq. 40*a* becomes

$$E = 2.88 \times 10^5\, T^{-0.5}\, p_S - 2.88 \times 10^5\, T^{-0.5}\phi(\mathbf{R}, c_A) \quad \text{.......}(42)$$

in which **R** is the Reynolds number; and c_A describes the temperature and vapor concentration of the ambient air. In Eq. 42, the first parameter 11,330 $T^{-0.5}\, p_S$ is the same as that in Eq. 40*b* and has been determined as in Fig. 17. The second parameter, however, must be determined empirically. The following typical cases serve to illustrate the foregoing principles.

Case 1.—First consider the case of a large lake, bounded on the windward side by a broad smooth plain, with very little difference in the shore and lake elevations. Assume that the surface temperature of the lake is constant, that the general wind velocity distribution over the plain and lake is uniform, and that the ripples on the lake give it the same roughness as that of the land. With these conditions prevailing, the turbulence of the wind near the water surface will likewise be uniform and the only variable factor influencing the rate of evaporation at various points across the lake is the vertical vapor-concentration gradient $\partial c/\partial x$. As shown in Fig. 18, the maximum rate of evaporation will occur at the water's edge; then, as the air immediately above the surface develops a partial pressure of water vapor, the gradient becomes smaller; and, hence, the rate of evaporation asymptotically approaches a minimum value. The total evaporation per unit width across the lake is represented by the area under the curve.

Case 2.—If the land on the windward side is not smooth but extremely rough, the turbulence of the oncoming air will be higher and at the shore the initial rate of evaporation will also be higher than in case 1. However, the turbulence will be partly damped across the lake by the viscosity of the air (the roughness of the lake not being great enough to maintain the initial turbulence) until the turbulence and resulting rate of evaporation approach the same limit as that of case 1—although the total evaporation across the lake is obviously greater.

Case 3.—If the windward land conditions are the same as those in case 1 except that there are waves on the lake, the initial rate of evaporation will be the same as that in case 1 but will approach some higher minimum value as the turbulence reaches equilibrium for the given surface (lake) roughness.

Case 4.—If the conditions are again the same as those in case 1, except that the land is considerably higher than the water surface because of a cliff at the shore, then a large eddy will result at the down-wind side of the cliff; and, along the upper edge of the eddy, considerable turbulence will be created and carried into the main wind stream. Because the turbulence is greater at point A than in case 1, the rate of evaporation tends to be greater; however, this is partly offset by the fact that the vapor concentration has also increased. Hence, the resulting evaporation rate may be greater or smaller than that

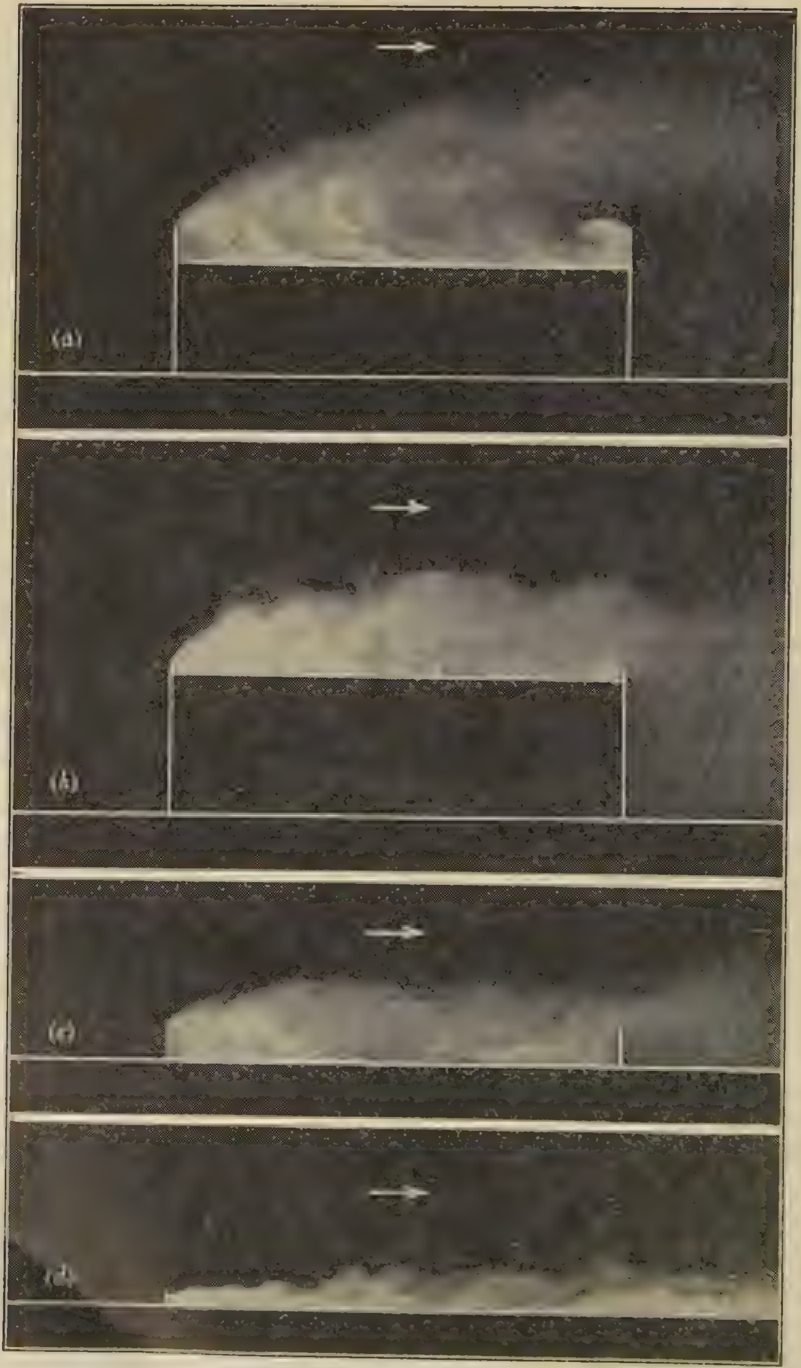

Fig. 19.—Concentration of Smoke over Variously Shaped Schematic Evaporation Pans with the Same Oncoming Wind Velocity

indicated at point A but will approach the minimum value of case 1. Within the primary eddy zone the rate of evaporation is obviously much less than in the previous cases because the eddy tends to recirculate the same air, thereby maintaining a high vapor concentration over this region.

Case 5.—Finally, assume for the sake of argument that the conditions are the same as those in case 1 but that a high wall is at or near the shore; turbulence will be created in much the same manner as in case 4 except that the eddy will extend higher and farther from the shore, causing the greatest rate of evaporation at point B. Again, the effect of increased turbulence is offset partly by a high vapor concentration at point B, and the evaporation curve may lie above or below that shown except that it approaches the same minimum as that in cases 1, 2, and 4.

Of particular concern to the hydrologist is the evaporation from a standard evaporation pan which may be considered as a slightly modified miniature of one or another of the foregoing cases. The turbulence at ground level is determined by the roughness of the terrain and objects immediately upwind from the point in question; and in many cases, such as the Weather Bureau Standard Class A pan, the governing turbulence over the pan is determined by the shape of the pan itself. This is quite graphically seen in Figs. 19(*a*), 19(*b*), 19(*c*), and 19(*d*) which are photographs of the diffusion of smoke over the surface of schematic two-dimensional pans—the concentration of smoke being analogous to the concentration of water vapor over an evaporation pan. To obtain these photographs, titanium tetrachloride was placed on the surface of the pans in a glass-walled air tunnel, 2 in. wide by 22 in. high and 36 in. long. For the range of conditions investigated, the geometry of the pans fixed the scale of the turbulence and the eddy pattern whereas the wind velocity determined only the violence of the turbulence.

As the wall in case 5 creates an eddy, so the side of the evaporation pan creates a similar eddy in miniature. At the left edge of the water surface in Fig. 19(*a*) is a relatively stagnant zone where, as described in cases 4 and 5, there is less evaporation than farther to the right where the concentration gradient $\partial c/\partial x$ is greater. When the freeboard is reduced, as in Fig. 19(*b*), the primary eddy (in these cases extending to the other edge of the pan) is changed only slightly—its size being determined mainly by the height of the pan above ground level. When the pan height is reduced, however (as in Figs. 19(*c*) and 19(*d*) which simulate buried pans), the primary eddy is so small that it covers only a fraction of the pan width, thereby leaving a considerable portion of the surface exposed to the small but violent eddies shown in the photographs. From these photographs it is readily seen that, when the pan is so placed that the turbulence of the air immediately above it is different from that of the surrounding atmosphere, an abnormal evaporation rate will result. Examples of this condition are obtained from placing a standard Class A pan on the surface of level ground or among scattered clumps of underbrush or trees. Evaporation in the first example will be more, and that in the second will be less, than when the turbulence of the air along the ground remains relatively unchanged as it passes over the water surface. Before deciding upon the shape and position of a pan to be used at a given location, consideration should be given to the general roughness and other features of the surrounding terrain which create turbulence so that a pan which will not cause abnormal turbulence may be chosen.

Many investigators in the past have studied evaporation of different liquids from various surfaces using wind tunnels to control the wind velocity. However, the writer could find no place in the literature where adequate measurement of the turbulence or the velocity gradient above the liquid surface has been described. These variables obviously must be determined for a complete analysis and understanding of evaporation. Thus, there is an excellent opportunity for much desired research in a wind tunnel, designed and operated so that the turbulence of the oncoming air and the eddy form over the liquid may be controlled and measured. There is also a need for wind-tunnel studies of the flow patterns over standard evaporation pans and actual measurement of the evaporation from them.

G. H. Hickox,[11] M. Am. Soc. C. E.—The discussion evoked by this paper is gratifying. Many valuable additional data have been submitted, particularly in the discussions by Messrs. Young and Albertson.

Mr. Albertson's amplification of the kinetic theory of evaporation is welcome. A detailed mathematical treatment was omitted from the original paper to save space. It is urgently recommended that every engineer who undertakes to study evaporation familiarize himself with the applicable kinetic theory. An excellent treatment by L. B. Loeb (5) is available. If more of the investigators of evaporation phenomena had recognized the validity of the kinetic theory, much more rapid progress would have been made. It should be noted that the equations apply only to momentary or equilibrium conditions and that agreement need not necessarily be expected by trying to use figures based on daily averages.

Mr. Thornthwaite questions the applicability of the analogy between heat transfer and mass transfer. He seems to be of the opinion that turbulent transfer cannot be predicted unless the mass concentration controls the coefficient of turbulent transfer. This objection does not seem to have interfered with the successful prediction of the vertical distribution of silt in a turbulent stream in which the silt concentration has no appreciable effect on the turbulence. The applicability of the analogy can only be judged from the results obtained by its use.

The literature on heat transfer in which over-all transfer coefficients, or film coefficients, have been used is very extensive and forms the basis of present-day studies of heat transfer. Reference is made to such standard texts as those by W. H. McAdams (64) and W. J. King (11). The mass transfer analogy has been used successfully in diffusion problems (13).

Mr. Thornthwaite refers to the observations by Carl Rohwer, M. Am. Soc. C. E. (16), in which vapor pressure of the air was determined within an inch of the water surface by means of an aspiration psychrometer; and he refers to the writer's measurement of relative humidity by means of a sling psychrometer as "crude." It has not been generally recognized that the use of the aspiration psychrometer by Mr. Rohwer required a volume of about 9 cu ft of air per minute, which is the rate necessary to maintain the required velocity past the wet and dry bulb thermometers. During an observation period of one minute, therefore, a volume of 9 cu ft of air was drawn through the instrument. This scarcely can be considered as representing a sample one inch from the surface. The writer agrees that the use of a sling psychrometer disturbs still air but he is not sure that the disturbance is much greater than that caused by removing a volume of 9 cu ft from the vicinity of the tests. In the experiments described under the heading, "Evaporation as a Mass Transfer Process: Evaporation into Still Air," the chamber containing the evaporation pan was placed in a room in which the humidity was controlled rather closely and in which the air was continually circulated to maintain a uniform distribution. All measurements within the chamber were made with thermocouples and the air within the chamber was not disturbed except by the evaporation process. Provision was made for circulation of air through the chamber as required by natural convection processes within the chamber. The false floor was placed one-quarter inch from the wall to allow entrance of air and the top of the chamber was open. It was provided with vertical baffles, however, so that the circulation of air in the room outside would not set up disturbances within the chamber itself. The relative humidity was measured outside the chamber and the air within was not disturbed. Under these circumstances the determination of relative humidity can scarcely be considered crude.

---

[11] Senior Hydr. Engr., TVA, Hydraulic Laboratory, Norris, Tenn.

Mr. Rohwer questions whether two sets of interference bands might not be obtained from the two surfaces of the mirror A shown in Fig. 3. The production of two sets of interference bands requires much greater optical accuracy than does the reflection of two images. Two sets of bands could be produced only if both the surfaces of mirror A were optically flat and nearly enough parallel to produce interference bands either with respect to each other or mirror B. The interferometer constructed by the author utilized plate glass from a broken automobile windshield. Considerable selection was necessary to find a piece having one surface flat enough to serve. It would be extremely unusual to find the two sides of one piece of glass both flat and parallel. This is a refinement that has not yet been reached in the manufacture of automobile windshields. No difficulty from this source was experienced.

Mr. Rohwer observes that the evaporation below the break in the curve of Fig. 5 is about four times that computed by Eq. 5 and considers that this is an indictment of the equation, because when the water is colder than the air, the cold air above the evaporation pan is stationary and water vapor can escape by diffusion alone. This is not quite correct. Eq. 5 was obtained by analogy with heat transfer from a circular surface into a semi-infinite solid. The analogy is not complete for two reasons. First, the condition of a semi-infinite solid is not fulfilled, as it would require the presence of an infinite mass of cold, perfectly quiet air above the surface of the water. It is clear that the mass of cold air is not infinite. Second, the air is not quiet, as Mr. Rohwer has assumed, but is in motion. Most of the experiments plotted in Fig. 5 were made on a pan with zero rim height. Smoke injected into the chamber showed that the air mass above the pan settled slowly and spread out on to the false floor around the pan. The result was that the air above the pan was moving slowly. This accounts fully for the increase in observed evaporation over that given by the theoretical equation.

Mr. Meyer's correction regarding the point of measurement of wind velocity used in his formula is gratefully acknowledged.

Mr. Rohwer comments on the application of Eq. 15*b* to diameters greater than 10 ft. Eq. 15*b*, showing the effect of pan diameter on the evaporation rate, was based on heat transfer experiments made on areas having a maximum diameter of probably 3 or 4 ft. Since the value of the exponent of Reynolds' number in Eq. 14 is empirical, one should not expect to find agreement outside the range of experiment. It is perhaps surprising to find that the agreement is as good as it is for diameters up to 10 or 12 ft.

Professor Kalinske concludes that the effect of pan diameter on evaporation varies as the diameter to the -0.125 power. The experimental data available appear to indicate that the exponent is somewhat less than the -0.25 predicted from the mass transfer analogy. Various experimenters have found exponents varying from -0.11 to -0.19.

Mr. Young's observations on the effect of rim height are interesting. They are in direct contradiction to those offered by the writer, but may be explained by the observations reported by Mr. Albertson.

Mr. Young presents additional data on the effect of pan color on evaporation. The effect of pan color appears to be well known but does not appear to be reflected in very many of the published data. The standard galvanized pan changes its surface characteristics very rapidly in summertime because of the growth of algae. It would seem that standard operating instructions for any evaporation pan installation should stress the necessity for frequent cleaning and restoration of the pan surface to a standard condition.

The effect of a screen over a pan in reducing temperature fluctuations is what might be expected. The screen intercepts incoming radiation from the sun during the day and also shields the pan from the low effective space temperatures at night. The result is less absorption of heat in the daytime and a lower maximum temperature, and a reduced back radiation at night with less cooling and a resulting higher minimum temperature.

The photographs of Fig. 19 are valuable additions to current knowledge as to the effect of turbulence. Study of these photographs leads to the conclusion expressed by Mr. Albertson that the surroundings should be taken into consideration in the mounting of a pan. It should be noted also that any pan with a projecting rim possesses inherent boundary effects that should be taken into consideration when an attempt is made to apply the results of pan measurements to large reservoirs where the boundary effects may be insignificant.

Mr. Meyer's statement regarding the absorptive capacity of water is substantiated by Fig. 12, in which the transmission factor is equal to one minus the absorptivity. Fig. 12 indicates that 18% of the incident solar energy is absorbed in the first millimeter of depth and 31% in the first centimeter. This is a convincing argument for the necessity of measuring water temperatures as near to the surface as possible.

The answer to Mr. Meyer's question about the relative evaporation of a Weather Bureau Standard Class A pan 2 ft deep compared to the 12-in. depth now in use is intimately related to the problem of applying the results of pan observations to reservoirs. The various factors affecting evaporation are so interrelated that it is scarcely possible to change one without affecting all the others. For this reason the writer is not able to give a categorical answer to this question.

The writer regrets that the scope of the paper prevents a discussion of the transfer from pan records to reservoirs. The dissertation filed in the Engineering Societies Library contains additional material which bears on the subject. The problem is complicated and lengthy and has not been worked out in detail. Much additional research will be necessary before it can be solved satisfactorily.

Mr. Blaney asks for detailed specifications of a standard evaporation station. The writer wishes that he was able to present these specifications. Although he has some ideas of what might constitute a suitable installation, it is recognized that they are based largely on incomplete data. The first objective for further study is the establishment of a suitable standard station. Without specifying the details of such an installation it is felt that it should satisfy at least the following six requirements:

1. Water temperatures should be measured as close to the surface as practicable and the measuring device should be sheltered from the direct rays of the sun so that the recorded temperature will be that of the water very close to the surface. The temperature gradient in still water is very high near the surface in daytime and it is the surface temperature that controls evaporation. In large bodies of water that are exposed to wind and wave action the temperature is practically uniform throughout the upper 2 to 5 ft and measurements made a few inches from the surface may be satisfactory. This is not the case with still water pans and this difference should be recognized in the installation.
2. It is probably desirable that the pan be insulated to minimize the boundary effects which do not exist or are negligible in reservoirs. The Weather Bureau Standard Class A pan probably departs more widely from reservoir or lake conditions than any other pan.
3. The pan should be as deep as feasible in order to simulate more closely lake or reservoir conditions.
4. The exposure should undoubtedly be governed by criteria similar to those outlined by Mr. Albertson in his excellent discussion of the effect of exposure on turbulence.
5. Care should be taken to maintain the interior surface so that large variations in rate will not occur.
6. The effect of the fences and instrument shelters in producing turbulence should be investigated and evaluated. It may be found desirable to enlarge the enclosure and to place instruments with regard to the direction of the prevailing winds in so far as this can be done without shading the pan.

Further research is indicated to establish the type of installation that will be most useful both in furthering the knowledge of evaporation and in supplying useful data to the practicing engineer.

It is hoped that Professor Kalinske and Mr. Albertson will have the opportunity to complete the research outlined in their discussions. If the studies are carefully made and properly interpreted, they will lead to a much better understanding of the problem than has been possible with the type of analyses heretofore made.

No attempt was made to submit a complete bibliography with this paper, and many valuable references were omitted simply because it was not necessary to refer to them. A complete bibliography, existing as it does, in the fields of civil, mechanical, and chemical engineering, meteorology, hydrology, oceanography, biology, and plant ecology, would occupy an entire volume. Two publications, by Mr. Meyer (62) and by A. A. Young, Assoc. M. Am. Soc. C. E. (65), however, contain so many data that they should be included in any comprehensive list.

In conclusion, the writer wishes to express his thanks to those who took time to read the paper and to submit criticism, discussion, and additional data.

TRANSPORTATION OF SUSPENDED SEDIMENT BY WATER

By Vito A. Vanoni,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Ralph W. Powell, E. R. Van Driest, Weston Gavett, Berard J. Witzig, A. A. Kalinske, Paul F. Nemenyi, and Vito A. Vanoni.

Synopsis

Measurements of the sediment and velocity distributions in a laboratory flume were made for various values of rate of flow, slope of channel, and size and amount of suspended load. The experimental sediment-distribution measurements were compared with the theoretical distribution derived on the assumption that the coefficient for the turbulent transfer of suspended sediment is the same as the coefficient for the turbulent transfer of momentum.

The following are the main findings:

(1) The measured sediment distributions have the same form as the theoretical distribution but do not agree quantitatively with them. This shows how invalid is the basic assumption that the transfer coefficient for sediment was equal to that for momentum. In general, the measured relative concentrations were larger than those given by the theory, the difference being greatest for the fine sediment and diminishing as the suspended load became coarser.

(2) Suspended sediment in a flow tends to reduce appreciably the turbulent transfer of momentum and hence the resistance to flow, allowing the sediment-laden water to flow more rapidly than a comparable clear water flow. This effect varies with the total sediment load and the grain size of the sediment.

(3) Suspended load in a flow may be a factor in causing the secondary circulation observed in rivers.

Introduction

Many important practical problems of today involve the movement of sediments by water, and their complete solution requires more knowledge of

this subject than now exists. Flood control and channel maintenance on streams, both large and small, are just as much problems of sediment movement as of water flow. Established practices, in fact, are successful in handling the water flow of floods, but the problem of passing the sediment load is still unsolved. In recent years the work of the United States Department of Agriculture in developing methods of reducing accelerated erosion on agricultural lands has encountered many new sediment-transportation problems, which have shown the urgent need for additional fundamental knowledge of this subject. It is in connection with this need that this study was undertaken.

Sediment may be transported by flowing water in two essentially different ways—by rolling or sliding along the bed of the stream channel or in suspension in the body of the fluid. The material transported is called, respectively, the "bed load of the stream," or simply "bed load," and the "suspended load." Just above the bed a continual interchange of material is occurring between the bed and the overlying fluid and in this locality it is obviously difficult to distinguish between the bed load and suspended load. The two types of transportation are by no means independent. They are separated only for convenience in studying them and referring to them.[2] This paper deals only with suspended load.

PREVIOUS WORK

Theories.—Modern theories of suspended-load transportation are based on developments in the mechanics of turbulent flow of fluids. Consider a two-dimensional turbulent flow in the x-direction with a velocity $u(y)$, in which y is normal to x. Then, according to Osborne Reynolds,[3] the shear parallel to x on a plane normal to y may be expressed by

$$\tau = -\rho\,\overline{u'\,v'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1a)$$

in which ρ is the mass density of the fluid, and u' and v' are the turbulent velocity fluctuations in the x and y directions, respectively, and the bar denotes mean value.

M. J. Boussinesq[4] introduced an expression for the shear of the form,

$$\tau = \rho\,\epsilon_m \frac{du}{dy} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1b)$$

in which the quantity $\rho\,\epsilon_m$ (often called the eddy viscosity) is analogous to the coefficient of viscosity in the expression for viscous shear; and u is the mean velocity in the x-direction. The quantity ϵ_m has the dimensions of a kinematic viscosity ν, but unlike its counterpart it is a function of flow conditions and, therefore, varies from point to point. The quantity ϵ_m is a coefficient expressing the exchange of momentum between neighboring filaments.

This quantity is called the turbulent momentum transfer coefficient. Obviously it has the dimensions, length × velocity.

Theodor von Kármán,[5] M. Am. Soc. C. E., introduced the equation,

$$\tau = \beta \, \rho \, v' \, l \frac{du}{dy} \quad \text{(2)}$$

in which β is a correlation coefficient, v' is the average of the absolute values of the fluctuations normal to the main flow, and l is the mixing length. From Eq. 2 it is seen that the turbulent momentum transfer coefficient, ϵ_m, has the value,

$$\epsilon_m = \beta \, v' \, l \quad \text{(3)}$$

and the dimensions, velocity × length.

Just as Eq. 2 expresses the rate of transfer of momentum due to turbulent mixing, it is possible to write by a similar equation the transfer of suspended particles, or any other property that is carried by the fluid. Thus, the rate of transfer of mass of suspended particles per unit area is

$$G = - \beta \, v' \, l \frac{dC}{dy} \quad \text{(4)}$$

in which C is the concentration of suspended material in mass per unit volume. Professor von Kármán[5] pointed out that the values of β, v', and l in Eqs. 2, 3, and 4 need not necessarily be the same.

For steady conditions the upward transport of material due to turbulence is balanced by the settling due to the force of gravity. This is expressed by

$$- \beta \, v' \, l \frac{dC}{dy} = w \, C \quad \text{(5)}$$

in which C is now the concentration of the fraction of the sediment with a settling velocity w. Transposing, the differential equation for suspended sediment becomes,

$$w \, C + \epsilon_s \frac{dC}{dy} = 0 \quad \text{(6)}$$

in which ϵ_s is the sediment transfer coefficient that is similar to ϵ_m but not necessarily equal to it. Solution of Eq. 6 gives,

$$\log_e \frac{C}{C_a} = - w \int_a^y \frac{dy}{\epsilon_s} \quad \text{(7)}$$

in which C_a is the concentration at an arbitrary reference level $y = a$.

If ϵ_s is constant over the depth, that is, $\epsilon_s(y) =$ constant, Eq. 7 may be integrated to give

$$\frac{C}{C_a} = e^{-i} \quad \text{(8)}$$

in which e is the base of the natural logarithms; and, to simplify typography,

$$i = \frac{w}{\epsilon_s}(y - a) \qquad (9)$$

Eq. 8 was apparently first given by Wilhelm Schmidt,[6] who applied it to the study of suspension of dust particles in the atmosphere. Eq. 6 was derived by a formal procedure by Morrough P. O'Brien,[7] M. Am. Soc. C. E. The more direct derivation is the work of Professor von Kármán.[5]

In general, ϵ_s is a function of y and must be so expressed before Eq. 7 can be integrated. Since the expression for ϵ_s is not known, the assumption is made that $\epsilon_s = \epsilon_m$ and Eq. 7 is integrated on this basis. From Eqs. 1b and 2,

$$\epsilon_m = \beta\, v'\, l = \frac{\tau}{\rho \dfrac{du}{dy}} \qquad (10)$$

Introducing Eq. 10 into Eq. 7 yields the relation

$$\log_e \frac{C}{C_a} = -\rho\, w \int_a^y \frac{\dfrac{du}{dy}}{\tau}\, dy \qquad (11)$$

which was first presented by Professor von Kármán[5] in 1934.

In a uniform open-channel flow whose ratio of width to depth is large, these relations will apply. The expression for the shear stress is given by

$$\tau = \tau_0 \frac{y_m - y}{y_m} \qquad (12a)$$

in which τ_0 is the shear at the bottom, or,

$$\tau_0 = \gamma\, y_m\, S \qquad (12b)$$

Introducing Eq. 12a into Eq. 11,

$$\log_e \frac{C}{C_a} = \frac{w}{\dfrac{\tau_0}{\rho}} \int_a^y \frac{\dfrac{du}{dy}}{\dfrac{y_m - y}{y_m}}\, dy \qquad (13)$$

An expression for the velocity gradient is given by the von Kármán[8] universal velocity defect law,

$$\frac{u - u_{\max}}{\sqrt{\dfrac{\tau_0}{\rho}}} = \frac{1}{k} \log_e \frac{y}{r_0} \qquad (14)$$

which has been shown by J. Nikuradse[9,10] to apply to pipes and by G. H. Keulegan[11] to apply also to open channels. In Eq. 14, k is a universal constant (0.40 for pipes) and y is the distance from the wall of the pipe of radius r_0. For wide open channels, as discussed here, r_0 in Eq. 14 is replaced with y_m, the depth of the flow. The derivative of the velocity then becomes,

$$\frac{du}{dy} = \frac{1}{k}\sqrt{\frac{\tau_0}{\rho}}\,\frac{1}{y}\ldots\ldots\ldots\ldots(15a)$$

which, when introduced into Eq. 13, gives

$$\log\frac{C}{C_a} = -\frac{w}{k\sqrt{\frac{\tau_0}{\rho}}}\int_a^y \frac{dy}{y\left(\frac{y_m - y}{y_m}\right)}\ldots\ldots\ldots\ldots(15b)$$

Integrating Eq. 15*b*,

$$\frac{C}{C_a} = \left(\frac{y_m - y}{y} \times \frac{a}{y_m - a}\right)^z = H^z\ldots\ldots\ldots\ldots(16)$$

in which, to simplify typography,

$$z = \frac{w}{k\sqrt{\frac{\tau_0}{\rho}}} = \frac{w}{k\sqrt{g\,y_m\,S}}\ldots\ldots\ldots\ldots(17)$$

From Eq. 16 it is possible to plot curves of relative sediment distribution as was first done about 1936 by Arthur T. Ippen, Assoc. M. Am. Soc. C. E., at the suggestion of Professor von Kármán.[12]

Eq. 16, as well as the equations preceding it, gives only a relative concentration and therefore does not make possible the calculation of the total transport of the stream. To make this possible a value for C_a is needed, and the problem of obtaining the transporting capacity of a flow may be simply stated as one of determining this value. In discussing the magnitude of C_a, Professor von Kármán[5] states that it probably depends on the size of the sediment and on the magnitude of the shearing stress acting at the ground. Hunter Rouse[13] has suggested that the limiting value of a in Eq. 16 be made equal to the height of the roughness elements h_s. He further suggests that the corresponding concentration C_k for this level be calculated from Eq. 8, assuming that in the interval $y = 0$ to $y = h_s$, $\epsilon(y) = \epsilon(h_s) =$ constant, and that the concentration at $y = 0$ be set equal to that of the bed material. approaching the problem statistically, argue[14] that only those particles having settling velocities w less than the vertical fluctuations v' of the bed velocity will be picked up. By assuming a normal distribution of v' and setting the root mean-square fluctuation $\sqrt{\overline{(v')^2}}$ proportional to the friction velocity $\sqrt{\frac{\tau_0}{\rho}}$, they proceed to calculate the probable rate of suspension of material.

As a result of an analysis of the energy balance of a stream carrying suspended load, Robert T. Knapp,[15] M. Am. Soc. C. E., advanced the hypothesis that the capacity of a stream is limited only if the settling velocity w of the sediment is greater than the rate of fall of the stream $\bar{u}\,S$, in which $\bar{u}$ is the average velocity of flow and S is the slope of the channel. Furthermore, he deduced that when the settling velocity is less than $\bar{u}\,S$ the material contributes energy to the flow, thus making it possible to pick up additional load until extremely high concentrations are reached.

Verification of Theories.—Although no comprehensive suspended-load experiments have been made in which the important variables have been investigated systematically, some noteworthy experimental work has been done.

Mr. Schmidt[6] appears to have first applied the turbulence theory to the problem of suspended load in his studies of the suspension of dust particles in air. He obtained Eq. 8, which assumes a constant value for the exchange coefficient.

In 1929 H. E. Hurst,[16] reported a series of experiments on the suspension of sediment in a cylindrical column of water agitated uniformly by a series of propellers much the same as those used by Joule in his experiments on the mechanical equivalent of heat. At various levels in his apparatus he measured the concentrations of three well-graded sands (mean size 0.9 mm, 0.4 mm, and 0.2 mm) for several propeller speeds and found that the distribution of sediment followed an exponential relationship of the form of Eq. 8. Mr. Hurst was also able to derive his relationship from an analysis based on the kinetic theory of gases.

Professor Rouse[17] performed some experiments similar to those by Mr. Hurst using an agitator of coarse mesh bars that was oscillated in the vertical direction with simple harmonic motion. The results of Professor Rouse's work indicate that Eq. 8 is valid, and verify the theory. Professor Rouse observed a systematic deviation of the value of ϵ obtained for the coarse sand from that obtained from fine sand. The deviation was attributed to a difference in the correlation factor β of Eq. 3 for mixing of the fluid and of the sediment.

In 1932 John B. Leighly[18] outlined a method of calculating the exchange coefficient ϵ for natural streams and discussed its effect in suspending sediment in the body of the flow. In a later paper Mr. Leighly[19] calculated the exchange coefficient from some sediment measurements on natural streams by using Eq. 8. He also calculated the sediment distribution from the exchange coefficient by step integration.

[18] "Toward a Theory of the Morphologic Significance of Turbulence in the Flow of Water in Streams," by John B. Leighly, *University of California Publications in Geography*, Vol. 6, No. 1, 1932, pp. 1–22.

In 1935 J. E. Christiansen,[20] Assoc. M. Am. Soc. C. E., attempted to check Eq. 7 by applying it to sediment measurements made by Harry F. Blaney and the late Samuel Fortier, Members, Am. Soc. C. E., in the Colorado River and Imperial Canals.[21] In general the observations agreed with Eq. 7, but the results were not entirely conclusive since complete data were not available and it was necessary to estimate such quantities as the slope of the canals and the settling velocity of the sediment before calculations could be made.

E. G. Richardson[22] made some simultaneous sediment and velocity measurements in a flume 5 cm wide, 8 cm deep, and 150 cm long which led him to conclude that the vertical distribution of sediment is nearly exponential. This agrees with Eq. 8 and would indicate that the mixing coefficient had approximately a constant value over the depth. Such a condition could be approximated in a channel downstream from a disturbance such as might occur in the inlet to a flume. In a later paper[23] this same author reports the results of experiments in a somewhat larger channel (1 ft by 1 ft by 6 ft) and concludes that in the boundary region the concentration of suspended sediment is inversely proportional to y and that in the open stream it varies exponentially, much as expressed by Eq. 8.

APPARATUS AND PROCEDURE

Main Flume.—The experiments were performed in a flume 33$\frac{1}{4}$ in. wide by 60 ft long, arranged so the slope and discharge could be varied. The slope was adjusted by means of four pairs of screw jacks, and the discharge was varied from 1 cu ft per sec to about 5.5 cu ft per sec by changing the speed of the pump in the system through a variable-ratio transmission in the electric motor drive. The sides of the channel were made of 12-in. structural channels lined with $\frac{1}{8}$-in. rubber. The bottom was a $\frac{5}{16}$-in. steel plate artificially roughened with sand. By making the circulation system closed circuit with the minimum velocity in the flume, it was possible to recirculate the suspended sediment with the water without danger of depositing material in the piping system.

The flume as first constructed was described in considerable detail[24] by Robert T. Knapp and Robert M. Oaks and is shown diagrammatically in Fig. 1(a). Experiments with this circuit yielded fair results but indicated that

the disturbances due to the pump and inlet were exerting an appreciable effect on flow in the flume.

The flow was improved by revising the circuit as shown in Figs. 1(*b*) and 2. Moving the pump and venturi meter to the discharge end of the flume provided a run of about 50 ft of 10-in. pipe to "equalize" the flow before it entered the transition to the 33¼-in. flume section. To eliminate the possibility of separation the included angle between the sides of the transition was made 5°.

Fig. 3 shows a general view of the flume from the inlet end. The beam spanning the channel at about midlength carries the instruments used in making measurements. The diffuser lid at the flume inlet is shown at the left.

Adjustment of Flow.—The flow in the flume was readily adjusted to a given depth by pumping the correct volume of water into the system and varying the discharge until uniform flow was reached. Uniform flow for a given discharge was obtained easily (once the flow was set with the water manometer on the venturi meter) by adjusting the amount of water in the closed system. No difficulty was ever experienced with the closed system because of pendulation or any other instability. The flow was adiusted easily and remained steady for indefinite lengths of time.

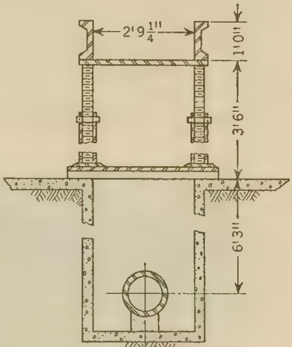

FIG. 2.—SECTION THROUGH A-A, FIG. 1(*b*)

Depth Measurements.—Water depths were measured with a point gage which can be read to 0.001 ft by means of a vernier scale. Depth measurements were made by first adjusting the elevation of the bracket holding the instrument so that the scale read zero when the point was resting on the bottom and then lifting the point so that it just came in contact with the surface. The average depth for the channel was obtained from measurements of at least 10 or 15 points.

Velocity Measurements.—Velocities were measured with a pitot static tube (diameter, $\frac{3}{16}$ in.) of the standard Prandtl design. The differential pressure on the tube was read to 0.001 ft on a water manometer and converted to velocity by assuming a coefficient of unity for the tube. (That this assumption is justified is shown by H. Peters.[25])

Sediment Sampler.—The distribution of sediment was determined from samples siphoned from the flume through a brass-tube pipette (outside diameter, $\frac{5}{16}$ in.) shaped much like a pitot tube. The tip of the sampler was flattened so its inside dimensions were 0.490 in. by 0.139 in. The average velocity at which the sediment-laden fluid entered the flat-tip section (sampling velocity) was made equal to the stream velocity at the sampling point by adjusting the head on the siphon.

The time to remove a 1-liter sample was calculated for each point from the measured stream velocity and the area of the flat-tip sampler (0.064 sq in.), the head on the siphon required for the rate of flow was determined by trial, and three 1-liter samples were taken. The sediment was removed from the sample by filtering and was dried and weighed. The average weight of the three samples was taken as the concentration at the point. Sample weights of more than 1 g were determined to 1 cg, and the smaller quantities were determined to 1 mg.

---

[25] "Druckmessung," by H. Peters, *Handbuch der Experimentalphysik*, Leipzig, Vol. 4, Pt. 1, 1931, pp. 489–510.

Water removed from the flume in sampling was replaced in order to keep the depth uniform. It was found that removing or adding as little as 3 gal of water made a measurable difference in the tailwater depth.

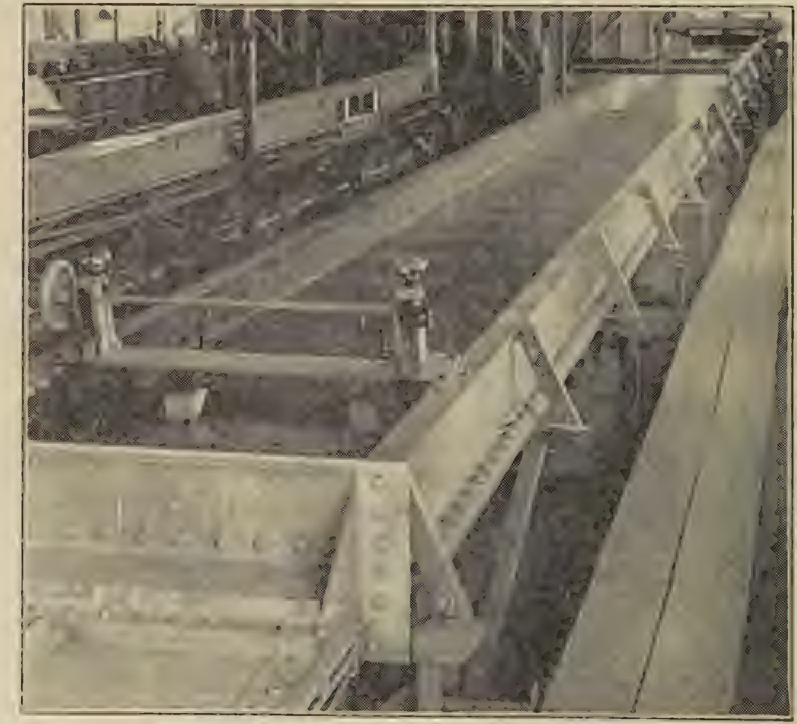

Fig. 3.—General View of Flume from Inlet End

The effect of the sampling velocity on the amount of sediment removed with the sample was studied experimentally. Several 1-liter samples were removed from a point at sampling velocities equal to 1.00, 0.86, and 0.75 times the local stream velocity at the sampling point. The sampling point was 0.5 ft from the center of the flume, 44 ft from the inlet (that is, at station 44), and 0.1 ft from the bottom. The local velocity was 3.19 ft per sec, the flume was set to a slope of 0.0025, and the water was flowing at an equilibrium depth of 0.495 ft. The suspended load had a mean settling rate in still water of 0.058 ft per sec.

The results of this experiment, presented in Table 1, show that, as the sampling velocity decreases, the quantity of sediment collected per given volume of fluid increases. When the sampling velocity is lower than the local stream velocity, the fluid streamlines curve away from the sampler tip.

TABLE 1.—EXPERIMENTAL DETERMINATION OF THE EFFECT OF THE SAMPLING VELOCITY ON THE AMOUNT OF SEDIMENT COLLECTED

No.	Observations[a]	$\frac{u_s}{u} = 1.00$	$\frac{u_s}{u} = 0.86$	$\frac{u_s}{u} = 0.75$	Definitions
1	$\bar{C}$	1.03	1.08	1.12	
2	$\frac{\bar{C}}{\bar{C}_s}$	1.00	1.05	1.09	[a] u_s/u is the ratio of sampling velocity to the velocity of the stream at the sampling point; $\bar{C}$ is the average sediment concentration, in grams per liter, for the series of samples; $\bar{C}/\bar{C}_s$ is the ratio of $\bar{C}$ to the average concentration obtained when the sampling velocity is equal to the stream velocity; and $C/\bar{C}$ is the ratio of the sediment concentration for individual sample to $\bar{C}$.
3	$\frac{C}{\bar{C}}$	0.99 1.04 0.99 0.95 0.97 1.06	0.98 0.94 1.08 0.90 1.00 0.99 1.05 0.91 1.10	1.13 0.99 0.95 0.99 1.00 0.97	

Because of their greater inertia the sediment particles follow paths of less curvature than the fluid, with the result that sediment is transferred to the fluid entering the sampler and the apparent concentration is increased. When the sampling velocity is greater than the stream velocity the curvature is toward the sampler, and a tendency to decrease the amount of sediment collected would therefore be expected.

The values of $C/\bar{C}$ in line 3, Table 1, give some idea of the fluctuation in concentration at a point in the flow. Although the deviation of the weights of individual samples from the mean was as high as 10%, it is interesting to note that the deviation of the average weight of three consecutive samples from the mean does not exceed 3%. Furthermore, the length of a filament of fluid having a volume of 1 liter and an area equal to that of the sampler tip is well in excess of the length of the flume, which is 60 ft.

Sediment Used as Suspended Load.—Sediments used as suspended load were prepared by grading a silica sand in a wind-tunnel classifier constructed[26] by George H. Otto and Professor Rouse. Fig. 4(*a*) shows a logarithmic probability chart of the size distributions of the three sands used as suspended load. The parameters that describe size and grading of these sands are listed in Fig. 4(*b*).

The quantity D_m is the geometric mean sieve diameter and is read directly from the chart. For a normal distribution (that is, when the curve is a straight line), the geometric mean and median diameters are equal. The quantity σ_g (Fig. 4(*b*)) is known as the geometric standard deviation of the sieve diameters. It is the ratio of the geometric mean size D_m to the size corresponding to the ordinate value 15.9%, which in turn is also equal to the ratio of the size corresponding to the ordinate value 84.1% to D_m. The method of plotting the size distribution and of calculating these parameters was shown by Mr. Otto.[27]

---

[26] "Wind-Tunnel Classifier for Sand and Silt," by George H. Otto and Hunter Rouse, *Civil Engineering*, July, 1939, pp. 414–415.

The quantity $\bar{D}_s$ is a weighted mean sedimentation diameter, the sedimentation diameter of a particle being defined as the diameter of a sphere having the same density and the same settling velocity as the particle. The mean settling velocity $\bar{w}$ of the center of mass of a group of particles was determined from observed settling times of individual particles of a representative sample of the sediment. The mean sedimentation diameter $\bar{D}_s$ is then the diameter of the quartz sphere having the settling velocity $\bar{w}$ in water. Calculation of the sedimentation diameter was based on the resistance coefficients for spheres as outlined by Professor Rouse.[28] The mean sedimentation diameter was also determined from sieve analyses by taking a weighted mean of the sedimentation diameters of the material held in each sieve, which were determined from actual settling-velocity measurements of samples taken from the sieve separates.

The average sediment concentration C_m for the entire flow was determined from samples siphoned from the collection tank through a $\frac{3}{4}$-in. pipe and rubber hose. The entrance of the siphon was directed vertically upward so the downward flow in the tank could enter without changing direction. During sampling the pipe was moved around to obtain fluid from all parts of the cross section.

2	0.120	1.11	0.133
3	0.091	1.13	0.100

FIG. 4.—LOGARITHMIC PROBABILITY GRAPH OF SIZE DISTRIBUTION OF SANDS USED AS SUSPENDED LOAD

Bottom Roughness.—As mentioned previously, the sides of the flume were lined with rubber, and the bottom was roughened with sand. The two bottom roughnesses used in the experiments were designated as sands 4 and 5. The mean diameters $\bar{D}_s$ for sands 4 and 5 were, respectively, 0.47 mm and 0.88 mm, and the corresponding standard deviations, σ_g, were 1.12 and 1.10. These sands were graded in the wind-tunnel classifier described previously. The sand was stuck to the bed of the flume with a water-resistant bitumastic paint. The metal surface was first painted and the sand immediately applied in sufficient quantity to cover the surface one layer deep. Any excess material was swept off after the paint was dry.

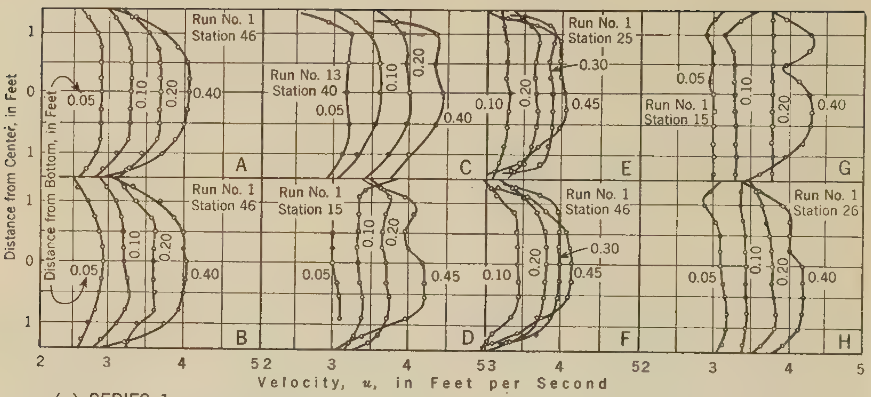
RESULTS

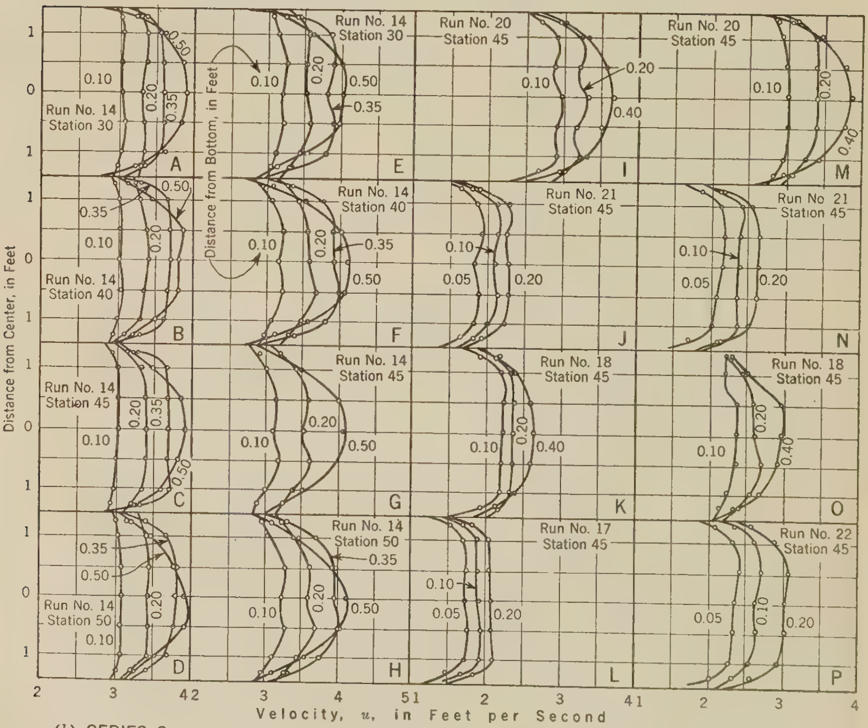
General Outline of Experiments.—The experiments in this study may be divided into two series. In the first series, in the flume circuit shown in Fig. 1(*a*), the slope of the flume ($S = 0.0025$) was kept constant and only one bottom roughness (sand 4) and one suspended load (sand 1) were used. Only the rate at which water was discharged and the amount of sediment in the system were varied. As mentioned under the heading, "Apparatus and Procedure," this circuit gave a disturbed condition at the entrance and was not considered entirely satisfactory. The disturbances were due to the pump, which was near the inlet to the flume, and to separation of the flow in the transition from the pipe to the flume. The latter separation of the flow was remedied, at least in part, by baffles, which, of course, introduced considerable resistance and, therefore, turbulence. A good index of the performance of the system is given by the head loss or the head developed by the pump, which amounted to about 5 ft for a discharge of 5 cu ft per sec.

The second series of experiments was made in the revised circuit shown in Fig. 1(*b*). No separation occurred in the transition section, and the velocity distribution was uniform and symmetrical. Only about 3 ft of head was required to circulate a flow of 5 cu ft per sec in the revised system. In this series, complete measurements were made with one bottom roughness (sand 5), three sizes of suspended load, and two depths at each of two slopes.

Velocity Distribution.—Eq. 16 for the distribution of sediment over a vertical section of a stream was derived for a flow with a large width-depth ratio—that is, two-dimensional conditions—and for the case of logarithmic velocity distribution. Before the relation can be applied to the present experiments it is necessary to show that the assumed conditions obtain. Fig. 5(*a*), with Table 2(*a*), shows the velocity distribution across the flume for the first series of experiments (runs 1 to 13). Typical velocity distribution curves for series 2 (runs 14 to 22) are shown in Fig. 5(*b*), with Table 2(*b*). Comparison of Fig. 5(*b*), distributions A to D, with Fig. 5(*a*), distributions D to F, shows at once the improvement in the flow effected in series 2 by changing the system from that shown in Fig. 1(*a*) to the one in Fig. 1(*b*). These velocity distributions also show that the influence of the walls of the channel does not extend to the center of the flume and that the assumption of two-dimensional conditions near the center of the flume is justified. The only way the resistance of the walls can be transferred to the center of the channel is by turbulent shear or momentum transfer, which can exist only if there is a horizontal velocity



(a) SERIES 1



(b) SERIES 2

Fig. 5.—Velocity Distribution Over Cross Section of Flume (see Fig. 1 for Circulation Systems)

gradient. The fact that this gradient is zero or very small permits the conclusion that near the center of the flume the influence of the walls is negligible.

Fig. 5(*a*), distributions D to F, and Fig. 5(*b*), distributions A to D, give the velocity at various distances from the inlet, and show the gradual stabilization of the velocity. Here again may be noted the improved flow conditions in series 2 (Fig. 5(*b*)). Despite the higher discharge, the equilibrium velocity is established in a short distance and obtains over the remaining length of the flume. The distortion of the velocity at depth 0.5 ft at station 50 (Fig. 5(*b*), distribution D) is due to backwater from the discharge end, which is at station 57. Fig. 5 also shows the effect of the sediment on the flow, discussed subsequently.

Figs. 6 and 7 show dimensionless semilogarithmic graphs of velocity profiles for series 1 and 2, respectively. The relative distance from the bottom $\frac{y}{y_m}$ is plotted on the logarithmic ordinate scale against the dimensionless velocity $\frac{u}{\sqrt{g\, y_m\, S}}$ on the abscissa scale. The quantity $\sqrt{g\, y_m\, S}$ is the so-called friction velocity, commonly written $\sqrt{\frac{\tau_0}{\rho}}$. The abscissa scale is shifted for each curve, the abscissa value 15 being indicated for each curve. The curves in Fig. 6 are arranged in four groups according to the average sediment content of the

flow. Those in Fig. 7 are grouped according to size of the sediment being transported.

In all runs the velocity distribution fits the logarithmic law very well, although near the bottom there is a systematic deviation from the law, which is not understood. A departure is expected near the bottom since the viscous forces are no longer negligible and the conditions for which the logarithmic law was derived no longer obtain. The viscosity tends to suppress the turbulence and to reduce the exchange coefficient ϵ_m in Eq. 1*b*, and, in order to develop the shear, the velocity gradient must increase. This would cause the velocity to decrease more rapidly than is indicated by the logarithmic law, and the result is opposite to the results shown in Figs. 6 and 7. In the present experiments, the origin of the depth coordinate was assumed to be at the top of the sand grains forming the bottom roughness. An inspection of the velocity profile curves will show that the fit could be improved by assuming the origin below this level although the justification for doing so is not clear. The deviation from the law was first attributed to errors in measurement due to interference between the pitot static tube (diameter, $\frac{3}{16}$ in.) and the bottom. Tubes as small as $\frac{1}{16}$ in. in diameter gave substantially the same readings as the larger instruments and showed that the measurements were reliable. An apparent deviation from the law is also to be noted at the free surface. However, because of surface waves and the disturbance of the pitot tube itself, it is felt that these measurements are not too reliable and that conclusions based on them must be drawn with reservation.

The fact that the velocity profiles fit the logarithmic law so well means that the average velocity will always occur at the relative depth $\frac{y}{y_m} = 0.368$.[29] This point is marked on the curves of Figs. 6 and 7 by a short dash. The average velocities determined by this method agree within 1% or 2% with those determined by graphical integration. The velocities $\bar{U}_1$ in Table 3 were determined by this method.

The velocity curves of Figs. 6 and 7 are of the form,

$$\frac{u}{\sqrt{g\,y_m\,S}} = \frac{u_{\max}}{\sqrt{g\,y_m\,S}} + \frac{2.3}{k}\log\frac{y}{y_m} \qquad (18)$$

in which k is a universal constant. The quantity $2.3/k$ is the slope of the curve on the semilogarithmic graph, and should be constant if k does not vary. A close inspection of the curves will show that the slopes do vary, as the size and concentration of sediment are varied. The values of k for each curve are shown in Figs. 6 and 7, and in Table 3. In general, k decreases as the concentration is increased or as the size of sediment in suspension is decreased.

Fig. 8 shows the velocity profiles for series 1 and 2, respectively, plotted according to the von Kármán velocity defect law (Eq. 14). In Fig. 8(*a*), the data of Fig. 6 have been combined according to the sediment content of the flow and show clearly the variation of k. In Fig. 8(*b*), the data of Fig. 7

have been grouped according to the values of k. The curves show that k is decreased by the presence of the sediment, but the relation between size of sediment and the universal constant k is not clear. Fig. 8 does show, however, that the logarithmic velocity law is valid and that its use is justified in developing Eq. 16 for suspended load distribution.

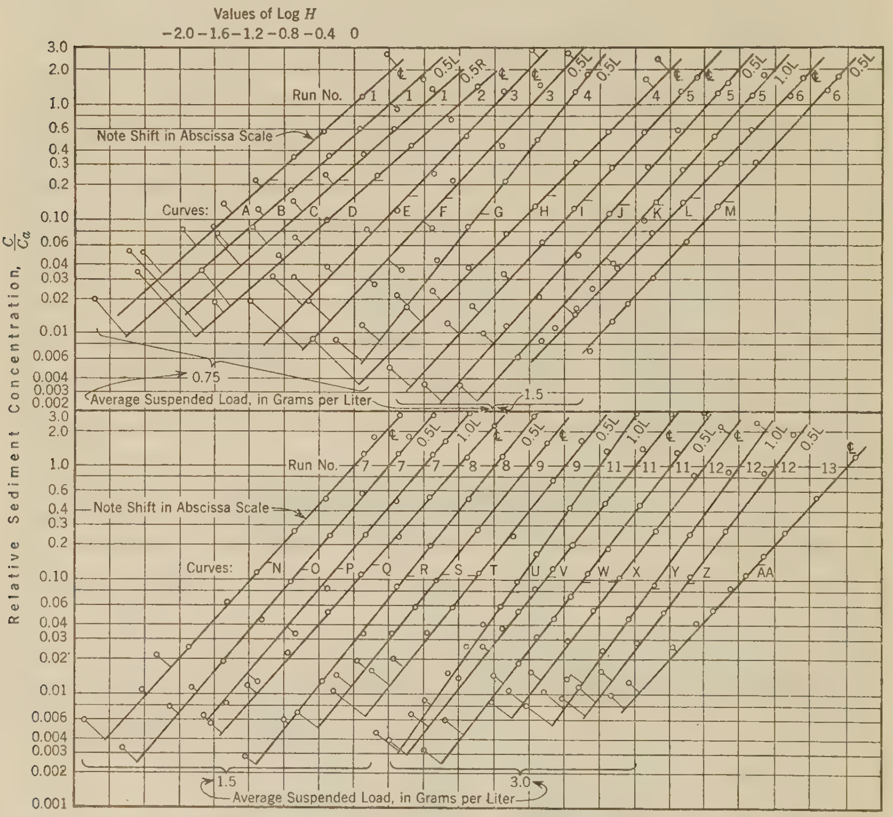

FIG. 9.—SERIES 1; MEASURED SEDIMENT DISTRIBUTION PLOTTED AGAINST THE DISTRIBUTION FUNCTION, H

Distribution of Suspended Load.—Eq. 16 plotted logarithmically is a straight line with a slope,

$$z_1 = \frac{\log \frac{C}{C_a}}{\log H} \dots\dots\dots\dots\dots\dots\dots\dots (19)$$

which may be read directly from the graph. Figs. 9 and 10 show the sediment distribution data for series 1 and 2, respectively, plotted logarithmically; that is, $\log C/C_a$ is plotted against $\log H$. The origin of the abscissa scale ($\log H$), which occurs at $C/C_a = 1$, is shifted for each curve. (The results of experiment series 2 were first reported by the writer in 1941.[30])

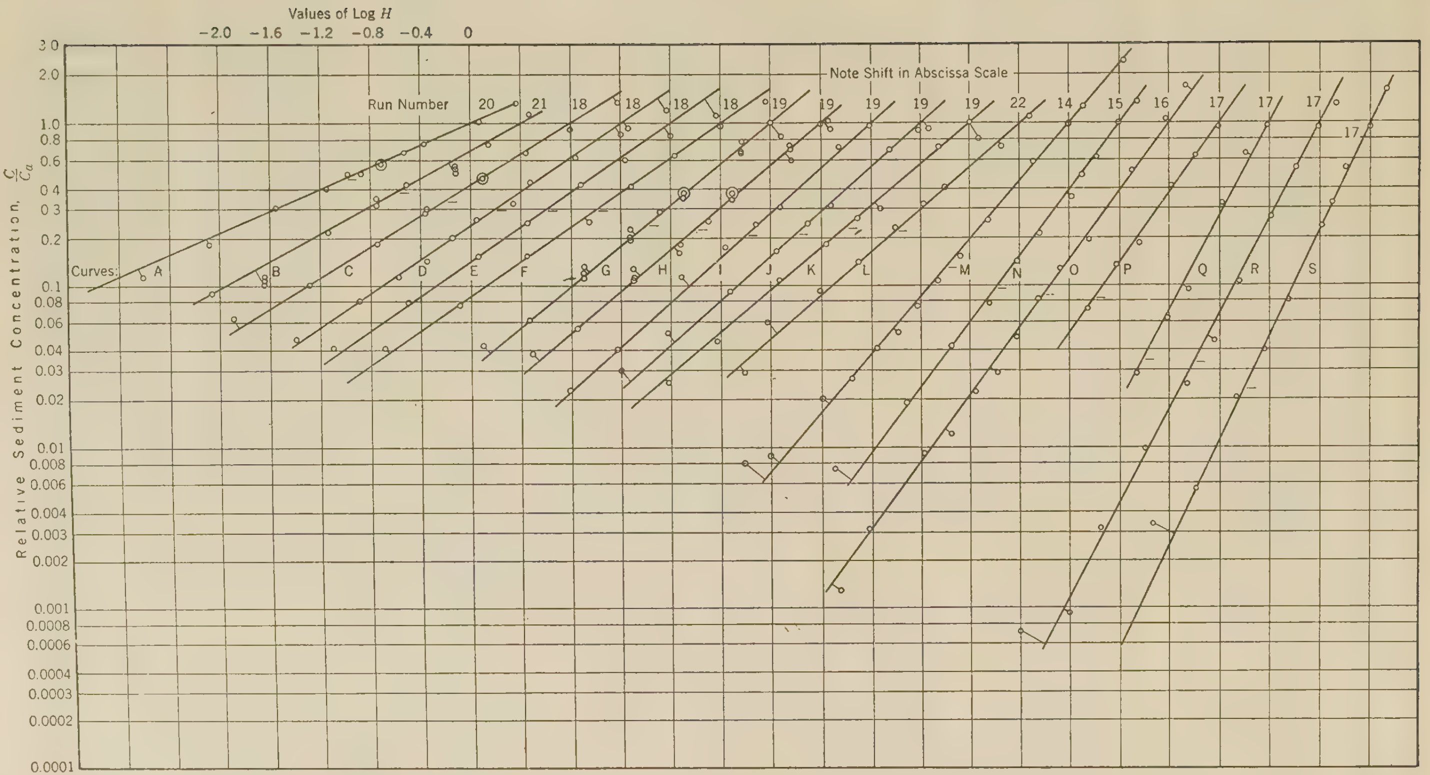

FIG. 10.—SERIES 2; MEASURED SEDIMENT DISTRIBUTION PLOTTED AGAINST THE DISTRIBUTION FUNCTION, H

The value of z may also be calculated from Eq. 17, in which w is the settling velocity of the sediment, k is the von Kármán universal constant, and $\sqrt{\frac{\tau_0}{\rho}}$ is the friction velocity. (In calculating z the value $\bar{w}$ of the settling velocity of the center of mass of a group of particles representative of the suspended load was used.) To distinguish between the value obtained by Eq. 17 and that obtained by fitting the experimental data in Figs. 9 and 10, the latter value is denoted by z_1. Obviously, if the theory is correct, the two values will agree.

The intersection of each curve with the line $\log H = 1.0$ is indicated by a short horizontal dash. The vertical distance from the origin ($C/C_a = 1$) to the dash, measured in cycles on the logarithmic scale is the value of z_1. Values of both z and z_1 are listed in Table 3. The two values agree well for runs 1 to 17, which were all made with the coarsest suspended load (sand 1). For all the runs with finer sand the value of z is from about 20% to 40% greater than z_1.

From inspection of Figs. 9 and 10, it is at once apparent that the results of series 2 are in much closer agreement with the distribution law (Eq. 16) than those of series 1. The disagreement occurs in the upper levels of the flow—that is, for small values of H—where more sediment is found than would be expected from the law. Results of the two series may be compared only for those runs made under comparable conditions with sediment of the same size. Runs 14 to 17 of series 2 were made with the same sediment as the runs of series 1 and may therefore be compared with runs of that series. These runs (14 to 17) also show more sediment in the upper levels than is given by Eq. 16, but the difference is slight. The rather large departures from the distribution law in series 1 are no doubt due to disturbances in the flow at the entrance, which, as stated previously, were appreciable compared with those occurring in the revised circulation system (Fig. 1(*b*)), used in series 2.

Figs. 9 and 10 show that the departures of the measured relative concentrations from the distribution law are small, and the curves also show conclusively that at least the form of the distribution function is correct. This conclusion is confirmed by Fig. 11, which shows $z_1 \log H$ plotted against $\log C/C_a$ for series 1 and 2. Here again the disagreement in the upper levels between measurement and the distribution function is noticeable, as is also the better agreement of the results of series 2.

Fig. 12 shows the relative sediment distribution as a function of the relative depth measured upward from the reference level $a = 0.05\, y_m$. The measurements are indicated by circles and the theoretical distribution is shown as a solid line. The agreement for series 2 (Fig. 12(*b*)), as previously seen, is good over the entire depth, whereas, series 1 (Fig. 12(*a*)) shows the departure in the higher levels noted before.

It is well to note that, in calculating the sediment distribution, the experimental values, z_1, of the exponents were used. Table 3 shows agreement between z and z_1 for only one sediment so it is not possible to say that the distribution law (Eq. 16) gives the correct values of the relative concentration, C/C_a. What can be said is that the distribution function is of the correct form.

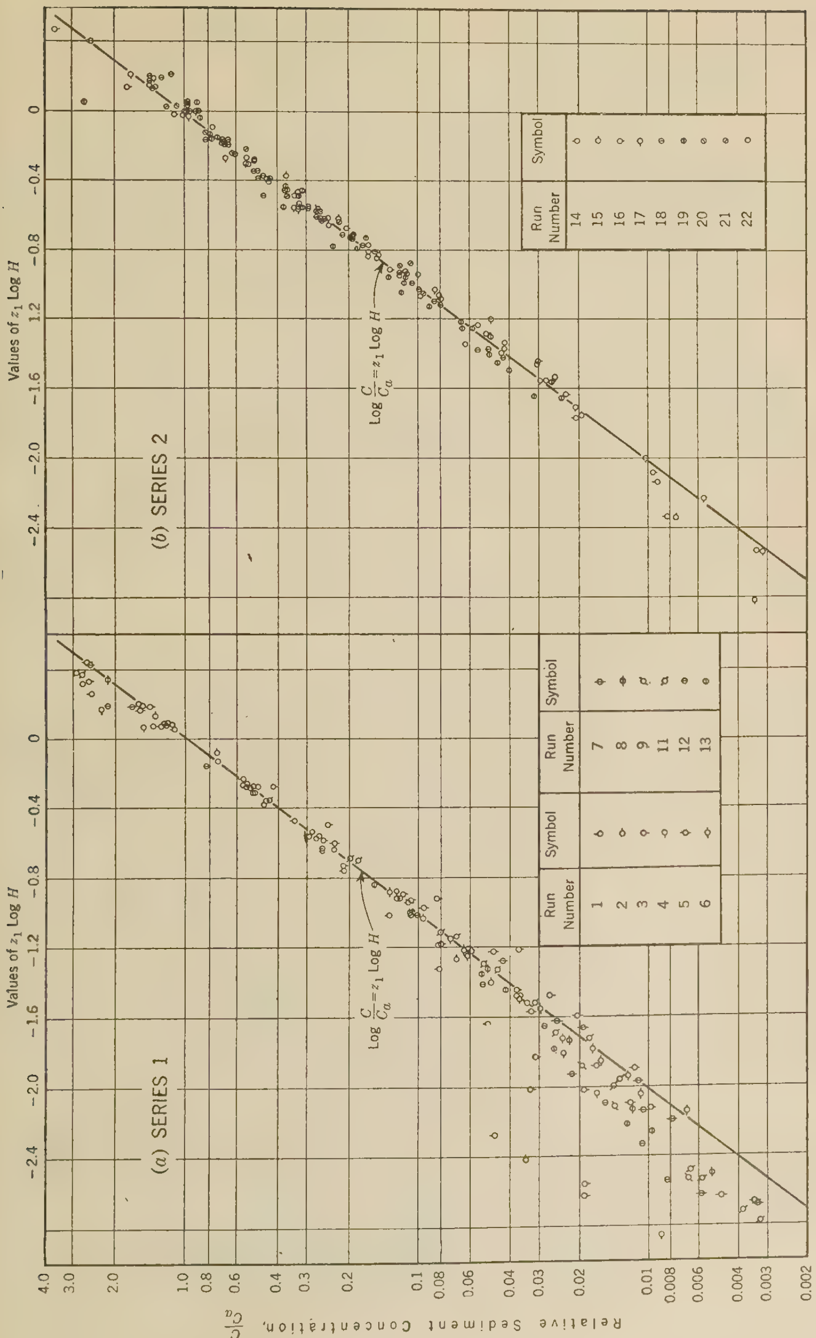

FIG. 11.—MEASURED RELATIVE SEDIMENT CONCENTRATION PLOTTED AGAINST CALCULATED SEDIMENT CONCENTRATION

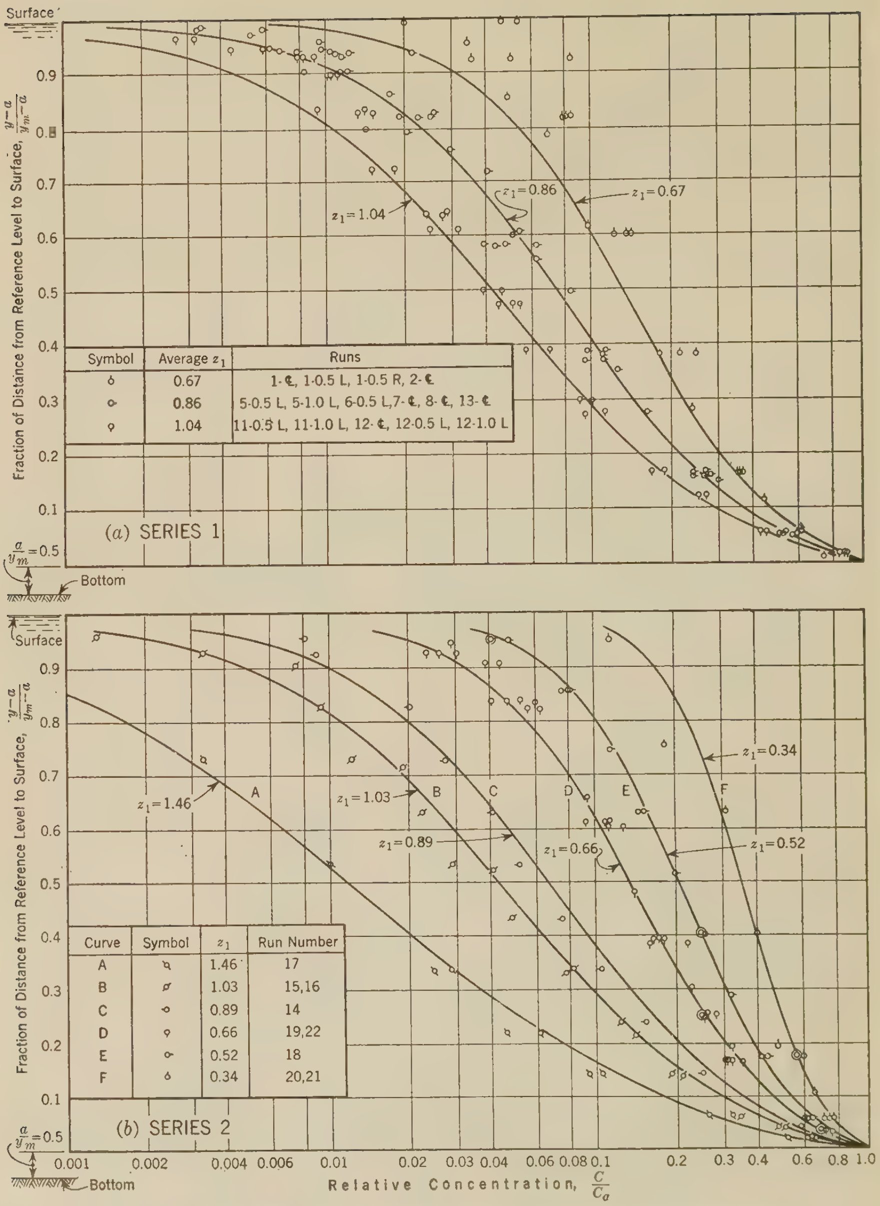

FIG. 12.—MEASURED AND CALCULATED RELATIVE SEDIMENT CONCENTRATIONS PLOTTED AS A FUNCTION OF RELATIVE DEPTH

Turbulent Transfer Coefficients.—The turbulent transfer coefficient for momentum is given by Eq. 10. Introducing Eqs. 12*b* and 15*a* into Eq. 10 gives

$$\epsilon_m = \beta v'_{\cdot} l = k \sqrt{\frac{\tau_0}{\rho}} \left(1 - \frac{y}{y_m} \right) y \ldots\ldots\ldots\ldots (20a)$$

Eq. 20*a* assumes logarithmic velocity distribution and linear distribution of shear and gives the coefficient ϵ_m for momentum transfer. In deriving Eq.16, the assumption was made that $\epsilon_m = \epsilon_s$. The measured sediment distribution now makes it possible to calculate the coefficient ϵ_s for the sediment by applying Eq. 6, which gives

$$\epsilon_s = \frac{w\,C}{\frac{dC}{dy}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20b)$$

The transfer coefficients may be reduced to a dimensionless form by dividing by the depth times the friction velocity as follows:

$$\frac{\epsilon_m}{y_m \sqrt{y_m\,g\,S}} = k \left(1 - \frac{y}{y_m} \right) \frac{y}{y_m} \ldots\ldots\ldots\ldots\ldots (21a)$$

and

$$\frac{\epsilon_s}{y_m \sqrt{g\,y_m\,S}} = \frac{w}{\sqrt{g\,y_m\,S}} \times \frac{C}{y_m \frac{dC}{dy}} \ldots\ldots\ldots\ldots\ldots (21b)$$

Fig. 13 shows both the coefficient for momentum (Eq. 21*a*) and for sediment (Eq. 21*b*) for four flow conditions. Figs. 13(*a*) and 13(*b*) are for series 1 with average suspended loads of 1.34 and 3.36 g per liter (Table 3), respectively, and in general are typical of this series. Figs. 13(*c*) and 13(*d*) are typical of results obtained in series 2, the former being for the coarsest sediment (sand 1).

The agreement between the two mixing coefficients for series 1 (Figs. 13(*a*) and 13(*b*)) is rather good. For the coarse sediment in series 2, the sediment coefficient is smaller than the momentum coefficient, whereas the opposite is true for the fine sediment. Eq. 7 shows immediately that small values of ϵ_s give small values of the concentration, C. It is also apparent from Eq. 16 that increasing ϵ_s, and therefore C, will tend to make the concentration more uniform, that is, it will decrease z. These effects may be noted in Figs. 13(*c*) and 13(*d*). In Fig. 13(*c*), ϵ_s is less than ϵ_m and the measured exponent z_1 is greater than z; whereas in Fig. 13(*d*) the opposite is true—z_1 is less than z.

DISCUSSION OF RESULTS

Effect of Suspended Load on Velocity Distribution.—The von Kármán universal constant k (Eqs. 14 and 18) depends only on the mechanism of turbulent mixing, and a change in k means that the mixing mechanism has in some way been altered. From Eqs. 1*b* and 15*a*,

$$\epsilon_m = k\,y \frac{\tau}{\rho \sqrt{\frac{\tau_0}{\rho}}} \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

or the momentum transfer coefficient is directly proportional to k. A decrease in k decreases ϵ_m, and if the shear (depth and slope) is kept constant the velocity gradient will have to increase to compensate for the reduced ϵ_m.

FIG. 13.—COEFFICIENTS FOR MOMENTUM TRANSFER AND SEDIMENT TRANSFER

This will result in an increase in the velocity of the flow. Thus it is seen that k is also a factor in establishing the velocity distribution.

The values of k obtained for various sediments and flow conditions are shown in Table 3. The effect upon k of increasing the sediment load is shown by series 1, runs 1 to 13. As the load, C_m, was increased, the k-values decreased. The results of series 2 show that the coarse sediment (0.160 mm), although reducing k somewhat, has less effect than the finer sediment. In general, k also appears to vary systematically with the friction velocity $\sqrt{g\, y_m\, S}$. However, there appears to be no simple relationship between the several factors. From these results one would expect k to be a function of w, the settling velocity of the sediment, the average sediment load, and the friction velocity $\sqrt{g\, y_m\, S}$.

Attention is called to the lack of agreement between the values of k obtained in series 1 and 2 for similar flows. For instance, the average k for clear water for series 1 was 0.372 whereas for series 2 it was 0.394. No straightforward explanation of these results can be offered. However, the difference is most likely due to the difference in the inlet conditions for the two series of experiments. The k-value obtained for series 2, which was run with very good flow conditions, checks very well with that obtained for pipes, and it is reasonable to assume that the results of this series are more reliable than those of series 1.

The Effect of Suspended Load on the Resistance to Flow.—As stated, a reduction in k results in an increased velocity, which will also give a reduction in the resistance coefficient of the channel. The Chézy formula for flow in conduits is,

$$\bar{u} = c\sqrt{R\,S} \quad \text{(23)}$$

in which $\bar{u}$ is the mean velocity in the cross section, c is the Chézy coefficient, R is the hydraulic mean depth (area of cross section divided by wetted perimeter), and S is the slope or pressure gradient. For open channels, c is given by the Manning formula,

$$c = \frac{1.486}{n} R^{1/6} \quad \text{(24a)}$$

in which n is a roughness coefficient. The Chézy coefficient can also be expressed in terms of f, the resistance coefficient,

$$c = \sqrt{\frac{8\,g}{f}} \quad \text{(24b)}$$

Eqs. 23 and 24 can be solved for n and f with the following result:

$$n = \frac{1.486}{\bar{u}} R^{2/3} S^{1/2} \quad \text{(25a)}$$

and

$$f = \frac{8\,g}{\bar{u}^2} R\,S \quad \text{(25b)}$$

Several values of n and f for flows with and without sediment are shown in Table 4.

The effect of the suspended load in reducing the resistance is seen clearly. The reduction in both n and f appears to be about the same for the two sediments but is greater for the low flows than for the high flows. The first three lines of Table 4 indicate that the resistance decreases as the sediment load increases.

The increase in velocity or decrease in channel resistance, as suspended load is added to the flow, can be explained by the effect of the sediment in reducing the turbulence. To keep the sediment from settling, work must be done on it. The energy for this work can be provided only by the turbulence which is damped and reduced in intensity when it gives up energy. This means that the momentum transfer coefficient is also decreased thus allowing the velocity and velocity gradient to increase according to Eq. 1*b*. (The late Henry M. Eakin, formerly head of the Sedimentation Section, Division of Research, Soil Conservation Service, had anticipated the effect of the sediment on the flow and advanced his idea on the subject to the writer in 1936 during a discussion of the suspended-load problem.)

[a] Feet per second. [b] Grams per liter.

A. B. Buckley[31] observed, from measurements on the Nile River in Egypt, that suspended load decreased the roughness coefficient of the channel. The reduction in resistance that he obtained for sediment loads of from 1.0 to 2.0 g per liter was in general greater than that obtained in the experiments described in this paper. Mr. Buckley attributed the reduction in resistance to the damping effect upon the turbulence of a heavily loaded layer of water near the bed of the stream. He expected the greatest reduction when a stream was depositing, for then the layer near the bottom would be most dense.

Distribution of Suspended Load.—All the measurements of suspended-load distribution followed very closely the form of the sediment distribution law, Eq. 16, but agreement between the calculated and measured value of the exponent z occurred only for the coarsest suspended load ($\bar{D}_s = 0.160$ mm). For the finer sediments the value z_1 of the exponent that fits the data, or the measured value, was about 20% less than the value calculated from the theory. (Measurements of suspended load in a natural stream made recently by Alvin G. Anderson,[32] Assoc. M. Am. Soc. C. E., show that z_1 was about half as large as z.) As noted previously, the smaller the value of z the more uniformly the sediment is distributed over the depth.

---

[31] "The Influence of Silt on the Velocity of Flowing Water in Open Channels," by A. B. Buckley, *Minutes of Proceedings*, Inst. C. E., Vol. 216, 1922–1923, pp. 183–211.

[32] "Distribution of Suspended Sediment in a Natural Stream," by Alvin G. Anderson, *Transactions*, Am. Geophysical Union, Pt. II, 1942, pp. 678–683.

The mixing coefficient ϵ is given by Eq. 3 and has the same form for both momentum transfer and sediment transfer but not necessarily the same value.[5] For a fine sediment the mixing coefficient for momentum was smaller than the corresponding coefficient for sediment transfer. It can readily be seen that increasing ϵ_s will tend to produce a more uniform sediment distribution, which results in z_1 being smaller than z.

The fact that the coefficients of sediment transfer and of momentum transfer are not the same may be explained by two differences in the transfer mechanisms for sediment and momentum. The first difference occurs because, for momentum transfer, a correlation is required between the horizontal and vertical turbulent velocity fluctuations and uncorrelated or random fluctuations do not contribute to the momentum transfer. For sediment transfer this kind of correlation is not necessary and the random fluctuations also transfer sediment and tend to make ϵ_s larger than ϵ_m. The second difference exists because of the "slip" between the fluid and the sediment. The theory assumes that the instantaneous vertical velocity of the sediment relative to the fluid is always equal to its settling velocity w in still fluid. This is true only for steady conditions and during acceleration the relative velocity must be greater than w and the sediment is carried a shorter distance than assumed. This will tend to make ϵ_s less than ϵ_m.

The experiments show that in flows carrying the coarsest sediment the two transfer coefficients are about equal and that, as finer sediment is introduced, ϵ_s becomes increasingly larger relative to ϵ_m. Apparently for the fine sediment the effect of the random turbulence in increasing ϵ_s is greater than the effect of the "slip" between the particles and fluid in decreasing ϵ_s. For the coarse sediment the two effects are about balanced and if still coarser sediment were used a resultant effect of opposite sign is expected and ϵ_s should be less than ϵ_m. The effect of the variation of the transfer coefficients relative to one another is reflected in the relative values of z and z_1 which may be noted in Table 1, For flows carrying the fine sediment where ϵ_s is greater than ϵ_m, z_1 is less than z. and when the two transfer coefficients are equal, z and z_1 are also equal.

The tendency for the sediment content near the surface of the flow to exceed that indicated by the distribution formula, Eq. 16, can be explained by the action of the random turbulence. Although the mixing coefficient for momentum goes to zero at the surface, the random velocity fluctuations carry sediment right up to the very surface, thus giving the mixing coefficient for sediment a finite value at the surface. This can be noted in Fig. 13.

Attention is called to the wide disagreement between the values of z and z_1 in the first two sediment profiles of run 17 (Table 3). Considerable difficulty was experienced in this run because the sediment was not distributed in a regular manner over the cross section. Since the flow was very low and the sand coarse, considerable material was moving along the bottom. Any irregularity in the distribution was therefore easily noticed. The first measurement (Table 3 and curve S, Fig. 10) was made over a point where considerable sediment was in motion in a narrow band on the bottom. The abnormally large value of z_1 could be accounted for by the occurrence of a transfer of sediment in the horizontal direction away from the measuring point, brought about by the existence of a concentration gradient across the flow. In the same way it is possible to account for the low value of z_1 obtained in the second measurement of run 17. This measurement was taken over a point where very little sediment was in motion on the bed but a few inches to one side of the section considerable sand was being carried. The transverse transfer of sediment into the measuring section would decrease the vertical concentration gradient and therefore the value of z_1. It is surprising that even under such conditions the distribution should follow the law expressed by Eq. 7.

Secondary Flow Due to Suspended Load.—The effect of the suspended load was first noticed in measuring the velocity distribution over cross sections of the flume. Symmetrical velocity distributions in clear flows became distorted by the addition of very small amounts of sand. This effect may be noted in Fig. 5(*a*), distributions A, B, and C, which show the velocity distributions for clear water and for average sediment concentrations of 0.75 and 3.0 g per liter, respectively. To give an idea how small the concentrations actually were, it might be well to remark that the first concentration ($C_m = 0.75$) was obtained by adding only 12.5 lb of sand to the entire system. The effect of this small concentration on the flow may also be seen by comparing the center column of Fig. 5(*a*) with the right column. The effect is small for this small concentration, but it is noticeable. Incidentally, attention is called to the uniform spacing of the velocity lines in Fig. 5(*a*), distribution A. This shows at once that the velocity distribution is logarithmic since the distances y from the bottom of the flume are spaced geometrically.

The disturbing effect of the sediment is also shown in Fig. 5(*b*). Distributions A to D, Fig. 5(*b*), for clear water, may be compared with distributions E to H, Fig. 5(*b*), which show the velocities under like conditions except that there is sediment in the flow. Distributions I and M, Fig. 5(*b*), show a case in which the sediment apparently has a stabilizing effect. In this one instance, the conditions were apparently just right to establish good flow at this particular station. The fact that the distorted velocity distribution with clear water was made more uniform by the addition of a small amount of sediment serves to illustrate again that the sediment has considerable influence on the flow.

The sediment appeared to be transported in clouds or ribbons parallel to the flow. At low flows when appreciable material was moving along the bottom, these ribbons appeared as bands of sand on the bottom. When proper flow conditions had been attained, these ribbons were symmetrically spaced about the center line and were stable regardless of the flow rate. Attempts to break them up artificially were only partly successful. Fig. 14 is a photograph of these bands of sediment taken after run 15, looking upstream. The photograph was taken after the flow had been stopped and the water slowly drained off. Material in suspension settled to the bottom, thus showing how it was distributed across the flow. Three main streaks occur in the center portion of the flume and two less pronounced streaks occur at the walls. This pattern, which was symmetrical, occurred over the entire length of the

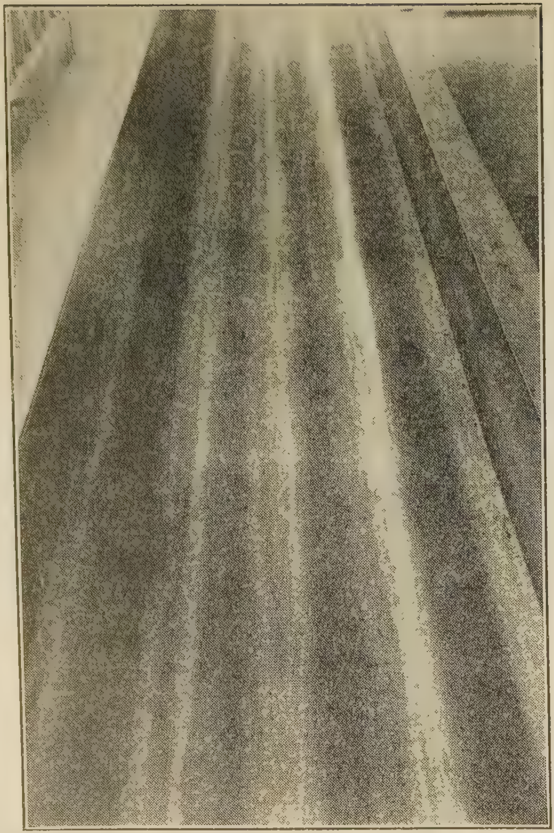

FIG. 14.—SEDIMENT ON FLOOR OF FLUME AS DEPOSITED BY THE FLOW OF RUN NO. 15

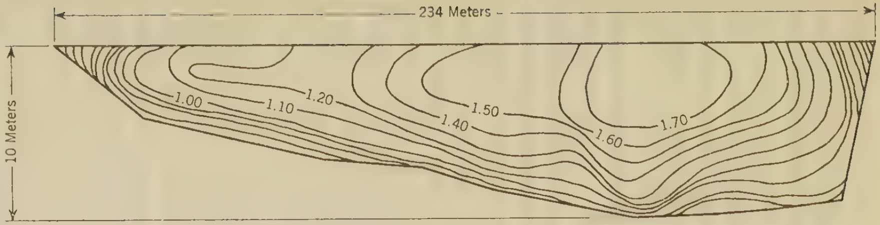
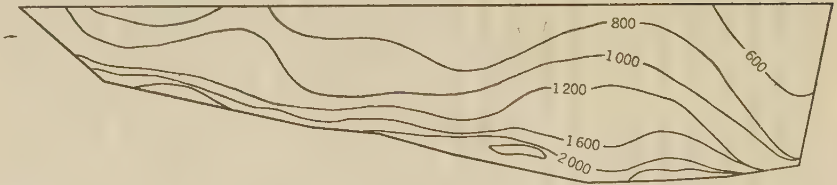
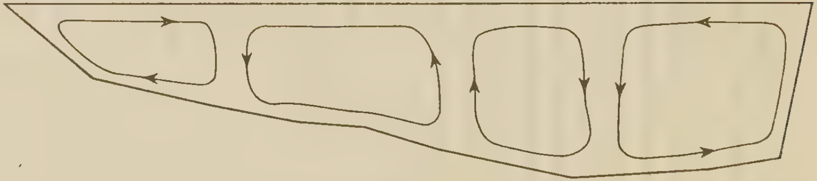


(*a*) VELOCITY IN METERS PER SECOND



(*b*) SUSPENDED LOAD IN GRAMS PER CUBIC METER



(*c*) CIRCULATION

FIG. 15.—FLOW CHARACTERISTICS, RIVER PO IN ITALY

flume. Measurement of suspended load at a distance of 0.02 ft from the bottom showed that the sediment was very nearly uniformly distributed over the center half of the flume, that it then suddenly dropped to about 25% of the center concentration as the clear areas near the walls (Fig. 14) were approached, and finally increased to about 50% of the center concentration near the walls. The concentration for the center 6 in. was about 5% less than that over the concentrated streaks at the side. (The flume is 33¼ in. wide by 12 in. deep.)

The cause of these longitudinal bands of sediment is not known, although it is believed that they are the result of secondary circulation and disturbances due to the presence of suspended load. Even the slightest departure from a uniform sediment distribution will cause horizontal density gradients that can set up secondary flows. This distribution shows a concentration gradient across the flow, and one could then expect a circulation with an upward flow at the points of low concentration and a downward flow where the load was high. Since there appear to be four points of low concentration, four pairs of circulations might be expected. No direct observations were made to attempt to check this hypothesis, and it is doubtful that this could be done without considerable work. However, this is a possible explanation of the action of the sediment in causing secondary circulations in the flow. Further investigation will show whether or not this idea is valid.

If circulation could be caused by sediment in a uniform and straight laboratory channel, there is a very good possibility that it will also occur in natural streams where irregularities and disturbances always exist. Therefore some measurements of suspended load in rivers were examined. Figs. 15(*a*) and 15(*b*) show measurements of velocity and suspended load at a cross section of the River Po in Italy, reported by Giandotti.[33]

Note the high concentration of suspended load at about the one-quarter points of the section. The circulation expected from this distribution is shown in Fig. 15(*c*). The writer is not able to state whether this distribution is typical of rivers. However, these measurements in the River Po are evidence that a circulation may be caused by the sediment. The circulation that would be induced is the same as that advanced as an explanation for the depression of the maximum velocity in natural streams. Although this circulation explains the velocity distribution, no satisfactory explanation was ever found for the circulation itself. The action of sediment on river flow may well prove to be an important factor in determining the velocity distribution.

Sediment-Transporting Capacity.—The idea that sediment in suspension reduces the turbulence furnishes a possible mechanism for establishing the capacity of a stream. Since the turbulence supports the sediment a reduction in the turbulence by adding sediment means that the stream then is less capable of supporting sediment than before a load was added. The capacity load is probably determined by continually decreasing the turbulence as more sediment is taken into suspension. The fact that the addition of sediment to a flow increases the velocity, therefore, does not mean that the sediment transporting capacity is also increased. On the contrary the capacity is actually decreased. The increase in velocity also means that the depth and, hence, the boundary shear is decreased and that particles in the bed are probably subjected to less entrainment force than when the velocity was lower.

---

[33] "Les Déplacements du Lit du Pô," by Mario Giandotti, Le Service Hydrographique Italien, XV Congres International De Navigation, Venice, September, 1931, pp. 297–322.

It is seen not only that turbulence is involved in the sediment transportation problem, but that the sediment changes the turbulence itself, the amount of change apparently depending upon the amount and size of the suspended load. In a clear flow the velocity can be expressed in terms of certain constants which characterize the turbulence mechanism. In sediment-laden flows these constants are now functions of the sediment load and sediment characteristics.

CONCLUSIONS

1. The distribution of the relative concentration of suspended load has the form of the derived distribution law (Eq. 16) but does not agree quantitatively with it; that is, the value of the exponent z given by the theory does not agree with z_1, the exponent that fits the experimental results. When the suspended sediment is fine, z_1 is less than z. This shows that the relative concentration is more uniformly distributed and has a greater average value than that indicated by the theory. In other words, a flow can support and, therefore, transport fine sediment more effectively than the theory indicates. As the size of the sediment is increased, the agreement between the two exponents improves up to a certain point, beyond which the value of z_1 may be expected to exceed z.

2. The disagreement between the calculated and measured distributions cited in conclusion 1 is attributed to (*a*) the action of the random turbulent fluctuations in suspending sediment, and (*b*) the "slip" between the fluid and the sediment as the sediment is accelerated. The theory is based on the assumption that the coefficient of sediment transfer is equal to the coefficient of momentum transfer, and therefore does not account for the action of the purely random turbulence and of the slip. Such disagreement was anticipated, aud the present results confirm it.

3. For fine material the coefficient of sediment transfer tends to exceed the coefficient of momentum transfer; for coarser sediment the opposite tendency is found. Conclusion 3 may be considered a corollary of conclusion 1, the physical reason for the conclusions being set forth in conclusion 2.

4. Suspended load decreases the coefficient of momentum transfer, the reduction varying with the amount of the load and being largest for fine sediment.

5. Suspended load reduces the value of the von Kármán universal constant of turbulent exchange k, which characterizes the effectiveness of the turbulence in transferring momentum. Reduction of k means that the mixing is less effective and would indicate that the sediment tends to suppress or damp out the turbulence. This conclusion follows directly from conclusion 4.

6. Suspended load reduces the resistance to flow, thus causing sediment-laden water to flow faster than clear water. This follows directly from con-

70849

clusions 4 and 5. In the laboratory channel an average suspended load of 1.2 g per liter reduced the friction factor, *f*, as much as 20%, and the corresponding Manning roughness coefficient was reduced as much as 10%.

7. Conclusions 1 to 6 can all be related to essentially three effects that occur in the flow in the presence of the sediment: (1) The sediment appears to damp out the turbulence in such a way that the momentum transfer is reduced, (2) random turbulence, which is not a factor in the transfer of momentum, contributes to the transfer of sediment, and (3) the "slip" between the fluid and the sediment tends to make the sediment transfer coefficient less than the momentum transfer coefficient.

8. The idea that suspended sediment damps the turbulence suggests that the transporting capacity of a stream is determined through the reduction of the turbulence by the sediment.

9. The increase in velocity, due to the addition of sediment to a clear stream, probably does not give rise to an increased sediment-transporting capacity since it is accompanied by a reduction in turbulence and in the entrainment force at the stream bed.

10. Suspended load tends to cause a flow to become unevenly distributed. Unsymmetrical sediment distribution within the flow may cause secondary circulation.

11. In rivers, density gradients due to suspended load may be an important cause of the secondary circulation, which has the effect of causing the maximum velocity to occur below the water surface.

12. The velocity distribution near the center of the flume used in these experiments was of the logarithmic form and followed the von Kármán universal velocity defect law.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the friendly assistance of Professors von Kármán and Knapp and of members of the staff of the Cooperative Laboratory of the Soil Conservation Service and the California Institute of Technology in which the experiments reported herein were performed. Acknowledgment is due also to Roy Peterson, Milton Wood, and Robert Wise for their assistance in collecting and analyzing the data.

Assistance in the preparation of these data was furnished by the personnel of Work Projects Administration, Official Project No. 65–2–07–58, Work Projects No. PS–11496.

DISCUSSION

RALPH W. POWELL,[34] M. AM. SOC. C. E.—The subjects covered in this paper have recently attracted much attention, and the quite complete treatment the author has given is most welcome. It is hoped that in his closure he will explain the relation of his results to those of A. A. Kalinske and C. L. Pien,[35] Assoc. Members, Am. Soc. C. E., which seem to be founded on an entirely different approach, but which also lead to laws of logarithmic vertical distribution of both longitudinal velocity and sediment concentration. It may be stated, however, that G. I. Taylor,[36] in his "modified vorticity transport theory," deduces that velocity distribution for two-dimensional flow is cycloidal (except for the laminar boundary layer at the bottom). Although the cycloidal equation is entirely different from the author's logarithmic one, the numerical values differ hardly enough to be distinguished experimentally. The writer once amused himself by deriving a simpler distribution by thinking of the laminar two-dimensional flow of oil of high viscosity with a thin layer of water between it and the bottom. The velocity profile, of course, proves to be the parts of two parabolas, the lower one in the water being practically a straight line, and the upper one with its vertex at the upper surface of the oil. This gives an approximate picture of two-dimensional turbulent flow, the water representing the laminar boundary layer, and the oil the turbulent part with its high (mechanical) viscosity. It is only approximate because the mechanical viscosity is not uniform, but is a function of the depth.

Neither this rough approximation nor the more accurate cycloidal or logarithmic equations fit the case where the flow is not two-dimensional, however—as, for example, in narrow rectangular channels or rivers of nonuniform depth. As is well known, in these cases the maximum velocity occurs some distance below the surface, and Eq. 15*a* could not possibly apply. The only satisfactory explanation of this depression, which the writer has seen, was

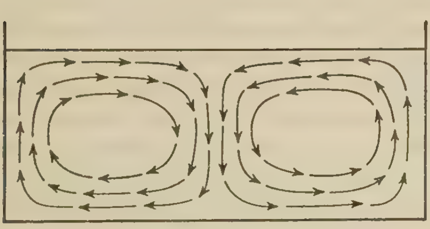


FIG. 16.—SECONDARY FLOW AS DESCRIBED BY STEARNS, MÖLLER, AND GIBSON

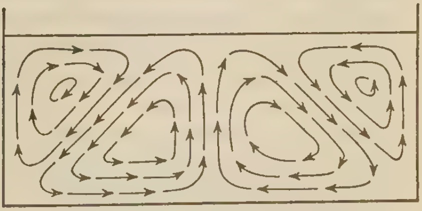

FIG. 17.—HYPOTHETICAL SECONDARY FLOW SUGGESTED BY THE WRITER

developed independently in 1882 by the late F. P. Stearns,[37] M. Am. Soc. C. E., in America and Max Möller[38] in Germany, although Mr. Stearns acknowledges that the explanation had been suggested to him some six years earlier by the late Hiram F. Mills, M. Am. Soc. C. E. The explanation is that in straight channels there is a double spiral flow as shown in Fig. 16, superimposed on the forward flow, which carries the slower moving water from the bottom up along the sides and out along the top to the center. At the center it mixes with what would otherwise be the fastest moving water, thus slowing the rapid water to a velocity somewhat less than that in the region just below.

[36] "Flow in Pipes and Between Parallel Planes," by G. I. Taylor, *Proceedings*, Royal Soc. of London, Series A, Vol. 159, 1937, pp. 496–506.

Those who inquire as to what causes these spirals discover a very amusing situation. A. H. Gibson[39] follows out the thinking of Mr. Stearns and states:

> "Frictional losses at the sides reduce the energy and thus the head of the water in their neighborhood, with the result that the surface level at the sides is lower than near the center of the stream, and the cross-sectional profile of the water surface is a curve concave to the bed. Owing to this superelevation of the water near the center and its tendency to find its own level, transverse currents are set up which travel downwards near the center of the stream; outwards along the bottom to either bank, upwards along the sides, and, for permanence of *régimé*, inwards along and near the surface."

Mr. Möller,[38] however, takes just the opposite view:

> "Each filament of water that approaches the bank * * * suffers retardation, and hence requires greater cross section, whereas the conditions in the center of the stream are reversed, water filaments there being accelerated and requiring less cross section. Both actions lead to the production of a slight transverse drop in the water surface * * * and in the formation of spiral motion on either side."

Mr. Möller then shows an illustration with the water surface highest at the sides; but all three agree that the spirals are as shown in Fig. 16. Hydrodynamics would seem to the writer to show that these spirals would cause the water surface to be slightly higher at both the sides and the center, and lower at the quarter points, but, since the velocity of the spirals is very small, the additional head due to curvature would be extremely minute, and at any rate it would be an effect, rather than a cause, of the spirals. The writer has the same feeling in regard to the author's conclusion (10), and believes that the double spiral flow is a cause of the unequal distribution of suspended load, rather than a result of it.

The cause of these double spirals is still obscure to the writer. L. Prandtl[40] has shown why there will be secondary flow toward the corners and away from the sides in the case of turbulent flow in rectangular pipes. Similar reasoning applied to a rectangular channel might explain spirals somewhat as shown in Fig. 17, but this is a pure flight of fancy on the part of the writer and he has no proof that it actually exists. There is just the possibility that such spirals might have been observed by Messrs. Stearns, Möller, and Gibson, and have been mistaken for the form shown in Fig. 16, but it does not seem very probable.

TABLE 5.—"EQUIVALENT ROUGHNESS" OF FLUME WITH VARIOUS SEDIMENT CONCENTRATIONS

Run No.	Number of values averaged	Average concentration, C_m (g per liter)	Mean diameter, $\overline{D}_s$ (mm)	Ratio of equivalent roughness to size of bottom sand
1, 2, 3	3	0	0	0.89
14, 20, 21	4	0	0	0.86
17	2	0.048	0.160	0.34
19	5	0.17	0.103	0.19
2	1	0.35	0.160	0.65
15, 16	2	0.59	0.160	0.40
1	4	0.72	0.160	0.78
4	2	0.79	0.160	0.89
3	2	0.85	0.160	1.02
18	4	1.18	0.103	0.40
20, 21	2	1.2	0.103	0.51
22	1	1.3	0.134	0.42
8, 14	3	1.34	0.160	0.68
9	2	1.41	0.160	0.36
5, 7	6	1.60	0.160	1.07
6	2	1.78	0.160	0.60
12	3	2.56	0.160	0.41
13	1	3.19	0.160	0.54
11	3	3.36	0.160	0.50

The other point which the writer wishes to discuss is the reduction in resistance to flow which the author finds accompanies the presence of sediment. The writer has suggested,[41] as a formula for resistance to flow in rough channels,

$$c = 40 \log \frac{R}{\epsilon} + c_s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26a)$$

in which c is the Chézy coefficient, R is the hydraulic radius, ϵ is the equivalent roughness of the channel bottom (in the same units as R), and c_s is the shape correction coefficient proposed by G. H. Keulegan[42] to correct the Chézy coefficient to a corresponding channel of infinite width; that is, to eliminate the effect of the side-walls. (The value of c_s is 14.18 times the value of β given by Mr. Keulegan.) In the author's experiments the side-walls were smooth and relatively far away from the sections studied, so that c_s may be taken as zero and R as y_m, the depth; thus:

$$c = 40 \log \frac{y_m}{\epsilon} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26b)$$

---

[41] "Flow in a Channel of Definite Roughness," by Ralph W. Powell, *Proceedings*, Am. Soc. C. E., December, 1944, p. 1521.

[42] "Laws of Turbulent Flow in Open Channels," by Garbis H. Keulegan, *Journal of Research*, National Bureau of Standards, Vol. 21 (December, 1938), p. 719.

Values of c were computed for all the data of Table 3, and from these the value of ϵ, the equivalent roughness, given by Eq. 26b, was determined. These values were then divided by the diameter (in feet) of the sand forming the bottom roughness. For water without sediment it might be expected that this ratio would be 1, but the scale of roughness used in Eqs. 26 is not quite the same as that of Nikuradse, values of the writer's ϵ being somewhat smaller than Nikuradse's sand size.[41] All runs with approximately the same concentration were grouped together and the ratios of ϵ to size of bottom sand were averaged. Table 5 shows the results, arranged in ascending order of sediment size. The general weighted average for each size of sediment, irrespective of concentration, was as follows:

Mean diameter, $\bar{D}_s$ in millimeters	Ratio of equivalent roughness to size of bottom sand
0	0.87
0.103	0.32
0.134	0.42
0.160	0.69
All runs with sediment	0.59

Although it is evident that in general the equivalent roughness is reduced by the presence of sediment, there is great variation in the effect and there are even a few cases in which there seem to be an increase (runs 3, 5, and 7, Table 5). There also seems to be no relationship between the amount of sediment and the reduction, run 17 with only 0.048 g per liter giving the largest reduction of any concentration of the 0.160 mm sediment. The only consistent variation is that shown by the average for each size, which indicates that the reduction is greater for the smallest size and least for the largest. This might be interpreted as meaning that the reduction in resistance is a function of the number of particles present rather than of their total mass. It should perhaps be pointed out that the variation is not quite as great as might be thought at first. If the bottom sand were 0.47 mm in diameter and the depth 0.50 ft in both cases, the values of c corresponding to the ratios of 0.34 and 1.07 (the smallest and largest shown in Table 5 for 0.160 mm sediment) are 119.2 and 99.3, a variation of only 9.1% each way from the mean.

The writer has not tried to touch on some of the most interesting points in this valuable paper, which can better be discussed by those more familiar with the details of this subject, but has tried to indicate a few directions in which he hopes that further investigation will be made.

E. R. Van Driest,[43] Assoc. M. Am. Soc. C. E.—Experimental investigations conducted with the accuracy and thoroughness that is evidenced by this paper are of fundamental importance in dealing with problems of applied fluid mechanics. Particularly is this true in the field of sedimentation in flowing water where the number of variables encountered is great. The paper depicts clearly the trials and tribulations of an experimenter (1) in building apparatus for the proper control of conditions and (2) in bringing theory and data together.

---

[43] Asst. Prof., Mech. Eng., Mass. Inst. Tech., Cambridge, Mass.

In the presentation of the theory, it might add to the paper to point out the fact that the problem of suspension of sediment by flowing water is but one of the three important turbulence transfer problems usually encountered in engineering. The most common is that of internal friction or momentum transfer expressed by Eq. 2. Another such problem which has received considerable attention is that of heat transfer, the formula for which is

$$q = -\rho\, c_h\, \epsilon_h \frac{dT}{dy} \dots\dots\dots\dots (27)$$

in which, in addition to the notation of the paper, q is the rate of heat transfer across a unit area normal to the y-axis; c_h is the specific heat of the fluid; T is the temperature; and ϵ_h is the heat transfer coefficient. Through the assumption that $\epsilon_h = \epsilon_m$ (the basic assumption of the Reynolds analogy between heat transfer and skin friction), great progress has been made in heat transfer for flow in pipes. The third transfer problem—that of sediment transfer—has for its basic relation Eq. 4. The paper proceeds to show that progress is now being made in the sedimentation field when ϵ_s is assumed equal to ϵ_m or when the mechanism for the transfer of sediment is assumed the same as the mechanism for the transfer of momentum. Since these three phenomena are of the same nature, they can be derived from one general transfer formula,

$$Q_\theta \doteq -\epsilon \frac{d\theta}{dy} \dots\dots\dots\dots (28)$$

in which Q_θ is the mean rate of transfer of any property θ per unit volume across a unit area perpendicular to y. By merely substituting any of the foregoing properties per unit volume—that is, momentum $\rho\, u$, heat content $\rho\, c_h\, T$, or sediment concentration C—into Eq. 28, the aforementioned equations will result. Indeed, any other properties may be assumed to be transferable in the same sense.

The author shows some concern about the fact that the velocity distribution data do not fall entirely on a straight line when plotted on semilogarithmic paper. Furthermore, he states that this departure is due to viscous action, but finds that such an assumption does not explain the results. The truth of the matter is that Nikuradse's data do not fall exactly on a straight line either.[44] Neither do his data for smooth pipes[45] fall precisely on a straight line when one plots the data separately for each run. All Nikuradse's data for smooth and rough pipes, except those for the lowest three Reynolds numbers in the smooth pipes when the viscous layer does show its presence, have a characteristic S-shape. A straight-line plot does appear to exist when all the data are plotted on the $\left(\frac{u}{\sqrt{\frac{\tau_0}{\rho}}}, \log \frac{y}{e}\right)$-scales, in[46] which e is the linear dimension characterizing roughness; however, even here the prevailing S-pattern can be observed for each run. That the viscous layer does not affect the author's data is evidenced by a simple computation which will show that the position of the data taken nearest the bottom is at least ten times as far from the bottom of the roughness grains as the edge of the laminar boundary layer which is at the most one half as thick as the sand roughness grains. Measuring the distance y from the bottom of the grains makes the measurements consistent with those of Nikuradse who measured his distances from the wall or, rather, from the base of the sand grains, and this does have a decided effect upon the plotting of the data very close to the wall. In Nikuradse's plots for individual runs, the straight line drawn for $k = 0.40$ passes through the data as a mean line. It appears that such a line for $k = 0.40$ has the same mean relation to the data of Fig. 8 for no sediment added, even after the data are shifted to conform with measurements from the bottom of the grains.

[44] "Strömungsgesetze in Rauhen Rohren," by J. Nikuradse, *Forschungsheft 361*, Vereines Deutscher Ingenieure, Vol. 4, 1933, Figs. 15*a*, 15*b*, 15*c*, 15*d*, 15*e*, and 15*f*, p. 9.

[45] "Gesetzmässigkeiten der turbulenten Strömung in Glatten Rohren," by J. Nikuradse, *Forschungsheft 356*, Vereines Deutscher Ingenieure, Vol. 3, 1932, pp. 1–36.

[46] "Strömungsgesetze in Rauhen Rohren," by J. Nikuradse, *Forschungsheft 361*, Vereines Deutscher Ingenieure, Vol. 4, 1933, Fig. 14.

The data of Fig. 8 seem to prove quite conclusively that the value of k is decreased by the presence of sediment, and it appears logical that this should be so, because of the dampening effect of the sediment. However, the absolute effects of size and quantity are still uncertain, thus showing the need for further controlled experimentation. If the concentration has a decided effect upon k, then it should be logical to assume that the velocity distribution curve should be distorted considerably because of the large variation of concentration over the depth. This effect does not appear to exist.

An intriguing observation is that the exponent z_1 suddenly changes from the theoretical value when the size, and not the amount of sediment, is changed. The only explanation that the writer can give for this disagreement follows from the apparent circulation of sediment. Since the value of ϵ in any vertical line is more uniform near the wall than in the central part of the channel, the sediment transfer theory requires the sediment concentration to be more uniform vertically near the wall than farther in the channel thereby causing the concentration to be greater at the water surface near the wall than in the channel. This variation along the surface then causes a horizontal flow of sediment toward the center of the channel. In this process, however, all the sediment at the bottom corner is picked up, leaving a sediment gradient along the bottom decreasing toward the corner, which in turn results in a flow of sediment along the bottom toward the corner. The entire process obviously results in a circulation of sediment, not necessarily water, which may develop into a complex circulation pattern. It follows that heavier or larger grains should not be diffused too far into the flow and therefore that such sediment should be more uniformly distributed horizontally in the central part of the channel. On the other hand, the lighter or smaller grains would be diffused farther into the flow, thus easily causing higher concentrations near the surface at the central part of the flow and therefore producing values of z_1 smaller than the theoretical values. It is concluded, therefore, that complete sediment traverses throughout the stream are necessary to interpret, fully, the results obtained.

As mentioned by the author, sediment appears at the stream surface even though the momentum transfer coefficient there must become zero if the logarithmic velocity distribution law is assumed to hold all the way to the surface. This inconsistency promptly disappears when it is noted that the logarithmic law does not hold at the surface if the velocity gradient there is to be zero because of a presumably zero shear. Although one would expect the transfer coefficient to approach zero at the surface as a result of a zero approaching velocity gradient, yet some agitation should be expected because of the migration of eddies from the adjacent lower layer of turbulent fluid. Evidence of this diffusion can be observed readily on the surface of turbulent rivers. A more simple case of such diffusion is demonstrated by the movement of eddies from a point of disturbance at the bottom of a jar of water into the overlying quiet fluid.

The writer wishes to re-emphasize the need and importance of such basic experimental work in sediment transportation. The paper unquestionably represents considerable progress in this field.

WESTON GAVETT,[47] ASSOC. M. AM. SOC. C. E.—Velocity distribution profiles, obtained from careful observations of velocities in a wide open channel with known bottom roughness, are an important part of this comprehensive paper.

The author states (see heading, "Results: Velocity Distribution") that "In all runs the velocity distribution fits the logarithmic law very well, although near the bottom there is a systematic deviation from the law, which is not understood." Figs. 6 and 7 are plotted with semilogarithmic coordinates in accordance with the von Kármán velocity defect law (Eq. 14), which the author states (see heading, "Previous Work") "* * * has been shown by J. Nikuradse[9,10] to apply to pipes and by G. H. Keulegan[11] to apply also to open channels."

The general acceptance of the von Kármán law which the author endorses in this and in an earlier paper[29] may discourage interest in the exponential formula of the form,

$$u = u_{\max}\left(\frac{y}{y_{\max}}\right)^{n} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(29)$$

which, although not universal, seems to give better agreement with observations.

Nikuradse[45] showed that his velocity distribution curves for smooth pipe followed the exponential law and that n varied with the Reynolds number. Prandtl[48] has mentioned the seventh-power law based on Blasius' experimental law of pressure drop and has shown that, although the seventh-power law breaks down for Reynolds' numbers above about 50,000, similar derivations may be made for other powers. The writer has plotted a number of velocity profiles from various sources on log-log paper and has found that the greater number show good agreement with the exponential formula.

---

[47] Asst. Engr., Clyde Potts, New York, N. Y.

[48] "Applied Hydro- and Aeromechanics," based on lectures of L. Prandtl, by O. G. Tietjens, McGraw-Hill Book Co., Inc., New York, N. Y., 1934, p. 70.

The velocity defect law has the advantages of being universal and of locating the approximate velocity profile when the friction velocity is known, without regard to roughness.

The exponential formula also has merits: (1) In giving a more accurate expression for velocity distribution and (2) in providing a simple expression for the velocity distribution in a pipe or channel and perhaps also for that in a plate or side of a ship. To apply the exponential formula, it is necessary to know the appropriate value of n, which appears to vary in accordance with definite laws that should be determinable from sufficient experimental data. For smooth pipe, n varies with the Reynolds number and decreases as $\mathbf{R}$ increases. It also varies in smooth pipe with δ, the laminar thickness, showing an exponential relationship. If n is plotted against δ, the laminar thickness for smooth pipe, and ϵ, the equivalent sand size for rough pipe, on log-log paper, the (n-ϵ)-curves for rough pipe appear to intercept the (n-δ)-curve for smooth pipe at points determined by a value of r/ϵ and to branch off with slopes greater than the smooth pipe curve.

The author states (see heading, "Results: Velocity Distribution") that "The fact that the velocity profiles fit the logarithmic law so well means that the average velocity will always occur at the relative depth $\frac{y}{y_m} = 0.368$.[29]" If the exponential law is valid, there will be some variation of y/y_{max} with n because

$$\frac{u_{avg}}{u_{max}} = \frac{1}{n+1} \qquad \text{(30a)}$$

and

$$\frac{y_{avg}}{y_{max}} = \left(\frac{1}{n+1}\right)^{1/n} \qquad \text{(30b)}$$

By replotting the points from Figs. 6 and 7 on log-log paper, the writer obtained a mean value of n of 0.145 for runs 1A, 2B, and 3C with a bottom roughness of 0.47-mm sand and no suspended load. For bottom sand size of 0.88 mm and no suspended load (runs 14A, 14B, and 21C), the value of n was 0.175. For these values of n, the mean velocity depths from Eq. 30b are as follows:

Description	Runs 1A, 2B, and 3C	Runs 14A, 14B, and 21C
Bottom sand size, in millimeters	0.47	0.88
Roughness coefficient n	0.145	0.175
Relative depth ratio $\frac{y_{avg}}{y_{max}}$	0.393	0.398

The variation in y_{avg}/y_{max} is not great, but, for the extreme values of n for smooth and rough surfaces of about 0.10 and 0.36, the corresponding values of y_{avg}/y_{max} would be 0.385 and 0.425.

For pipe, the author[29] has given a constant mean distance of 0.223 r_0. The following expressions are derived from the exponential formula for pipe:

$$\frac{u_{avg}}{u_{max}} = \frac{2}{(n+1)(n+2)} \qquad \text{(31a)}$$

and

$$\frac{y_{\text{avg}}}{r_0} = \left[\frac{2}{(n+1)\,(n+2)}\right]^{1/n} \ldots\ldots\ldots\ldots\ldots\ldots (31b)$$

For values of n of 0.1 and 0.36, the corresponding values of y_{avg} would be $0.237\ r_0$ and $0.269\ r_0$.

The author's data indicate that the bottom sand size, equivalent to that used by Nikuradse, is smaller than the actual size of sand used, possibly because a part of the sand was embedded in the coating.

The average velocities computed by Eq. 30*a* check closely with the average velocities given by the author as computed from the velocity defect law, indicating that the von Kármán law may be correct for the average velocity. If so, the formula of B. A. Bakhmeteff,[49] M. Am. Soc. C. E., is simple and convenient:

$$\frac{u_{\max} - u_{\text{avg}}}{\sqrt{\frac{\tau_0}{\rho}}} = \frac{3}{2\,k} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Substituting $k = 0.4$ in Eq. 32, $\dfrac{u_{\max} - u_{\text{avg}}}{\sqrt{\frac{\tau_0}{\rho}}} = \dfrac{3}{2} \times \dfrac{1}{0.4} = 3.75$. The same value of 3.75 results from substituting 0.223 for y/r_0 and $k = 0.4$ in Eq. 14. Prandtl's value for this constant according to Professor Bakhmeteff is 4.07, which agrees better with values computed from Nikuradse's data.

BERARD J. WITZIG,[50] ASSOC. M. AM. SOC. C. E.—An excellent service to the science of hydraulics has been rendered by Professor Vanoni in enlarging and completing his previous paper on sediment transportation,[30] and he is to be commended for a careful exposition and presentation of details leading to logical conclusions. The problem of sediment suspension and transportation by water involves fundamental principles that are only imperfectly understood, and only by painstaking research will limited existing knowledge of the phenomena be expanded.

In the "Introduction," the author mentions two essentially different modes of sediment transportation—"bed load" and "suspended load." As long as it is remembered that the distinction between these modes is merely arbitrary[51] because of the insurmountable difficulties of treating the sediment load of a stream as a whole, there should be no slighting of the possibility that a much larger quantity of sediment in some streams may move as bed load than as suspended load.

The relations and the results given in this paper should not be applied indiscriminately to the total suspended load. The exponential vertical distribution of sediment applies only to the coarse suspended load. However, in some streams, a large part of the total suspended load consists of very fine silt, termed the "wash load,"[52] and is very nearly uniformly distributed over the stream cross section. Any conclusions based on a logarithmic or exponential distribution of the wash load would be misleading or erroneous. Apparently an appreciable wash load did not occur in the author's experiments, in which a carefully graded sand was used. It would be of interest, however, to know Mr. Vanoni's views on the probable influence of a uniformly distributed wash load, in combination with a logarithmically distributed coarse suspended load, on the sediment transfer coefficient.

[49] "The Mechanics of Turbulent Flow," by Boris A. Bakhmeteff, Princeton Univ. Press, Princeton, N. J., 2d Ed., 1941, Eq. 116, p. 70.

[50] Engr. (Civ.), U. S. Engr. Office, Buffalo, N. Y.

[51] "Fluid Mechanics for Hydraulic Engineers," by Hunter Rouse, McGraw-Hill Book Co., Inc., New York, N. Y., 1938, p. 331.

Although probably of merely academic interest, it seems appropriate to point out that a transitional mode of sediment transportation exists, known as "saltation." In saltation, grains of bed material are lifted momentarily into the moving fluid, then bouncing back on to the bed, possibly dislodging other particles. When the turbulence of the stream exceeds a certain level, these particles move into the suspended load zone. Quantitatively, the saltation load is probably insignificant. Prof. A. A. Kalinske,[53] Assoc. M. Am. Soc. C. E., concluded that, when the water velocity is great enough to cause saltation, the turbulence level is also sufficient to obscure the saltation effect entirely, by placing the material lifted from the stream bed into suspension.

The paper succinctly summarizes modern fluid turbulence theory as applied to sediment suspension. The present state of knowledge and research necessitated the author's initial assumptions that the sediment transfer coefficient, ϵ_s, is equal to the momentum transfer coefficient, ϵ_m, and that these coefficients are constant over the depth. The experimental results described demonstrate the falsity of the former assumption, but it is not apparent whether they either prove or disprove the latter. The writer considers it probable that some of the apparent discrepancies in the published data, such as the large variation in the values of z and z_1, run 17, Table 3, might be due to some unaccountable deviation in the $(\epsilon - y)$-relation.

The author explains that the laboratory flume used in his experiments had rubber sides, with apparently a very small roughness coefficient. A narrow flume, however, is bound to exert a pronounced "side-wall effect," especially where the bottom itself is comparatively smooth, as was the case here and as is shown in Fig. 5. Although Fig. 5 demonstrates that the side-wall effect of the experimental flume extended only about one sixth of the flume width from each side, the writer is of the opinion that such an extensive series of tests should have been made in a wider flume. A fundamental assumption for the two-dimensional analysis of the problem is that the theoretical equations for the vertical distribution of velocity and of sediment are valid only in "wide" channels. In this case, the ratio of depth to width was about 1:5.5, and its recognized effects on the experimental observations are indicated by the fact that all measurements in Table 3 were confined either to the center line of the flume, or to a vertical not more than 0.5 ft from the center line. Laboratory limitations, of course, specify the practicable width of flume, but some increase in the ratio of width to depth should be desirable in future experiments.

[52] Discussion by Joe W. Johnson of "Sedimentation in Reservoirs," by Berard J. Witzig, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 1072.

[53] "Criteria for Determining Sand-Transport by Surface Creep and Saltation," by A. A. Kalinske, *Transactions*, Am. Geophysical Union, Pt. II, 1942, pp. 639–643.

The effect of the depth-width ratio in a turbulent and rapidly flowing natural stream is illustrated by discharge measurements made in 1943 under the writer's direction near the head of the Cascades, in the American channel of the Niagara River at Niagara Falls, N. Y. At the time of the measurements, the average depth was about 6 ft; the width at the gaging section, about 480 ft; the measured discharge, 16,150 cu ft per sec; and the mean velocity, 7.5 ft per sec. Vertical velocity traverses made with a current meter showed that a generally exponential gradient existed, with the maximum velocities occurring at the surface. These measurements also indicated that the mean velocity in a vertical occurred, on the average, at the 0.55 depth from the surface, instead of at the 0.6 depth commonly assumed in discharge measurements. The logarithmic law places the mean at the 0.632 depth from the surface. It seems probable that such variation in field observations from theoretical assumptions and laboratory results must place in doubt the validity of generally applying the latter to the large-scale phenomena existing in natural streams.

The writer was particularly interested in the analysis of the effect of sediment loads on the roughness coefficient of the flume. Runs 18, 20, and 21, Table 4, however, apparently indicate some inconsistencies. For the clear water run in each case, Manning's n was 0.0118, 0.0121, and 0.0128, respectively; whereas, with a sediment concentration of 1.2 g per liter, n was 0.0107, 0.0116, and 0.0116, respectively. Runs 18 and 21 showed a ratio of 1.10 for clear flows compared with silt flows, but run 20, under practically identical conditions, gave a ratio of 1.04. Can this apparent inconsistency be explained by the change in slope and velocity, or should it be ascribed to the difficulties of laboratory measurement?

It would be of interest to find some explanation of the mechanism whereby the channel roughness is decreased by the presence of sediment in the fluid. May not the lamina of high concentration fill the rough projections of the channel bed, thereby acting as a lubricating film and decreasing the apparent roughness coefficient? Merely as a speculation, it is also suggested that an increase in silt load may decrease the apparent roughness at a diminishing rate to a certain point, and that thereafter a further increase in silt content may produce a result similar to an increase in viscosity, with greater resistance to flow.

The author suggests that one of the reasons for the difference between the momentum and sediment transfer coefficients is the "slip" between the fluid and the sediment particles. The writer considers that this "slip" is due in part to the inertia and the "drag" of the particles. The difference in the effect of fine and coarse sediments on ϵ_s compared with ϵ_m might reasonably be expected. Small particles, with a relatively larger surface area per unit of mass as compared with larger particles, should naturally be more readily moved or kept in suspension by the random turbulence; the "slip" effect also should be less because of the smaller mass and drag; and molecular impact should be more pronounced.

It is suggested that discrepancies between z and z_1, as well as the consistent variation actually demonstrated, might be caused by secondary, or more properly "tertiary," circulation in the third (horizontal) dimension. If such variations appear in carefully controlled laboratory tests, even wider variations may be expected in natural streams, where complex circulations are induced by winds at the surface, bends in alinement, tributary and surface inflow, and irregularities of the sides and bed.

The description of the horizontal distribution of sediment in segregated bands and clouds omits reference to any observed vertical segregation. Did such vertical separation exist, and, if so, did the sediment tend to follow the fluid filaments of highest velocity? The writer's observations of silt-laden natural streams indicate that sediment flows appear to move in "slugs" or clouds, but he has not noticed band-like movements. It is probable that these may not occur in natural streams because of the large degree of turbulence. With reference to Fig. 15(*c*), it is not readily apparent how the secondary circulation is derived from the velocity and sediment diagrams.

It is questionable whether the increase in velocity accompanying silt flows results in an actual decrease in the entrainment forces exerted on bed particles. An increase in stream velocity causes increased erosion when the stream is not burdened to capacity with its sediment load. When the stream is fully charged with sediment, it seems probable that the concentration near the bottom may be so great that no net increase in load may result, although a continual interchange takes place. Such a stable condition may be due, not so much to the theoretical decrease in shear accompanying the smaller depth and greater velocity, as to the fact that the full transporting capacity is already in use.

The writer considers that the author has ably and amply demonstrated previously anticipated effects of sediment loads on the transfer coefficient, and that his experiments indicate the relative magnitude of these effects for the range of concentrations and sizes of sediments studied. The apparent effect on channel roughness or resistance suggests that further intensive research on this particular aspect of the problem would be of interest economically, as it may appreciably affect practical design of pipe lines or flumes for commercial or industrial transportation of materials in suspension.

The author has shown that a very complex problem in hydraulics is susceptible, at least in part, to rational and experimental analysis. Other experimenters should find encouragement in his report of progress.

A. A. KALINSKE,[54] ASSOC. M. AM. SOC. C. E.—Data from an extensive series of measurements of the transportation of suspended material by water in an open channel are presented in this paper. The writer does not in any way question the value or accuracy of these data; however, he does seriously disagree with many of the conclusions drawn from the data, especially with the conclusions in regard to the effect of suspended sediment on the turbulence and hydraulic characteristics of the water flow. Specifically, the paper contains no real concrete evidence to prove the validity of the conclusions relating to: (1) The action of random velocity fluctuations on suspended sediment; (2) the effect of suspended sediment on the von Kármán k-values; and (3) the hypothesis that suspended load reduces resistance to flow.

---

[54] Associate Prof., Univ. of Iowa, and Associate Director, Iowa Inst. for Hydr. Research, Iowa City, Iowa.

So far as similarity of the transfer of sediment by turbulence to the transfer of momentum in an open water channel is concerned, the writer does not believe any too definite statements can be made as yet—for the one important reason that it is difficult to calculate the correct value of the momentum-exchange coefficient. All such computations must be based on some assumption as to the value and distribution of the shear. It is doubtful if, in a channel such as that used by the author, the shear is distributed linearly, due to the side and free surface effects and secondary currents. The author calculated the value of ϵ_m using the logarithmic velocity distribution law, which is not quite correct either near the water surface or near the bottom. Thus, the value of ϵ_m in the paper may not necessarily be the true value of the coefficient of momentum transfer. Any rigid comparison between ϵ_m and ϵ_s, therefore is not really warranted.

The author's remarks regarding the presence or absence of correlation between the turbulent velocity components are somewhat confusing. The correlation that exists when momentum is exchanged in two-dimensional flow is the relationship between the vertical component v' and the horizontal component u'. The presence or absence of any such correlation has no relation to the transfer of sediment since the horizontal component u' has nothing to do with keeping sediment in suspension. If the shear is zero, the correlation between u' and v' is zero, since, according to Reynolds, the shear in the turbulent flow can be expressed as

$$\tau = \rho \, \overline{u' \, v'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

However, this does not mean that the turbulent exchange coefficient is zero. Thus, in the center of a pipe the shear is zero, but ϵ has a finite value since heat or mass can be transferred across the center of a pipe even though momentum cannot be transferred. So far as the writer knows, the only way to obtain an accurate idea of the transfer coefficient in a region of flow where the shear is difficult to estimate is by direct measurement using diffusion experiments. The writer has reported such measurements elsewhere.[35]

The writer's chief criticism of the author's laboratory procedure is that the experiments were not made with the channel bed completely covered with the sand being transported in suspension. If the bed is not completely covered with unconsolidated sand, a particular flow is not transporting all the sediment in suspension that it is capable of transporting. Of course, there is always some loose sand on the bottom; however, the patches of sand are constantly changing and, of course, are influencing the bed roughness. Thus, the bed roughness for one discharge may be different from that for another discharge. In other words, the bed undoubtedly differed for the various runs, thus very likely producing the effects on velocity, friction factor, and k that the author attributes to changes in concentration or size of material in suspension.

For the study of the transportation of sediment in suspension and of the effects that this suspended sediment may have on the hydraulic characteristics of the water flow, it is necessary that the flow take place over a bed entirely covered with the material being transported in suspension and that the suspended matter be in equilibrium with such a bed. Unless this is done, the data obtained will be useful only for the study and analysis of the vertical distribution of suspended sediment in turbulent flow.

In similar experimental studies made by the writer, the channel bottom was always covered with the material being moved in suspension and the results from these studies do not in any way confirm the author's conclusions. In 1943 an extensive series of experiments was made at the Iowa Hydraulics Laboratory, University of Iowa, Iowa City, on the transportation of a fine sediment (median diameter 0.011 mm) in a flume 2¼ ft wide with about ½ ft of water.[55] Runs were made with water velocities varying from 0.84 to 2.73 ft per sec and with sediment concentrations varying from 0.64% to 11.1% by weight. Some of the conclusions drawn from these studies were as follows:

(1) The velocity distribution in the center of the channel followed the logarithmic law very well and no difference was noted even when the sediment concentration was 11.1%;

(2) Manning's *n* was influenced by the form of the bed, which varied with the bottom shear, and not by sediment concentration; and

(3) The value of the von Kármán *k*-factor changed from 0.32 to 0.44 without any regular variation with respect to sediment concentration.

The sediment concentrations in the studies at the Iowa Hydraulics Laboratory were considerably higher than those in the author's experiments and also had a wider range. However, the size of the material used was very much smaller. The writer is forced to state that the results of the studies at the Iowa Hydraulics Laboratory do not seem in any way to confirm the author's conclusions which apparently were intended to be quite general in scope.

PAUL F. NEMENYI,[56] ESQ.—The investigations made by Professor Vanoni represent a considerable advance in the study of sediment dynamics and of the relation of sediment dynamics to turbulence. Professor Vanoni's analysis of the deviations between the distribution of momentum transfer and sediment transfer in the cross section of a conduit seems particularly valuable. The highly controversial subject of secondary currents, too, has been advanced considerably by the author (see heading, "Discussion of Results: Secondary Flow Due to Suspended Load), by the phenomenon observed in connection with run 15.

The first observations on this subject were made by the German geophysicist, Max Möller,[38] and the American hydraulic engineer, the late F. P. Stearns,[37] M. Am. Soc. C. E., simultaneously and independently of each other in 1882. Both writers agreed that secondary circulation consists of two perfectly symmetrical parts tending toward the middle of the open conduit at the top and tending outward at the bottom of the open conduit. Fig. 18(*a*) represents the Möller interpretation of this flow. The phenomenon was rediscovered, independently of both Messrs. Möller and Stearns, by A. H. Gibson,[39] in 1909 (see Fig. 18(*b*)), who found the order of magnitude of the cross-velocity component to be 5% of the longitudinal main velocity. Mr. Gibson's investigations seem to improve upon those of Messrs. Möller and Stearns both as to exactness and range of observations. Mr. Gibson found the surface convex whereas Mr. Möller thought it to be somewhat concave. There is a good theoretical reason to believe that in this point Mr. Gibson's observation is correct, because roughness protuberances, like any other obstacles, tend to produce a locally lowered average pressure. The theoretical explanations offered by Mr. Möller are "begging the question," whereas those by Mr. Gibson appear to be obscure.

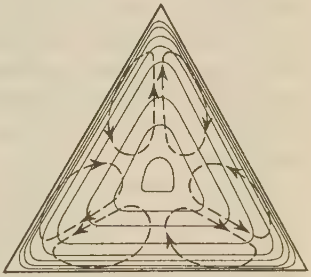
(*a*) MAX MOLLER

(*b*) A. H. GIBSON

Fig. 18.—Original Observations on Secondary Currents

The three independent investigators agree remarkably well, in assuming the simplest imaginable general pattern of secondary circulation. This very reassuring finding, which is generally accepted by most hydraulic engineers, is challenged by the more elaborate research of L. Prandtl[40] concerning turbulent flow in conduits. Although Mr. Prandtl's investigations refer mainly to closed conduits (see Fig. 19), their implications for open channels and rivers are obvious. Mr. Prandtl's starting point is the surprising shape of the "isovels" in a closed conduit with turbulent flow. The following translation (by the writer) will give an idea of the experimental facts and the hypothetical conclusions based upon them by Mr. Prandtl—



(*a*) TRIANGULAR SECTION

(*b*) RECTANGULAR SECTION

Fig. 19.—Secondary Currents in Closed Conduits, According to the Prandtl Hypothesis

> "Instead of a velocity distribution having increasingly rounded (convex) isovels proceeding inward, as they are known in laminar flow, remarkable types of velocity distributions are found, as shown by the particularly

> surprising illustrations for the rectangle. For a long time no reasonable explanation was attainable. A paper concerning some old observations on helicoidal movements in straight channels gave a clue which led to an adequate explanation. The water in any conduit with a noncircular cross section has such a secondary movement that in any corner the secondary movement is directed along the bisectrix of the angle toward the corner, whereas, along the adjoining sides, the secondary movement is away from the corner. These secondary streams, together with the turbulent pulsations, explain the observations well. The secondary streams are always carrying longitudinal momentum toward the corner, thus causing the unexpectedly high longitudinal velocities found there. However, how can the existence of the secondary streams be explained? There is no explanation unless the pulsatory, mixing movement along the isovels of the cross section—the 'asimutal' pulsation—is assumed to be more vigorous than that perpendicular to it along the velocity gradient. Indeed, if this is true, a simple consideration of the momentum distribution shows that the type of pulsations assumed to be particularly vigorous is connected of necessity with forces pointing toward the convex side of the isovels—forces which are particularly strong where the isovels have sharp curvatures. The question of why the pulsations are of the particular type assumed, however, is part of the 'great problem of turbulence' for which even a tentative solution, for the time being, is unattainable."

It is obviously impossible to draw a system of secondary streamlines for any cross section, such that each line is closed and, at the same time, is an orthogonal trajectory to the isovels. The best procedure to follow, therefore, is to start by tracing orthogonals to the system of isovels in the region where they have very sharp curvature and to consider these as part of the secondary streamlines. The remainder of the secondary streamlines, even if Mr. Prandtl's basic assumption is accepted as correct, will be based more or less upon conjecture.

Some uncertainty, however, is inherent in every theory that is merely qualitative. More serious than these uncertainties in practical application is the question as to the acceptability of the fundamental conceptions underlying the Prandtl hypotheses. For a statistically steady and permanent flow it is strictly meaningless to consider the steady secondary streams as caused by certain pulsations, and the shape of the isovels as caused by the secondary streams, because all are present at the same time and identically present in any cross section. The basic idea of causation, the explanation of the future from the present (or the present from the past), is inapplicable here. Therefore, in the background of Mr. Prandtl's too schematically expressed hypotheses one must seek an explanation as to the gradual development of the statistically steady, fully turbulent flow from laminar flow. If the investigator begins with laminar flow and assumes that with increasing average velocity the flow becomes turbulent gradually (an assumption which is by no means always justified) he can evolve a rational form to the Prandtl hypotheses. As soon as turbulence develops, comparatively strong pulsations along the originally laminar isovels may be assumed, which would indeed generate the secondary stream. The secondary stream, in its turn, starts to alter the isovels. With increasing turbulence, the "asimutal" pulsations (that is, pulsations favoring the isovels as orbits), and with them the secondary streams, increase and modify the isovels so long as, with fully developed turbulence, a statistical equilibrium is established. Stated in this way, the Prandtl hypothetical secondary currents, and the hypothetical prevalence of asimutal pulsations, would give a probable explanation for the surprising shape of the isovels, provided the turbulent régime develops gradually from the laminar régime. To the writer's knowledge, however, no direct experimental verification, even of the existence of secondary currents, much less of the particular patterns assumed by Mr. Prandtl, is as yet available for any closed conduit.

For open channels, Mr. Prandtl did not indicate the pattern of secondary currents. The uncertainty of the practical application of his hypothesis to open channels is particularly great. In Fig. 20, the writer has applied the hypothesis tentatively to a broad, very rough channel and to a somewhat narrow channel—in one case tracing the hypothetical secondary circulations on the basis of the velocity measurements by H. Bazin and, in the other case, on the basis of Mr. Prandtl's isovels. In each case, there is a rather complicated pattern of circulation which is thoroughly at variance with the simple results obtained by Mr. Gibson and his precursors. However, in the latter example on the surface (Fig. 20(*b*)), and in the former example (Fig. 20(*a*)), both on the surface and at the bottom, the secondary currents are qualitatively the same according to both assumptions, so that only a more exact investigation can provide sufficient information for a decision between the conflicting possibilities.

Fig. 20.—Secondary Currents in Open Rectangular Channels, According to the Prandtl Hypothesis

The latest information concerning secondary currents in a straight conduit containing homogeneous water comes from a very stimulating paper[57] by M. A. Welikanov, published in 1936. This work is a survey of fairly recent contributions of hydrologists and hydrodynamists of the U.S.S.R. to the understanding of river forms on a fluid dynamic basis. A considerable part of the paper deals with secondary currents in straight open channels.

Apart from somewhat questionable theoretical arguments Mr. Welikanov adduces the experimental results of Mr. Lossievsky in favor of the presence of steady secondary currents in any straight conduits with turbulent flow. Mr. Lossievsky found:

(1) For a broad rectangular cross section, the same result as Mr. Gibson;

---

[57] "Flussbettbewegungen und Geschiebefuhrung," by M. A. Welikanov, *Bulletin No. 6, D*, Fünfte Hydrologische Konferenz der Baltischen Staten, Helsinki, Finland, 1936.

(2) For rectangular channels with large ratio of depth to width, two secondary currents but with circulation opposite to the Gibson pattern;

(3) For intermediate depth-width ratio, a more complicated and rather unstable pattern of secondary currents, and

(4) For a strongly unsymmetrical cross section, one single stable secondary current.

Only item (2) is in direct contradiction to the expectation based on Mr. Gibson's results, whereas all four items (with the possible, but doubtful, exception of item (3)) are at variance with what one would expect on the basis of the Prandtl hypothesis.

A possible explanation of these contradictions is that Mr. Lossievsky failed to observe the entire pattern of secondary currents in the cross section and, on the basis of observations at the surface and the bottom, reached unwarranted conclusions; or that his results are thoroughly vitiated by the use of insufficiently long channels. Of course, it is also possible that Mr. Lossievsky's results are reasonably exact and that Mr. Prandtl's work, as well as that of Mr. Gibson, needs to be revised. Mr. Lossievsky's item (3) would be probable enough, provided that items (1) and (2) were correct. Indeed, an unstable, shifting pattern of flow can be expected under transitional conditions between two substantially different, distinct types of flow.

The great number of contradictions and discrepancies among the various investigations available on this subject suggests also the possibility that all the secondary currents are a mere consequence either of an insufficiently permanent régime of flow or of temperature influences or other nonhomogeneities in the force field. Professor Vanoni seems to be precisely of this opinion when he ascribes the interesting secondary circulations observed by him entirely to the presence of sediment. However, a simple theoretical consideration shows that, even in a perfectly homogeneous fluid, if the flow is turbulent, secondary currents of appreciable intensity will normally be present. Indeed, however questionable may be Mr. Prandtl's assumption that the pulsations favor everywhere the isovels as orbits, it is perfectly rational to assume that at most points of the cross section there will normally be a favored circle of curvature for the pulsations just as there is a favored direction of pulsations. A strictly isotropic pattern of turbulence is an exceptional (actually only an artificially produced) type of turbulence. On the average, straight pulsations are less exceptional; but still it is reasonable to assume that, unless the cross section is circular, in most points of the cross section there will be a favored circle of curvature for the pulsations. Wherever there is such a favored finite circle of curvature for the pulsations, Mr. Prandtl has shown convincingly that a permanent, steady momentum tending to generate secondary currents is present. The writer is convinced, therefore, that nonhomogeneities in the force field are not necessary conditions for the presence of secondary currents.

It must be admitted, however, that nonhomogeneity of the fluid can create substantially stronger secondary currents, at the same time that their pattern may be transformed. The first to observe this new type of secondary currents

---

[58] "Report of the Aeronautical Research Institute," by Terada, Tokyo Imperial Univ., Tokyo, Japan, Vol. III, 1928, and Vol. IV, 1929.

was Mr. Terada,[58] who showed that the particles of a fluid flowing in a very wide open flume, slightly and uniformly heated from below, move along a helicoidal curve (Fig. 21) so that the movement can be resolved into a straight flow along the channel axis, with secondary circulatory motions in the cross section. The regular striped clouds (popularly called "mackerel sky") were formerly considered "ripple" clouds and were attributed, in accordance with G. H. Darwin, to the rippling influence of a wind perpendicular to the stripes. Many hydrodynamists and meteorologists are of the opinion that this phenomenon may in most cases be due more probably to forced convection streams connected with wind parallel to the stripes—that is, to vortices with a longitudinal axis similar to those which were produced under laboratory conditions by Mr. Terada.

Although Mr. Terada's paper[58] is not accessible to the writer, analogy with other convection phenomena makes it possible to infer that a vorticity with a longitudinal axis of this kind can be generated by convection in the nonturbulent as well as in the turbulent régime of flow.

In their brilliant vortex study,[59] M. Luntz and P. Schwartz remarked aptly that the Terada phenomenon is closely analogous to the vortices[60] in the fluid between two coaxial rotating cylinders discovered by G. I. Taylor—the nonhomogeneity of the centrifugal force field replaces the nonhomogeneity of the gravity force field conditioned by temperature differences in the Terada experiment.

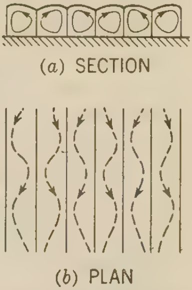

FIG. 21.—OBSERVATIONS OF SECONDARY CURRENTS, BY TERADA, IN AN OPEN, WIDE, AND STEEP CHANNEL HEATED FROM BELOW

In a paper by Hugh Casey,[61] there is a photograph which was made in a channel with turbulent flow and movable bed. No temperature influence was present in this case (at least not intentionally); yet the pattern of the secondary currents which is assumed by Mr. Casey (see Fig. 22) shows a surprising likeness to the convective secondary currents in the Terada study, of which Mr. Casey had no knowledge. Equally striking is the qualitative resemblance between these studies and Professor Vanoni's new observations. At the same time, it is important to observe that the number of the stripes is very different in the various cases; it is probably controlled primarily by the depth-width ratio of the flow.

FIG. 22.—SECONDARY CURRENTS IN THE CROSS SECTION OF A BROAD CHANNEL, WITH MOVABLE BED, AS OBSERVED BY HUGH CASEY

Related to these phenomena, although somewhat less closely, are the longitudinal ridges observed in the African desert by R. A. Bagnold.[62] They differ from the stripes observed by Messrs. Casey and Vanoni in the essential fact that they are interrupted; the interruptions in the ridges observed by Mr. Bagnold are arranged in a more or less regular echelon-like pattern.

[62] "The Physics of Blown Sand and Desert Dunes," by R. A. Bagnold, William Morrow & Co., New York, N. Y., 1942.

The foregoing leads to the decisive question of the rôle played by the secondary currents in the distribution of sediments in suspension and on the bottom. Mr. Möller was the first to demonstrate the rôle played by secondary currents in the distribution of sediment, in the sorting of sediment in the cross section, and in the gradual alteration of the shape of the bed. There is much valuable material in Mr. Möller's observations and ideas; but it will have to be analyzed, in the light of modern concepts concerning turbulent flow, when knowledge of the secondary currents has become more accurate.

The effect of secondary currents in sediment flow has a twofold significance. First, if the magnitude of these secondary currents reaches a few per cent of the main longitudinal flow, these currents are capable, in their upward reaches, of carrying the finer particles of sediment directly although they may not be able to move the coarser sediment particles. It is necessary to emphasize this point, because John B. Leighly[63] denies the competence of the secondary currents to carry material even in curved rivers where the circulatory movement is very much stronger. Of course, the final decision concerning the relative importance of this effect must be postponed until more exact information is available, but it is obvious that the steady secondary currents constitute a ponderable factor in the analysis of suspension and distribution of finer particles. Second and even more important than this direct effect may be the indirect influence of the secondary currents on sediment distribution. If it is true, as Mr. Prandtl's studies indicate, that the longitudinal velocity distribution and the distribution of pulsations are inseparably interconnected with the steady secondary currents, then the distributions of the shearing stresses and of the Austausch coefficient are also linked, and thus even the phenomena at the bottom itself cannot be properly understood and analyzed without reference to the secondary currents.

For this reason, the writer believes that—in explaining the deviation of sediment distribution from the results of the simple theory—in addition to the two factors considered by Professor Vanoni, as a third, equally important factor the secondary currents (and, with them, the essentially three-dimensional character of the entire flow) should be taken into account.

This substantial deviation from a two-dimensional pattern of flow is probably the main reason also for the unsatisfactory agreement of the velocity distribution observed by Professor Vanoni with the theory advanced by Theodor von Kármán, M. Am. Soc. C. E. It would be quite justifiable to put the boundary of the profile a little below the top of the sand particles; but, even so, an appreciable discrepancy between theoretical and experimental velocity distribution would remain. It appears that there is no way to account for this discrepancy, except by studying the influence of the secondary currents and the entire essentially three-dimensional nature of turbulent flow in any open channel.

---

[63] "Turbulence and the Transportation of Rock Debris by Streams," by John B. Leighly, *The Geographical Review*, Vol. 24, No. 3, 1934, p. 461.

That such an approach is necessary follows immediately from scrutiny of Fig. 3. The substantial inadequacy of the assumption of a two-dimensional flow can be made particularly clear by drawing the distribution of velocities at the mid-channel vertical and at some near-by verticals—for example, at one sixth of the channel width from the middle on both sides.

If the foregoing reasoning is correct, the modification of any factor—the isovels, the pulsations, or the secondary currents—would influence all other factors and with them the sediment distribution and the bed shape. If the tentative experiments of Potapow can be accepted, it appears that the secondary currents are those elements that are most easily subject to deliberate modification; and thus the study of secondary currents may reveal a new method for the regulation of rivers. In the paper by Mr. Welikanov,[57] there is a short abstract of Mr. Potapow's experimental research which may be translated as follows:

> "The principle of the method is to arrange fixed leading walls in the rivers. To create a clockwise helicoidal movement, it is sufficient to divert the surface stream by the aid of surface screens toward the right. The bottom stream will then be diverted to the left, and a circulation pattern is produced which is maintained for a fairly long distance downstream, where it disintegrates gradually. Instead of surface screens, bottom screens may be used, arranged in the opposite direction; or both devices may be combined. The experiments of Mr. Potapow have established the following applications of these devices: (*a*) Through production of a double circulation [probably Mr. Welikanov means a reinforcement of the circulation according to Mr. Lossievsky's type (1) currents, previously mentioned herein], the axial strip of the bed can be deepened; (*b*) in a curve the existing circulation pattern can be reversed, bringing the scour to the convex side and making the concave side, on which the 'talweg' of the natural river was situated, shallower; (*c*) the increase of sand bars can be prevented through artificial diversion of the bed load from the bar threshold; and (*d*) in case of bifurcation the sediment can be directed, according to wish, into either branch. These four examples suffice to indicate the great importance of Mr. Potapow's results in various fields of hydraulic engineering."

To summarize:

1. The presence of nonhomogeneity in the fluid (caused either by temperature influence or by the presence of a dissolved or granular material) is by no means a necessary condition for the generation of steady secondary currents. The occurrence of such currents is normal, rather than exceptional, in turbulent flow.
2. The distributions of the longitudinal velocities, of the pulsations, of the steady secondary currents, and of suspended sediment (if suspendible material is present) are mutually and inseparably interconnected, so that an artificial change of any one of these factors would inevitably tend to modify all others.
3. Observations by Mr. Potapow suggest that an artificial modification of the secondary currents is easily practicable and that therefore these might be used as a steering effect to modify, or to stabilize, sediment distribution and bed formation.

4. From items 1 and 2, it follows that the three-dimensional nature of turbulent flow in an open channel is a major factor—probably the main factor—required to explain deviations of experimental findings from the two-dimensional von Kármán theory of velocity distribution and sediment suspension.

On the basis of the summary items 1 to 4, and supporting comment, the writer ventures to suggest that the greatest progress in turbulence research in the near future is not to be expected from a more accurate and more detailed investigation of the turbulence tensor in some exceptionally simple cases (for example, the flow in a circular pipe). Still less can be expected from further study of such artificial cases as isotropic turbulence. Rather, the greatest progress will result from an improved and broadened study of the actual flow conditions in a variety of straight open channels and in a few straight closed conduits of noncircular cross section.

Even if, in the first stages, such a study were restricted to the investigation of the exact shape of the isovels and of the secondary currents (that is, even if no measurements of fluctuations are made at first), by implication it would afford a deepened insight into the three-dimensional mechanism of uniform turbulent flow, making possible a better hypothesis concerning the nature of pulsations than Mr. Prandtl could put forward without any reliable experimental facts concerning the secondary currents. Later, more exact pulsation studies and studies on the distribution of salinity, fine sediment, and other quantities subject to Austausch will make possible the checking and, if necessary, the correction of the hypothetical conclusions drawn from the first stage of the research.

As a beginning, therefore, the problem is to find a reliable picture of the three-dimensional distribution of the time averages of the velocity vectors. Since the secondary currents are comparatively small, this problem is rather difficult, challenging the ability of the best experimenter. Indeed, the contradictions presented by the various writers—all of whom were, in their time, able observers and experimenters—indicate the difficulty of obtaining more exact and more conclusive results concerning the steady secondary currents. The difficulties, of course, are mainly due to the fact that the turbulent pulsations disturb the recording of the steady components. Another difficulty is that, since the angle of the actual time-average velocity vector with the channel axis is rather small, any measuring device introduced into the liquid may vitiate the result. For these and other reasons, the writer's opinion is that the investigation in question will depend essentially upon the further development of purely optical techniques related to the one suggested by A. Fage and H. C. H. Townend.[64] In this method the extremely fine submicroscopic particles, which are present even in the purest drinking water, are observed by the aid of an ultramicroscope. If this or a similar optical method could be combined with a photographic technique to record time averages of velocity vectors, a basis for the first stage of the investigation would be presented.

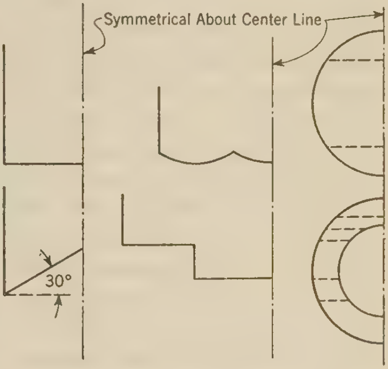
Another method, simpler but probably less accurate, could perhaps be developed through improvements of Mr. Gibson's technique of working with weighted wax pellets. If very small (preferably streamlined) solid bodies can be made of exactly the same weight as the water displaced by them, and if their orbit and speed are recorded photographically, kinematographically, or by aid of Charles Camichel's[65] "chronophotographic" process, the solution of the problem may be possible.

---

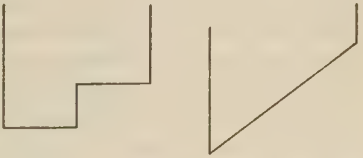
[64] "An Examination of Turbulent Flow with an Ultramicroscope," by A. Fage and H. C. H. Townend, *Proceedings*, Royal Soc. of London, Series A, Vol. 135, 1932, p. 656.

Those methods which restrict the study to the surface and the bottom (for example, the conventional use of silk threads and surface floats) have been tried and found insufficient. Only a study covering the entire cross section can lead to clarification of controversial points and to the attainment of new insight.

Of course, the greatest care is necessary in such investigations to establish a completely uniform régime of flow. The investigation of the fundamental questions of turbulent flow in an open channel presents a certain amount of additional difficulty compared to investigations in closed conduits. However, open channels have also certain practical advantages. The triangular cross section of an open channel affords excellent opportunities for the study of scale effects by the very simple device of varying the stages. On the other hand, the variation of stages in a nontriangular channel model makes possible the study of a large variety of geometrically dissimilar and, sometimes, even qualitatively very different cross sections. Thus studies of the few channel models indicated in Fig. 23 would give a very wide and highly instructive variety of flow patterns.



(*a*) SYMMETRICAL



(*b*) NONSYMMETRICAL

FIG. 23.—CROSS SECTIONS OF CHANNEL MODELS FOR PROPOSED INVESTIGATION

It is the writer's conviction that a research project along these or similar lines would clarify many problems which are essential to the understanding of turbulent flow in its relation to sediment propulsion, bed formation, and bed stabilization, and thus vital for river engineering. In addition, it may prove important for the most general and fundamental aspects of turbulence research.

The writer wishes to express his thanks to E. W. Lane, M. Am. Soc. C. E., of the Iowa Institute of Hydraulic Research, Iowa City, Iowa, for permission to use the results of an unpublished study that the writer made while he was a member of the staff of the Iowa Institute of Hydraulic Research.

VITO A. VANONI,[66] ASSOC. M. AM. SOC. C. E.—The subject of secondary circulation was discussed at considerable length by several individuals, although it was not considered of primary importance in the paper and little space was devoted to it. The writer especially appreciates the scholarly presentation of the subject by Professor Nemenyi, who covered a tremendous amount of material, some of which is not readily available to American engineers.

[65] "Rapport des oeuvres effectuées dans les années 1932–35," by C. Camichel, Toulouse, France, 1935.

[66] Project Supervisor, U. S. Dept. of Agriculture, SCS, California Inst. of Technology, Pasadena, Calif.

Professor Nemenyi advances the opinion that the problem of sediment suspension is essentially three dimensional and that secondary circulation is a factor of prime importance and therefore one which must be studied to insure sound progress in solving the sediment problem. There is no doubt that secondary circulations do exist in sediment-laden flows, and there is also every reason to expect that circulations will affect the sediment suspension process. The important question at this stage of the development of the science is the extent to which circulation affects the phenomenon. If the circulation is of first-order importance, even approximate results probably cannot be obtained without taking the circulation into consideration. On the other hand, there is always the possibility that the effect is relatively minor and that good, workable answers can be obtained from theories that do not give any consideration to the circulation. The engineer who is interested in obtaining results that can be applied to field problems probably assumes that the circulation is of second-order importance and neglects it until experience shows that circulation must be considered. On the other hand, the problem is intriguing from a purely scientific point of view, and one may be tempted to devote considerable time to it. The writer is inclined to adopt the point of view of the engineer and to neglect circulation, at least temporarily. Channel resistance to flow, like sediment suspension, also depends on the process of turbulence exchange; yet usable, practical friction formulas, like the Manning formula, have been obtained without considering circulations. Because one flow formula can be used for all cross sections by considering the hydraulic radius as the depth parameter of the flow thus far, at least, it has been possible to neglect the shape factors and resulting differences in circulation and still obtain usable results. This does not mean that in investigations of sediment transportation careful attention should not be given to secondary circulation and to the possibility that it may be a factor of the first-order importance. The attitude is merely that this factor may be neglected until there is proof that it is not negligible. The writer's interpretation is also accompanied by a sincere hope that secondary circulation does not prove to be an important factor. Investigation of this factor would be a very tedious, time-consuming task accompanied by the same difficulties as were the investigations of turbulence which have occupied so many engineers during the past several decades.

Professors Nemenyi and Powell appear to agree that the nonuniform distribution of sediment across the flow is the result, rather than the cause, of circulation, as suggested by the writer. The capacity of a stream to suspend sediment is not uniform across its width. Therefore, the amount suspended at various points in a cross section will be different. Thus, density gradients or forces are produced that can be of appreciable magnitude and will tend to cause correspondingly appreciable cross flows or circulations. These forces will be added to those which normally cause circulation in clear flows and the result will be a modified circulation pattern. The writer's objective in mentioning the subject of secondary circulations in the paper was to call attention to the fact that such density gradients occurred in streams carrying material in suspension and that these gradients could contribute to the circulation. The writer believes that the gradients set up by uneven distribution of sediment may cause circulations even greater than those occurring in clear flows, although this is merely an opinion without any quantitative data to substantiate it.

Professor Van Driest suggests that the discrepancy between the theoretical exponent z, in the sediment distribution equation, and the empirical exponent z_1 may be due, in part, to the transfer of sediment across the flow caused by a concentration gradient in that direction. This is undoubtedly a factor. However, the writer does not believe that the effect would be at all important in measurements made near the center of the flume, since the flume width was almost five times the maximum depth of flow. Professor Kalinske and Mr. Witzig believe that the discrepancy between exponents z and z_1 can be explained by secondary circulations. The writer believes that the discrepancies can be explained in terms of other factors that are more important and that have more effect on the flow. These ideas are outlined in conclusions 1, 2, and 3. Mr. Witzig questions the method of deducing the circulations presented in Fig. 15(c). It will be noted from Fig. 15(b) that the sediment concentrations at about the quarter points are higher than at other parts of the section. Because of the higher sediment concentrations, the fluid at these sections would be heavier than the fluid at other sections and, therefore, it would tend to sink and start the circulations indicated.

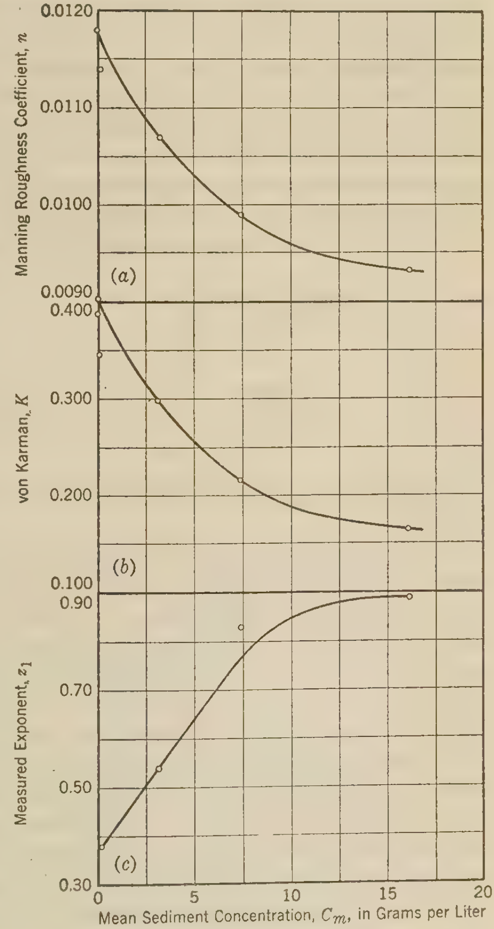

FIG. 24.—EFFECT OF CONCENTRATION OF SUSPENDED LOAD ON FLOW CHARACTERISTICS

From an analysis of the data in the paper, Professor Powell concludes that sediment in the flow tends to reduce the roughness, although no relationship is evident between roughness and sediment load. This conclusion agrees with the ones advanced by the writer. Fig. 24 shows additional data on the effect of sediment on the flow obtained by the writer from experiments made subsequent to those reported in the paper. These measurements were made in the flume with a slope of 0.0025, a bottom roughness of 0.88-mm sand, flow depth y_{max} of 0.295 ft, and varying amounts of suspended load, with a sedimentation diameter, $\bar{D}_s$, of 0.100 mm. Fig. 24(*a*), giving the Manning roughness factor, n, as a function of the average sediment concentration, C_m, shows clearly that the roughness decreases as the load increases. The experiments reported in the paper were made with sediment loads corresponding to the lower concentrations shown in the curve. The roughness factors for these rather small concentrations appear to vary considerably; and, for these curves, it will be noted that the point of the smallest concentration does not fit the general relationship very well. This phenomenon may account for the fact that a relationship between the roughness and the sediment concentration was not apparent from the original experiments.

The ratios of equivalent roughness to size of bottom sand calculated from Eq. 26*b* for the conditions shown in Fig. 24 are as follows:

Average sediment load C_m in grams per liter	Ratio of equivalent roughness to size of bottom sand
0	0.328
0.17	0.282
3.21	0.190
7.36	0.110
16.2	0.072

The relative roughness decreases very appreciably as the sediment load is increased.

Mr. Witzig suggests that fine sediment deposited between the sand roughnesses cemented to the bottom may account for the decrease in the roughness observed with suspended load. This explanation was considered during the experiments, but it was discarded after further investigation. A careful examination of the flow showed that the sediment load tended to decrease the roughness and to increase the velocity even when very minute quantities of suspended material were deposited on the bed. A more tenable explanation, as outlined in conclusion 6, attributes the decrease in the resistance to the effect of the sediment in damping out the turbulence and thus reducing the eddy viscosity of the flow and the universal constant k in the universal logarithmic velocity distribution formula. This effect is expressed as a reduction in the boundary roughness, although, in a strict sense, the boundary roughness does not change. Instead the change occurs within the body of the fluid. By reducing the intensity of the turbulence, the capability of the flow to transfer the boundary shear to the body of the flow is reduced, with the result that equilibrium between the gravity force tending to cause flow and the shear force resisting the flow is reached at a higher velocity.

Professor Van Driest's observation of the similarity between the velocity profile curves measured by Nikuradse and those reported in the paper is significant. The fact that the semilogarithmic velocity profile graphs do not follow precisely the logarithmic formula means that some judgment must be used in fitting a curve to the data. This may account for the variation in the values of von Kármán's universal constant, k, for clear flows, which has been reported in the literature. The values reported vary from 0.36 to 0.40 and it is easy to see that variations of this magnitude could occur between determinations by different workers.

Mr. Gavett has called attention to the interesting fact that a power law fits the measured velocity profiles better than the logarithmic law. The power law may be advantageous for certain problems but, in general, it is less desirable than the universal logarithmic law. Examination of the measured velocity profiles of Figs. 6 and 7 will show that the logarithmic law fits the measurements for more than 90% of the depth and that the most serious departures occur in the lower 7% or 8% of the depth. The error in calculating the position of the average velocity, due to this departure, is very small, probably much less than errors of measurements; and therefore it is not serious. The difference in velocity between relative depths of 0.368 and 0.393, which are the depths to the average velocity given by the logarithmic law and the one-seventh power law, is only about 1%.

The rather simple looking power law for velocity distribution, when substituted into formulas such as those for sediment suspension, may produce results that are much more complicated than those given by the more general logarithmic law. This is soon realized if an attempt is made to determine the distribution of suspended load, using the power law. The resulting expressions contain the maximum velocity, U_{max}, and the exponent, n, for which analytical expressions do not exist, whereas the logarithmic law gives expressions containing the friction velocity and k, both of which can be evaluated easily. Actually, the relationships between U_{max} and n are contained in the friction formulas which are expressed very conveniently by the more general laws and there is no need to develop the relationships between U_{max} and n.

Mr. Witzig's experience in measuring velocity profiles in the Niagara River cannot be taken as proof that the logarithmic distribution equation does not apply in nature. His experience is contrary to that of John C. Hoyt and Nathan C. Grover, Members, Am. Soc. C. E., who found[67] that the mean depth to the average velocity for 476 measurements in rivers was 0.62 y_{max}. It is possible that Mr. Witzig's measurements were made under conditions of nonuniform flow where the velocity profile could be distorted considerably from the profile expected for uniform flow.

The writer does not agree with Mr. Witzig's statement that the distribution law does not apply to the very fine sediments which are known as the wash load. The distribution of these sediments follows the general trend of the distribution equation, even though quantitatively the equation and the measurements do not agree. This disagreement also exists for the coarser sediments, as has been shown by the writer's experiments and by the experiments of Alvin G. Anderson,[32] Assoc. M. Am. Soc. C. E. In general, for fine sediments the actual distribution is more uniform than that indicated by the equations.

---

[67] "River Discharge," by John C. Hoyt and Nathan C. Grover, John Wiley & Sons, New York, N. Y., 1912.

In the present experiments, all the suspended load could be considered as wash load because very little of it was to be found in the bed; yet the distribution followed the law very well.

The writer has been asked to comment on the probable effect of uniformly distributed fine sediment in a flow. The principal effect of such a sediment is an increase in the effective specific gravity of the flow. Since the sediment is practically uniformly distributed, its settling velocity or its tendency to settle under gravitational forces is very slight compared to the lifting forces of the turbulence. Because of this fact there will be very little damping effect of the sediment on the turbulence, and in such cases the writer would expect that effects, such as reduction in friction factor and in the von Kármán k, would also be small. Experiments by Professor Kalinske and C. H. Hsia[55] seem to confirm this idea.

It is undesirable to classify the various modes of transportation into bed load, saltation load, and suspended load, because such a classification tends to build up the impression that the modes are fundamentally different. Actually, they are fundamentally the same and are caused by the same kind of fluid forces acting on the sediment. Therefore, the writer prefers to think of the modes as parts of one phenomenon, the only difference being in the intensity of transportation. As has been shown by H. A. Einstein,[68] Assoc. M. Am. Soc. C. E., movement of material on the bed is caused by turbulence fluctuations, which move sediment particles in steps or jumps. As these fluctuations increase in intensity with changing flow conditions, the steps or orbits of the particles increase in length and the sediment is said to "saltate." In the suspension processes, particles that have been lifted off the bed are given further impulses by turbulence in the body of the fluid and they may migrate well into the cross section before they are brought back to the bed. From this point of view, the transportation process is the same throughout its range, the only difference being in the intensity of the transporting forces and their result on the length of step taken by the particles.

Mr. Witzig's statement that the momentum and sediment transfer coefficients are constant over the depth of flow is incorrect. This is evident from Eqs. 21 and Fig. 13, which show that the coefficients have minimum values at the top and bottom and approach maximum values near mid-depth. Fig. 13 also shows that the two coefficients are not equal. In the discussion of Eqs. 2, 3, and 4, the coefficients were expected to differ, although in the development of the theory they were assumed to be the same in order to derive a working theory. In the discussion of the results, the writer has tried to show why the coefficients would not be the same and how this difference would be reflected in the theoretical exponent z and in the measured exponent z_1 for the sediment distribution equation.

Mr. Witzig asks if there was any vertical segregation of the sediment corresponding to the horizontal segregation represented by the sediment clouds or bands. All vertical sediment distribution measurements followed rather closely the form of the distribution formula, Eq. 16, and no discontinuities were evidenced. Since observing these bands of horizontal segregation in the flume, the writer has looked for them in natural streams and canals and has actually seen some bands in flows where the sediment load and depth of flow were small enough to permit seeing the bottom of the flume through the flow. The writer has also seen bands of this kind in dust storms. His observations appear to be contrary to those reported by Mr. Witzig.

---

[68] "Formulas for the Transportation of Bed Load," by H. A. Einstein, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), pp. 561–597.

The writer agrees with Mr. Witzig's statement that an increase in stream velocity caused by the addition of a sediment load will not result in an increase in sediment-transporting capacity. In discussing this point, the writer called attention to the fact that the depth of flow (and hence the average boundary shear) would decrease as the velocity is increased; and he presented this as another argument to indicate that the sediment-transporting power would not increase with the velocity. The fact that the boundary shear does diminish indicates the probability that the entrainment force will also diminish.

The writer disagrees with Professor Kalinske's statement that no concrete evidence was presented to support the conclusions regarding (1) the effect of suspended load on k and (2) the effect of suspended load in reducing resistance to flow. If Professor Kalinske accepts the measurements as being accurate, then the conclusions drawn by the writer will follow. Admittedly, no evidence is presented to support the conclusion regarding the effect of random fluctuations on suspended sediment. This point was presented to explain the discrepancy between the measurement and the theory and it is believed that the ideas are physically sound and explain the discrepancies qualitatively. The theory outlined in the paper has certain limitations, but the fact that it gives the correct form of the distribution equation is certainly evidence of correctness. This is also ample proof of the accepted theory that sediment and momentum transfer are similar, although Professor Kalinske apparently does not accept this theory.

The correlation between the horizontal velocity fluctuations U' and the vertical fluctuations V' enters into sediment distribution because in deriving the theory it was assumed that the momentum and sediment transfer coefficients were the same. The expression for the momentum transfer coefficient includes the correlation between U' and V'. Inspection of Eq. 1a will show that, to produce a shear, the fluctuations must be of opposite signs; or, in other words, a positive value of U' must be associated with a negative value of V' and vice versa. It is easy to imagine a positive V' occurring when U' is zero. This condition will not contribute to the shear, but it still may cause transfer of sediment. On the other hand, a situation can occur in which momentum is transferred by a V'-fluctuation without transferring sediment because the instantaneous concentration gradient is zero. In this way, one can reason that the coefficients for momentum transfer and sediment transfer need not be the same. Professor Kalinske's example of the condition at the center of the pipe illustrates this fact. Here the shear is zero and hence the correlation between U' and V' is also zero; but the sediment transfer coefficient has a finite value. The idea that the transfer coefficients are not equal was expressed by Theodor von Kármán,[5] M. Am. Soc. C. E., when he remarked that the quantities β, v', and l in Eqs. 2 and 4 which go to make up the turbulent transfer coefficient need not be the same for sediment transfer and momentum transfer.

The writer agrees that, to obtain data on the sediment-transporting capacity of a stream, the bed must be covered with loose material. However, he disagrees with Professor Kalinske's statement that, unless the bed is covered with sediment, the effect of sediment on the hydraulic characteristics cannot be studied. As a matter of fact, having a fixed bed has some definite advantages over having a movable bed, especially in making measurements near the bed. For instance, with a fixed bed the extremely important slope measurement can be made especially well. In this connection, it is possible that the inherent difficulty of measuring the slope with a movable bed may account for fluctuations in k obtained by Professor Kalinske.[55] The total drop in elevation of the bottom of the 80-ft flume, used in Professor Kalinske's experiments, varied from a minimum of $\frac{1}{4}$ in. to a maximum of about 1 in. Accurate measurements of such small slopes with a movable bed would be extremely difficult.

Deposits of some sediment on the fixed bottom of the flume used by the writer may have influenced the bottom roughness, but the amount was never great enough to do more than fill a small part of the space between the fixed sediment, and it is not believed to be an important factor. The strongest evidence of the effect of the sediment on the flow characteristics comes from the measured variations in the von Kármán k in the logarithmic velocity distribution formula. Fig. 24(*b*) offers additional evidence on this point. It will be noted that, as the load increases, k decreases; it is difficult to understand how any sediment deposited on the bottom will affect the value of k. This value can be changed only by modifying the turbulence in the interior of the flow and cannot be changed by merely altering the boundary roughness. The effect is caused by a damping of the turbulence since the turbulence must suspend the sediment against settling. This tends to reduce the momentum transfer coefficients as well as the sediment transfer coefficients. The reduction of the sediment transfer coefficients is reflected in an increase of exponent z_1, as shown in Fig. 24(*c*).

In comparing the results from Professor Kalinske's experiments[55] with those reported by the writer, the important differences between the two sets of experiments must be borne in mind. The principal differences were:

1. In Professor Kalinske's experiments, the average size of the suspended load was only 0.01 mm, or one tenth the size of the smallest material in the writer's experiments; and
2. In Professor Kalinske's experiments, the bed was always covered with sediment, whereas, in the writer's experiment, the bed was fixed.

With a very fine material, the distribution is practically uniform and the settling velocity of the material is small compared to the lifting ability of the turbulence. Therefore, one would expect that the damping effect on the turbulence would be minor. From this point of view the results of Professor Kalinske's experiments are in agreement with the deductions made by the writer rather than in conflict with them as Professor Kalinske reports. The fact that the von Kármán k, measured by Professor Kalinske, varies as much as it did may be attributed to the difficulties in measuring the slope of the flume with the movable bed.

Professor Powell's questions, regarding the adaptation of Professor Kalinske's turbulence measurements to the problem of sediment transportation, are answered in part in the discussion by Professor Kalinske. Two difficulties occur in connection with using these data: (*a*) Once these coefficients are measured in a flow, it is still necessary to determine the correlation coefficient β in Eq. 4 before the measured coefficients can be used for calculations; and (*b*) no readily available analytical expression exists for the transfer coefficient and therefore this coefficient cannot yet be used for the development of a quantitative theory.

ANALYSIS OF STATICALLY INDETERMINATE STRUCTURES USING REDUCED EQUATIONS

By Lee H. Johnson, Jr.,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Josef Sorkin, I. Oesterblom, Leon Beskin, Jaroslav Polivka, and Lee H. Johnson, Jr.

Synopsis

The method presented in this paper is useful in simplifying the analysis of certain types of statically indeterminate structures and is based upon a simple arithmetical principle. The principle is explained first and then applied for purposes of illustration to the solution of two-hinged arches. Practical data to aid the designer of two-hinged arches are derived. Additional applications of the method are mentioned in the conclusion.

The method may be applied either to framed or to solid-type structures. It permits a close approximation of the reactions of certain statically indeterminate structures solely from the geometry of the structure—that is, without having to assume the sizes of members or sections. This method does not replace the methods in current use; nor does it apply to all structures. It does serve, in certain instances, to eliminate most of the preliminary computations and to make the solutions short and direct.

The writer emphasizes that the paper explains and illustrates the method, but does not intend to present an exhaustive study of its applications. It is presumed that the reader is familiar with the current methods for solving statically indeterminate structures.

Notation

The letter symbols in this paper are defined where they first appear and are assembled for reference in the Appendix.

Basic Principle

The basic principle is one of simple arithmetic which applies to a fraction of the type, $\frac{a_1 k_1 + a_2 k_2}{b_1 k_1 + b_2 k_2}$, in which corresponding terms in numerator and

---

Note.—Published in November, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Dean and Prof. of Civ. Eng., School of Eng., Univ. of Mississippi, University, Miss.

denominator have the same multiplier; that is, a_1 and b_1 are both multiplied by k_1. Stated simply, the principle is that

$$\frac{a_1 k_1 + a_2 k_2}{b_1 k_1 + b_2 k_2} = \frac{a_1 + a_2}{b_1 + b_2} \quad \text{(1)}$$

provided either that $k_1 = k_2$ or that $a_1/b_1 = a_2/b_2$. This is obvious from an inspection of the difference of the two fractions, which in this paper is called the "difference term"; or, for brevity, G:

$$\frac{a_1 + a_2}{b_1 + b_2} - \frac{a_1 k_1 + a_2 k_2}{b_1 k_1 + b_2 k_2} = \frac{(a_1 b_2 - a_2 b_1)(k_2 - k_1)}{(b_1 + b_2)(b_1 k_1 + b_2 k_2)} = G \quad \text{(2)}$$

The two fractions on the left side are equal when G is equal to zero—that is, when $a_1/b_1 = a_2/b_2$; or when $k_1 = k_2$. Extending this principle for expressions with any number of terms, n:

$$\frac{a_1 + a_2 + \cdots + a_n}{b_1 + b_2 + \cdots + b_n} - \frac{a_1 k_1 + a_2 k_2 + \cdots + a_n k_n}{b_1 k_1 + b_2 k_2 + \cdots + b_n k_n}$$
$$= \frac{(a_1 b_2 - a_2 b_1)(k_2 - k_1) + \cdots + (a_{n-1} b_n - a_n b_{n-1})(k_n - k_{n-1})}{(b_1 + b_2 + \cdots b_n)(k_1 b_1 + k_2 b_2 + \cdots + k_n b_n)}$$
$$= G = 0 \quad \text{(3)}$$

provided either that $k_1 = k_2 = \cdots = k_n$, or that $a_1/b_1 = a_2/b_2 = \cdots = a_n/b_n$.

If the k-values are not all equal and the (a/b)-ratios are not all equal, the difference term will not be zero. The magnitude of G depends upon the magnitude of the variations between the k-values and between the (a/b)-values. For small variations in these values and for finite values of n, the difference term G is very small. The numerator will be small since it consists of small terms, some + and some −, formed by the products of small differences, but the denominator will be correspondingly large since it consists of the product of two sums of comparatively large terms. Expressed in terms of integrals, the principle is that—

$$\frac{\int f_1(x)\,dx}{\int f_2(x)\,dx} = \frac{\int f_1(x)\,k(x)\,dx}{\int f_2(x)\,k(x)\,dx} \quad \text{(4)}$$

—provided that $k(x) = a$, in which a is an arbitrary constant; or, that $f_2(x) = b\,f_1(x)$, in which b is an arbitrary constant. This is true for definite integrals provided that all integrals have the same limits of integration.

The function $k(x)$ may not be constant, although nearly so—for example, when

$$k(x) = a + \epsilon(x) \quad \text{(5a)}$$

in which $\epsilon(x)$ is a function whose absolute value can be made arbitrarily small. Furthermore, $f_1(x)$ may not have a constant coefficient as in the expression

$$f_2(x) = [b + \eta(x)]\,f_1(x) \quad \text{(5b)}$$

in which $\eta(x)$, like $\epsilon(x)$, is a function whose absolute value can be made arbitrarily small. Under the conditions expressed by Eqs. 5, the difference between the two fractions in Eq. 4 will not be zero, but can be expressed in the "difference term"—

$$G = \frac{\int f_1(x)\,dx \int \epsilon(x)\,\eta(x)\,f_1(x)\,dx - \int \epsilon(x)\,f_1(x)\,dx \int \eta(x)\,f_1(x)\,dx}{\int [b + \eta(x)]\,f_1(x)\,dx \int [b + \eta(x)]\,[a + \epsilon(x)]\,f_1(x)\,dx} \quad \ldots (6)$$

—simply by putting the difference of the two fractions over a common denominator.

Assume that all the integrals in the difference term are definite integrals with the same limits of integration. Also, let $f_1(x)$ be a continuous function in the region of integration, $c \leqq x \leqq d$, and let $\left| \int_c^d f_1(x)\,dx \right| \geqq B$, in which B is an arbitrary constant. These conditions exist in many engineering problems involving such equations. The difference term will approach the quantity,

$$G = \frac{0}{b^2\,a \int_c^d f_1(x)\,dx \int_c^d f_1(x)\,dx} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

as $|\epsilon(x)| \rightarrow 0$, and as $|\eta(x)| \rightarrow 0$. If $|\epsilon(x)|$ and $|\eta(x)|$ are not equal to zero but are arbitrarily small, the numerator of the difference term will also be arbitrarily small. The denominator, however, will remain comparatively large since $\left| b^2\,a \int_c^d f_1(x)\,dx \int_c^d f_1(x)\,dx \right| \geqq b^2\,a\,B^2$, regardless of the arbitrarily small terms involving $\epsilon(x)$ and $\eta(x)$. Hence the difference term will be small for small values of $\epsilon(x)$ and $\eta(x)$; that is, for small variations in $k(x)$ and in the ratio of $f_2(x)$ to $f_1(x)$. A formal mathematical proof of the foregoing statements is not offered in this paper, which is intended primarily for engineers. The conclusions can be verified by well-known mathematical procedures.

CLASSIC EQUATIONS APPLIED TO THE ANALYSIS OF TWO-HINGED ARCHES

The general equation for the horizontal reaction H of a solid, two-hinged arch neglecting rib shortening and temperature effects is

$$H = \frac{\int M\,y\,\frac{ds}{E\,I}}{\int y^2\,\frac{ds}{E\,I}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8a)$$

in which M = bending moment at any section due to given loads and vertical reactions only; y = ordinate of the arch at any section; ds = differential length of an element measured along the center line of the arch; E = modulus of elasticity; and I = rectangular moment of inertia of the arch section. In actual design, Eq. 8a is usually expressed as a summation, and the arch rib is divided into a finite number of segments of length Δs:

$$H = \frac{\sum M\,y\,\frac{\Delta s}{E\,I}}{\sum y^2\,\frac{\Delta s}{E\,I}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

For two-hinged arch trusses:

$$H = \frac{\sum \frac{\sigma\, u\, L}{A\, E}}{\sum \frac{u^2\, L}{A\, E}} \qquad \text{(8c)}$$

in which σ is the total stress on the section due to given loads and vertical reactions only; A is its area; L is the length of the member; and u is the total stress in the section due to a horizontal force of unity applied at the reaction.

It is presumed that Eqs. 8 are familiar to the reader. Their derivation can be found in texts on the theory of statically indeterminate structures.

The horizontal reaction is dependent upon the sizes of the sections or members of the arch. However, before the arch can be designed (that is, before the stresses that determine the size of sections or members can be computed) it is necessary to compute the horizontal reactions under various loads. Hence the sizes of sections or members must be assumed at the start and consequently the design is a process of successive approximations.

METHOD OF REDUCED EQUATIONS APPLIED TO TWO-HINGED ARCHES

The purpose of the "method of reduced equations" is to eliminate as many steps as possible in the process of successive approximations and to provide a more direct solution. The method is so named because the application of the basic principle to the solution of two-hinged arches, and other structures, eliminates several quantities from the classic equations, thereby reducing them. In particular, the sizes of sections or members are eliminated so that the solution by this method depends only upon the center-line geometry of the structures.

Definitions.—Four new terms are introduced in this paper, as follows—(*a*) "difference term," (*b*) "reduced equation," (*c*) "basic influence line," and (*d*) "correspondence of ordinates."

(*a*) The "difference term" is the analytical expression of the difference between two fractions of the types shown in Eqs. 2 and 4.

(*b*) In the classical equation, s is not necessarily the most convenient independent variable. Choosing x as the independent variable, Eq. 8*a* can be written in terms of x:

$$\frac{\int \frac{M\, y\, ds}{E\, I}}{\int \frac{y^2\, ds}{E\, I}} = \frac{\int \frac{M\, y}{E\, I} \frac{ds}{dx}\, dx}{\int \frac{y^2}{E\, I} \frac{ds}{dx}\, dx} \qquad \text{(9)}$$

In general, $ds/dx = \sqrt{1 + (dy/dx)^2}$, which depends upon the form of the arch axis. If the cross section of the arch is so chosen as to make $E\, I$ proportional to $\sqrt{1 + (dy/dx)^2}$—then the quantity $\left(\frac{1}{E\, I} \frac{ds}{dx}\right)$ will be constant and can be factored from Eq. 9.

A "reduced equation" is the classic equation (Eq. 8*a*) with the quantity $\left(\frac{1}{E\, I} \frac{ds}{dx}\right)$, or $\frac{L}{A\, E}$, assumed constant and factored from the equation, thus:

For the solid type of arch,

$$H = \frac{\int M\, y\, dx}{\int y^2\, dx} \qquad \text{(10a)}$$

or, if Δx is constant,

$$H = \frac{\sum M\, y}{\sum y^2} \qquad \text{(10b)}$$

and, for the arch truss,

$$H = \frac{\sum \sigma\, u}{\sum u^2} \qquad \text{(11)}$$

(*c*) A "basic influence line" is the one determined from the reduced equation of an arch.

(*d*) Two curves have "correspondence of ordinates" if the ratio of their ordinates at corresponding points on each curve remains approximately constant. For example, in Fig. 1(*a*), curves A and B have perfect correspondence of ordinates for their entire length; in Fig. 1(*b*), curves C and D have correspondence of ordinates, not perfect however, for their entire length; in Fig. 1(*c*), curves E and F have correspondence of ordinates only between 0 and point a; and, in Fig. 1(*d*), curves G and H have no correspondence of ordinates.

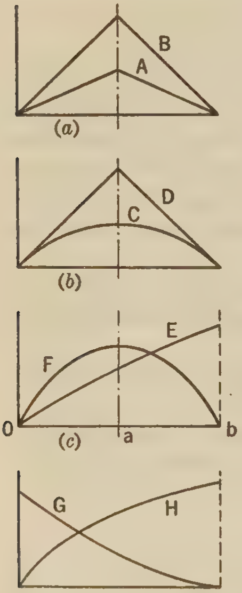

FIG. 1

The words "influence lines" and "influence values" throughout the discussion of two-hinged arches are understood to refer always to the horizontal reactions.

Procedure.—The use of the "reduced equations" (Eqs. 10 or 11) in the design of two-hinged arches is worth while when these equations give values sufficiently close for practical purposes to the final correct values determined from the classic equations (Eqs. 8).

The following procedure will be followed in applying the method of reduced equations to the solution of solid-type, two-hinged arches: First, the effect of variations in cross section upon the basic influence line will be studied for parabolic, circular, and semi-elliptic arches successively; and second, the effect of variation in curve or geometry of the arch upon the influence lines will be studied.

EFFECT OF VARIATION IN CROSS SECTION

General.—The difference between the two fractions in Eq. 2 is zero when $\frac{a_1}{b_1} = \frac{a_2}{b_2}$, regardless of the values of k_1 and k_2. Similarly (compare Eq. 9), the difference between $\dfrac{\sum_1^n M\,y}{\sum_1^n y^2} - \dfrac{\sum_1^n M\,y\,\dfrac{\Delta s}{E\,I}}{\sum_1^n y^2\,\dfrac{\Delta s}{E\,I}}$ is zero, when $\dfrac{M_1\,y_1}{y^2_1} = \dfrac{M_2\,y_2}{y^2_2} = \cdots$ $= \dfrac{M_n\,y_n}{y^2_n}$, regardless of the $\left(\dfrac{\Delta s}{E\,I}\right)$-values.

If the $\left(\dfrac{M\,y}{y^2}\right)$-values are not all equal, but nearly so, then the difference between the two fractions will be very small, regardless of the $\left(\dfrac{\Delta s}{E\,I}\right)$-values.

In terms of the integral equations, the difference $\dfrac{\int M\,y\,dx}{\int y^2\,dx} - \dfrac{\int M\,y\,\dfrac{ds}{E\,I}}{\int y^2\,\dfrac{ds}{E\,I}}$ will be zero or very small, if the ratio $\dfrac{M\,y}{y^2}$ is constant, or nearly so, for all values of x.

Parabolic Arch.—The equation of a parabolic arch with the origin at the left end, with span, L, and rise, h, is

$$y = \frac{4\,h}{L^2}\,(x\,L - x^2)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(12a)$$

and letting $l = L/2$,

$$y = \frac{h}{l^2}\,(2\,l\,x - x^2)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(12b)$$

For a parabolic arch with a unit load at the center, and $\dfrac{L}{h} = 4$, characteristic curves for M-values, y-values, $(M\,y)$-values, and y^2-values are shown in Fig. 2. For different values of x, the moment M is as follows: When $0 \leqq x \leqq l$,

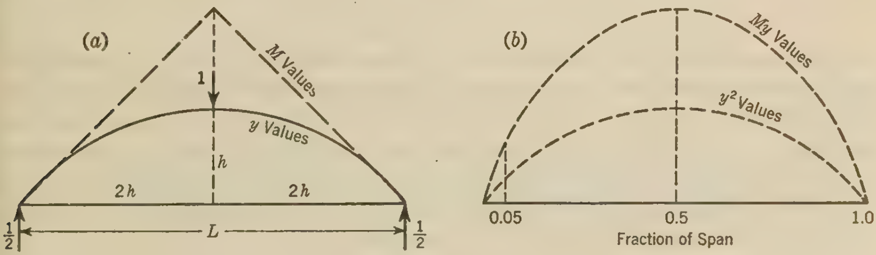

FIG. 2

$$M = 0.5\,x\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(13a)$$

and, when $l \leqq x \leqq L$,

$$M = l - 0.5\,x\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(13b)$$

Values of $H = \dfrac{M\,y}{y^2}$ (Eq. 10b) are given in Table 1 for l/h = 2, 4, and 8.

From Fig. 2, it is seen that there is "correspondence of ordinates" between the curves representing ($M\,y$)-values and y^2-values and that the difference term for a parabolic arch with center load will be small, regardless of the variations in cross sections or sizes of members.

TABLE 1.—VALUES OF $\frac{M\,y}{y^2}$ (Eq. 10*b*)

Fraction of span[a]	Values of L/h		
	2	4	8
0.05	0.26	0.52	1.04
0.50	0.50	1.00	2.00

[a] See Fig. 2(*a*).

For intermediate positions of the unit load, there is not correspondence of ordinates for the entire span length. In Fig. 3, the curves of M-values and y-values do not correspond between points B and C. However, the error introduced by the small lack of correspondence between points B and C is of opposite sign from the error introduced by imperfection of correspondence between points A and B and between points C and D, so that at one position of the intermediate load, there is no error. It must be kept in mind that the errors mentioned are those between the basic influence line determined from Eq. 10*a* and the actual influence line determined from Eq. 8*a*.

The correctness of the conclusion that variations in cross section will have but little effect on the influence values because of the correspondence of ordinates is shown by the following computations of the basic influence line and influence lines for several types of cross section. These computations also reveal the fact that the basic influence lines for the parabolic arch are directly proportional to the span: rise ratio. The basic influence line for the parabola is computed from Eq. 10*a* between the limits of 0 and L. By using a double unit load, placed symmetrically, it is necessary to integrate only over one half of the span, since both the arch and the moment diagram are symmetrical about the center line. Thus (see Fig. 4):

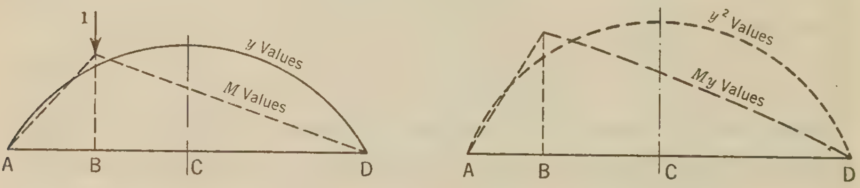

FIG. 3

$$2\,H = \frac{\int_0^a x\,y\,dx + \int_a^l a\,y\,dx}{\int_0^l y^2\,dx} \quad \text{(14a)}$$

or

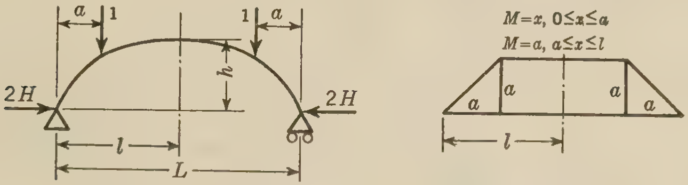
$$H = \frac{\int_0^a x\,y\,dx + \int_a^l a\,y\,dx}{\int_0^L y^2\,dx} \quad \text{(14b)}$$

In Eq. 14*b*, substituting the value of y from Eq. 12*b*:

$$H = \frac{\dfrac{h}{l^2}\displaystyle\int_0^a (2\,l\,x^2 - x^3)\,dx + \dfrac{a\,h}{l^2}\displaystyle\int_a^l (2\,l\,x - x^2)\,dx}{\dfrac{h^2}{l^4}\displaystyle\int_0^L (2\,l\,x - x^2)^2\,dx} \quad \ldots\ldots(15a)$$

which becomes

$$H = \frac{\dfrac{h}{l^2}\left[\dfrac{2\,l\,x^3}{3} - \dfrac{x^4}{4}\right]_0^a + \dfrac{a\,h}{l^2}\left[l\,x^2 - \dfrac{x^3}{3}\right]_a^l}{\dfrac{h^2}{l^4}\left[\dfrac{4\,l^2\,x^3}{3} - \dfrac{4\,l\,x^4}{4} + \dfrac{x^5}{5}\right]_0^L} = \frac{\dfrac{l^2}{h}\left[\dfrac{2\,l^3\,a}{3} - \dfrac{l\,a^3}{3} + \dfrac{a^4}{12}\right]}{\dfrac{4\,l^2\,L^3}{3} - l\,L^4 + \dfrac{L^5}{5}} \quad \ldots(15b)$$



(*a*) LOAD DIAGRAM (*b*) MOMENT DIAGRAM

FIG. 4

Let j = a fraction of the half span, and $a = j\,l = 0.5\,j\,L$; then Eq. 15*b* becomes

$$H = \frac{\dfrac{1}{h}\left(\dfrac{L}{2}\right)^6\left[\dfrac{2\,j}{3} - \dfrac{j^3}{3} + \dfrac{j^4}{12}\right]}{\dfrac{L^5}{3} - \dfrac{L^5}{2} + \dfrac{L^5}{5}} = \frac{5\,L}{128\,h}(8\,j - 4\,j^3 + j^4) \quad \ldots(16a)$$

For a unit load at the center, $j = 1$ and

$$H = \frac{25\,L}{128\,h} = 0.1953\,\frac{L}{h} \quad \ldots\ldots\ldots\ldots(16b)$$

It is observed that the basic influence line is a direct function of the (L/h)-ratio. Consequently, for basic influence lines, one curve can be plotted for all parabolic arches, as a function of that ratio. Influence lines for non-constant $\left(\dfrac{1}{E\,I}\dfrac{ds}{dx}\right)$-values are computed from Eq. 8*a* (between the limits 0 and l). In this paper, influence lines are computed first for six types of arch rib which were selected primarily because of their mathematical simplicity. These are shown in Fig. 5(*b*). Also shown in Fig. 5(*b*) is the diagram for an arch with a constant quantity $\left(\dfrac{1}{E\,I}\dfrac{ds}{dx}\right)$. For each type the quantity $\left(\dfrac{1}{E\,I}\dfrac{ds}{dx}\right)$ is expressed as a function of x in Col. 2, Table 2. Types 1, 2, 4, and 5 represent functions which are not symmetrical about the center line of the arch, and can

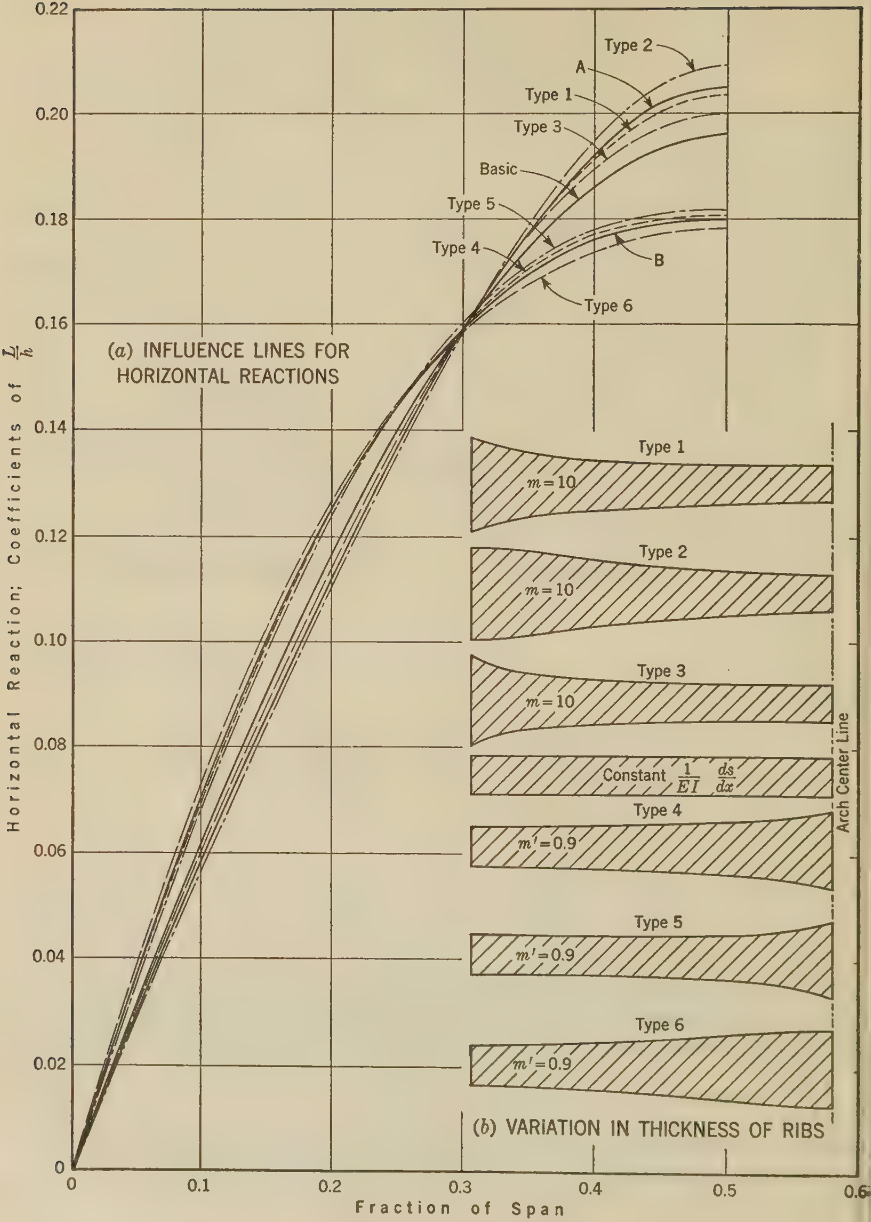


FIG. 5.—PARABOLIC ARCH RIBS

be applied only in integrations over the left half of an arch. A double unit load is used as in Eq. 14*a*.

TABLE 2.—COMPUTATION OF INFLUENCE LINES, PARABOLIC ARCH

Type (see Fig. 5) (1)	$\frac{1}{EI}\frac{ds}{dx}$ (2)	Difference term (3)
1	$\left[1 + m\frac{x}{l}\right]$	$\frac{m}{128\,(16 + 11\,m)}\,\frac{L}{h}\,(55\,g_1 - 16\,g_2)$
2	$\left[1 + m\left(\frac{x}{l}\right)^2\right]$	$\frac{m}{128\,(56 + 29\,m)}\,\frac{L}{h}\,(145\,g_1 - 112\,g_3)$
3	$\left[1 + m\frac{(2\,l\,x - x^2)}{l^2}\right]$	$\frac{m}{64\,(7 + 6\,m)}\,\frac{L}{h}\,(15\,g_1 - 7\,g_4)$
4	$\left[1 - m'\frac{x}{l}\right]$	$\frac{m'}{128\,(16 - 11\,m')}\,\frac{L}{h}\,(16\,g_2 - 55\,g_1)$
5	$\left[1 - m'\left(\frac{x}{l}\right)^2\right]$	$\frac{m'}{128\,(56 - 29\,m')}\,\frac{L}{h}\,(112\,g_3 - 145\,g_1)$
6	$\left[1 - m'\frac{(2\,l\,x - x^2)}{l^2}\right]$	$\frac{m'}{64\,(7 - 6\,m')}\,\frac{L}{h}\,(7\,g_4 - 15\,g_1)$

The quantities m and m' in Col. 2 are arbitrary constants such that: $0 \leqq m < \infty$ and $0 \leqq m' < 1$. The $\left(\frac{1}{E\,I}\frac{ds}{dx}\right)$-values are constant when m and m' equal 0. As m and m' increase, the difference between the $\left(\frac{1}{E\,I}\frac{ds}{dx}\right)$-values at the haunch and at the crown increases. The difference term for each type is given in Col. 3, Table 2.

Typical Derivation of Difference Term, Parabolic Arch.—A computation of the difference term for type 1 will serve to demonstrate the general procedure For this type (see Col. 2, Table 2),

$$\frac{1}{E\,I}\frac{ds}{dx} = \left(1 + \frac{m\,x}{l}\right) \qquad \text{.....................(17)}$$

The difference term is:

$$\frac{\int_0^a x\,y\,dx + \int_a^l a\,y\,dx}{\int_0^L y^2\,dx}$$

$$-\frac{\int_0^a x\,y\,dx + \int_a^l a\,y\,dx + \int_0^a \frac{m\,x}{l}\,x\,y\,dx + \int_a^l \frac{m\,x}{l}\,a\,y\,dx}{\int_0^L y^2\,dx + 2\int_0^l \frac{m\,x}{l}\,y^2\,dx} = G\,..(18)$$

From the foregoing derivation (Eqs. 14*a* and 15*b*):

$$\int_0^a x\,y\,dx + \int_a^l a\,y\,dx = \frac{h\,l^2}{12}\,(8\,j - 4\,j^3 + j^4) \ldots\ldots\ldots (19a)$$

and, letting $g_1 = 8\,j - 4\,j^3 + j^4$,

$$\int_0^a x\,y\,dx + \int_0^l a\,y\,dx = \frac{h\,l^2}{12}\,g_1 = \frac{h\,L^2}{48}\,g_1 \ldots\ldots\ldots\ldots (19b)$$

Also,

$$\int_0^L y^2\,dx = \frac{h^2}{l^4} \times \frac{L^5}{30} = \frac{16}{30}\,h^2\,L \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

The two expressions involving m in the numerator of Eq. 18 are now evaluated:

$$\int_0^a \frac{m\,x}{l}\,x\,y\,dx + \int_a^l \frac{m\,x}{l}\,a\,y\,dx = \int_0^a \frac{m\,h}{l^3}\,(2\,l\,x^3 - x^4)\,dx$$

$$+ \int_a^l \frac{m\,h\,a}{l^3}\,(2\,l\,x^2 - x^3)\,dx = \frac{m\,h}{l^3}\left[\frac{2\,l\,x^4}{4} - \frac{x^5}{5}\right]_0^a \frac{m\,h\,a}{l^3}\left[\frac{2\,l\,x^3}{3} - \frac{x^4}{4}\right]_a^l$$

$$= \frac{m\,h}{l^3}\left[\frac{l\,a^4}{2} - \frac{a^5}{5}\right] + \frac{m\,h}{l^3}\left[\frac{2\,l^4\,a}{3} - \frac{l^4\,a}{4} - \frac{2\,l\,a^4}{3} + \frac{a^5}{4}\right] \ldots\ldots (21)$$

Substituting $a = j\,l$, in Eq. 21:

$$\int_0^a \frac{m\,x}{l}\,x\,y\,dx + \int_a^l \frac{m\,x}{l}\,a\,y\,dx = m\,h\,l^2\left[\frac{j^4}{2} - \frac{j^5}{5} + \frac{2\,j}{3} - \frac{j}{4} - \frac{2\,j^4}{3} + \frac{j^5}{4}\right]$$

$$= \frac{m\,h\,l^2}{60}\,(25\,j - 10\,j^4 + 3\,j^5) = \frac{m\,h\,L^2}{240}\,g_2 \ldots\ldots\ldots\ldots (22)$$

in which $g_2 = 25\,j - 10\,j^4 + 3\,j^5$. The term involving m in the denominator of Eq. 18 is next evaluated; thus:

$$2\int_0^l \frac{m\,x}{l}\,y^2\,dx = \frac{2\,m}{l}\int_0^l x\,\frac{h^2}{l^4}\,(2\,l\,x - x^2)^2\,dx$$

$$= \frac{2\,m\,h^2}{l^5}\int_0^l (4\,l^2\,x^3 - 4\,l\,x^4 + x^5)\,dx = \frac{11}{30}\,m\,h^2\,L \ldots\ldots\ldots (23)$$

Evaluating the difference term (see Eq. 6) gives

$$G = \frac{\dfrac{h\,L^2\,g_1}{48}\,\dfrac{11\,m\,h^2\,L}{30} - \dfrac{m\,h\,L^2\,g_2}{240}\,\dfrac{16\,h^2\,L}{30}}{\dfrac{16\,h^2\,L}{30}\left(\dfrac{16\,h^2\,L}{30} + \dfrac{11\,m\,h^2\,L}{30}\right)}$$

$$= \frac{m}{128\,(16 + 11\,m)}\,\frac{L}{h}\,(55\,g_1 - 16\,g_2) \ldots\ldots\ldots\ldots\ldots (24)$$

The substitution constants g in Col. 3, Table 2, are as follows:

$$g_1 = (8\,j - 4\,j^3 + j^4) \ldots\ldots\ldots\ldots\ldots\ldots (25a)$$

$$g_2 = (25\,j - 10\,j^4 + 3\,j^5) \ldots\ldots\ldots\ldots\ldots\ldots (25b)$$

$$g_3 = (9\,j - 3\,j^5 + j^6) \ldots\ldots\ldots\ldots\ldots\ldots (25c)$$

$$g_4 = (16\,j - 10\,j^4 + 6\,j^5 - j^6) \ldots\ldots\ldots\ldots\ldots\ldots (25d)$$

An examination of the difference terms shows that the errors are also a direct function of the (L/h)-ratios. Consequently, the influence lines for any parabolic arch of any of these types of $\left(\frac{1}{E\,I}\frac{ds}{dx}\right)$-values can be obtained from one curve of that type, plotted in terms of L/h. The influence lines for these six types of arch sections are plotted with the basic influence line in Fig. 5(*a*). Values of $m = 10$ and $m' = 0.9$ were used.

The influence values are not greatly affected by variations in the ratio of haunch thickness to crown thickness. Different values of this ratio are obtained by using different values of m or m' in the expressions for the cross sections of types 1 to 6 (Col. 2, Table 2). Since the influence values are proportional to the (L/h)-ratio, illustrative computations are shown only for a specific arch of $L/h = 4$, the computations for any other parabolic arch being directly proportional to these. The maximum influence ordinate at the crown for the basic influence line of a parabolic arch of $L/h = 4$ is 0.781. Tables 3 and 4 show the amounts by which the maximum influence ordinates for the six types of cross sections differ from this value. It is observed that increasing the haunch thickness from twice to four times the crown thickness produces a maximum change in ordinate, for types 1, 2, and 3, of $0.061 - 0.046 = 0.015$. Increasing the crown thickness from one and a half to three times the haunch thickness produces a maximum change, for types 4, 5, and 6, of $0.106 - 0.045 = 0.061$. These effects are shown graphically in Fig. 7.

TABLE 3.—Influence Ordinates for Parabolic Arch Types 1 to 3—Cross Sections Decreasing from the End to the Center

$\left(\text{Using } m\text{-Constants and } \frac{L}{h} = 4\right)$ with a Unit Load at the Crown

Constant m	Ratio of haunch thickness to crown thickness	Type 1		Type 2		Type 3	
		Difference term	Ordinate	Difference term	Ordinate	Difference term	Ordinate
5	2.0 : 1.0	+0.029	0.810	+0.046	0.827	+0.017	0.798
10	2.5 : 1.0	+0.032	0.813	+0.053	0.834	+0.019	0.800
20	3.1 : 1.0	+0.034	0.815	+0.058	0.839	+0.020	0.801
40	3.9 : 1.0	+0.036	0.817	+0.061	0.842	+0.020	0.801

Influence values for a unit load at the center only were computed for several types of cross-section distributions, with thicknesses selected arbitrarily and shown in Fig. 6 as types 7 to 11. These types were selected as distributions not represented in types 1 to 6. The column analogy method was used for these computations, since the mathematical expressions of $\frac{1}{EI}\frac{ds}{dx}$ for these types are complicated. Results are shown in Fig. 7.

TABLE 4.—INFLUENCE ORDINATES FOR PARABOLIC ARCH TYPES 4 TO 6—CROSS SECTIONS INCREASING FROM THE END TO THE CENTER $\left(\text{USING } m'\text{-CONSTANTS AND } \frac{L}{h} = 4\right)$ WITH A UNIT LOAD AT THE CROWN

Constant m'	Ratio of haunch thickness to crown thickness	Type 4		Type 5		Type 6	
		Difference term	Ordinate	Difference term	Ordinate	Difference term	Ordinate
0.8	1.0 : 1.5	−0.045	0.736	−0.045	0.736	−0.045	0.736
0.9	1.0 : 1.9	−0.060	0.721	−0.055	0.726	−0.070	0.711
0.95	1.0 : 2.4	−0.070	0.711	−0.062	0.719	−0.091	0.690
0.975	1.0 : 3.1	−0.075	0.706	−0.065	0.716	−0.106	0.675

Inspection of the data shows that the influence lines fall in three groups—the basic influence line, a group of influence lines for diminishing cross section from end to center of arch, and a group for increasing cross section from end to center of arch.

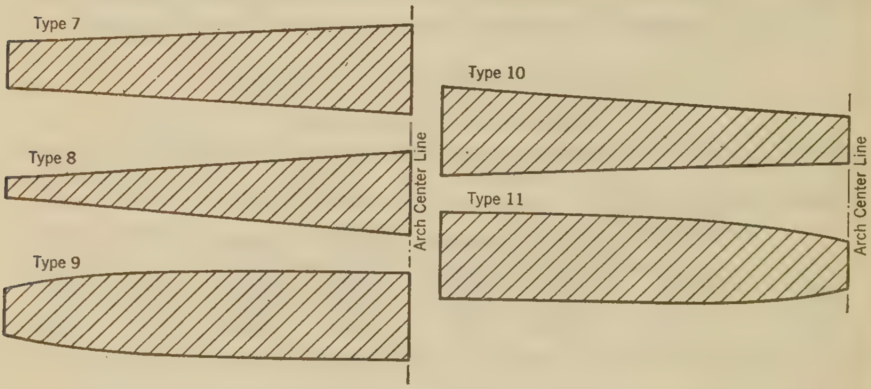

FIG. 6.—VARIATION IN THICKNESS OF PARABOLIC ARCH RIBS

Influence lines for the parabola can be generalized by plotting an average curve A for the group of influence lines above the basic influence line and an average curve B for the group below the basic influence line, as are shown in Fig. 5(*a*). The maximum percentage error encountered in using the average curve in each group is approximately 2% for the top group (cross section diminishing toward center) and approximately 6% for the bottom group (cross section increasing toward center), for a maximum ratio between thicknesses at crown and haunch of about 4.5:1, which is very high. Thus, if the arch is to have haunches, influence line A, Fig. 5(*a*), can be used to make a direct solution for the reactions and required cross-section dimensions. If the arch is to have practically constant cross section, the basic influence line can be used. If the arch is to taper from the center to the ends, influence line B, Fig. 5(*a*), can be used.

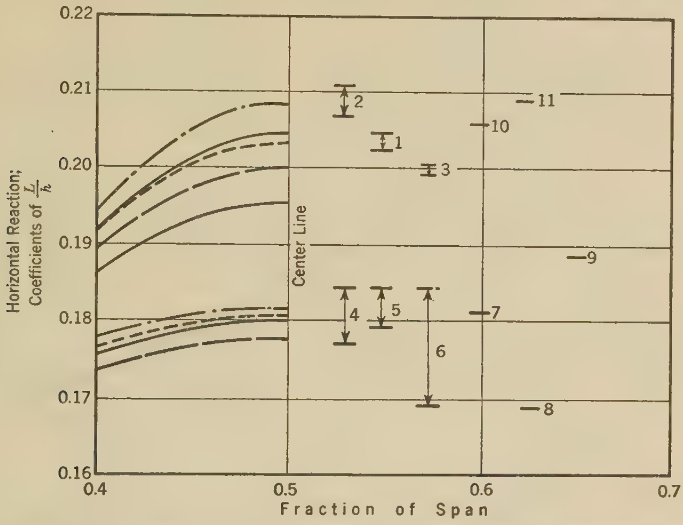

FIG. 7.—RANGES OF INFLUENCE VALUES FOR TYPES 1 TO 6 AND MAXIMUM VALUES FOR TYPES 7 TO 11

Circular Arch.—The equation of a circular arch of span L, radius r, and rise h, with the origin at the left end (Fig. 8), is

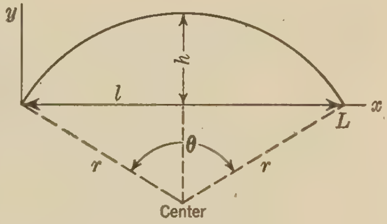

FIG. 8

$$y = h - r + \sqrt{r^2 - (x - l)^2} \qquad (26)$$

The basic influence value for the unit load at the crown is:

$$H = \frac{\int_0^l x\,y\,dx}{\int_0^L y^2\,dx} = \frac{3\,l\,r^2\,\theta + 6\,h\,r\,(h - r) - 2\,h^3}{12\,(h - r)\,r^2\,\theta + 12\,l\,r^2 - 4\,l^3} \qquad (27)$$

The influence values (see Table 5, lines 1 and 2) are not a linear function of L/h, as in the case of the parabola.

Basic influence lines for (L/h)-ratios of 8, 4, and 2 were computed by column analogy. Influence lines for variations in $\frac{1}{E\,I}\frac{ds}{dx}$ of types 1 to 6 were

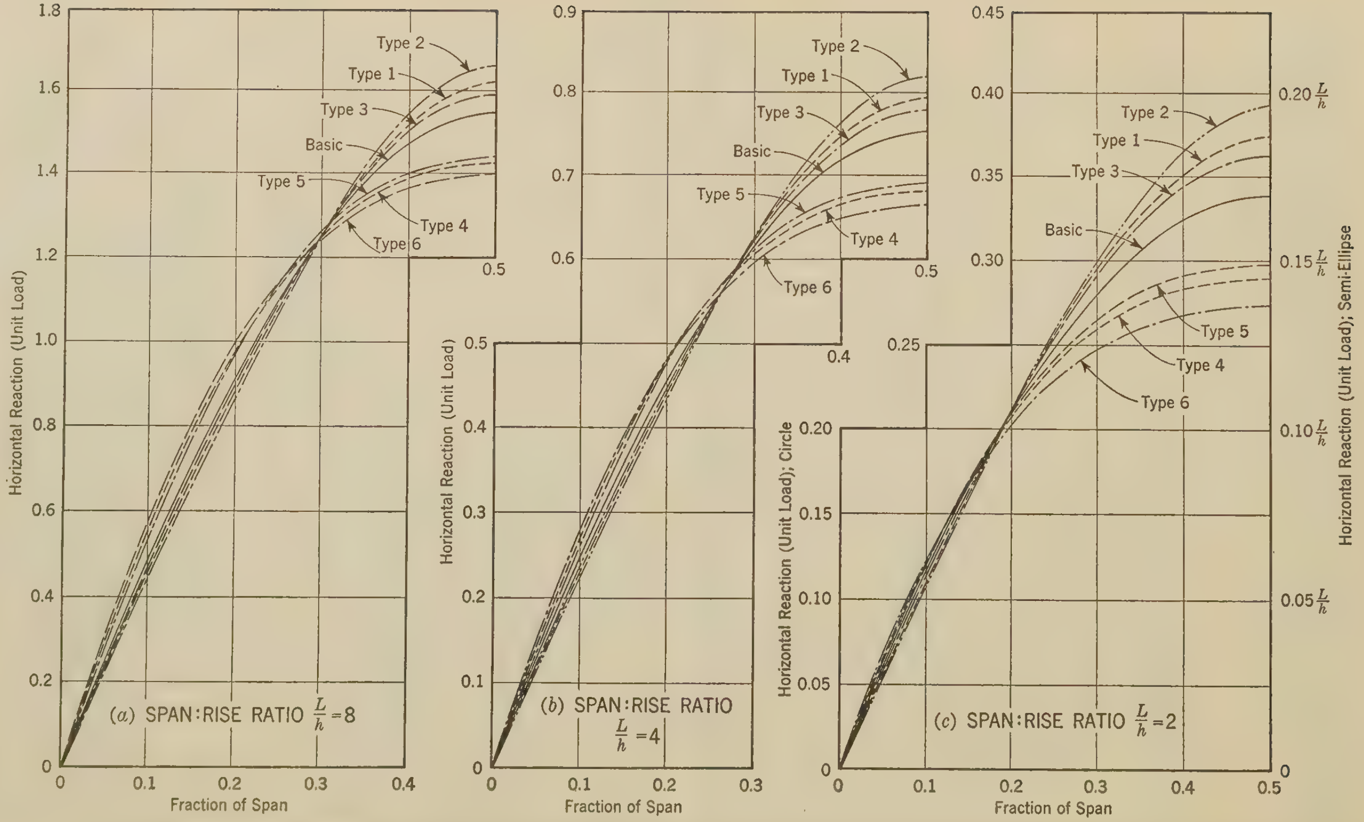

Fig. 9.—Influence Lines for Horizontal Reaction, Circular Arch Ribs, When a Unit Load Is at the Center of the Span

also computed by this method. The results are shown in Fig. 9. The variations from the basic influence line increase as the (L/h)-ratio decreases—that is, as the curve of the arch departs more and more from a straight line.

TABLE 5.—BASIC INFLUENCE VALUES AT THE CENTER OF CIRCULAR ARCHES, WITH A UNIT LOAD AT THE CROWN

No.	Description	RATIO OF SPAN LENGTH L TO RISE h								
		14 : 1	12 : 1	10 : 1	8 : 1	6 : 1	4 : 1	3 : 1	2.5 : 1	2 : 1[a]
	Basic Values:									
1	Actual	2.7240	2.3337	1.9404	1.5466	1.1512	0.752	0.548	0.4439	0.339
2	In terms of $L : h$	0.1946	0.1945	0.1940	0.1933	0.1919	0.1880	0.1828	0.1775	0.1695
3	Ratio[b]	0.9964	0.9959	0.9933	0.9898	0.9826	0.9626	0.9360	0.9089	0.8679

[a] Semicircle or semi-ellipse.

[b] $\frac{\text{Maximum coefficient for a circle}}{\text{Maximum coefficient for a parabola (that is, 0.1953)}}$.

Semi-Ellipse.—The equation of the semi-ellipse with the origin at the left end is

$$y = \frac{h}{l}\sqrt{2\,l\,x - x^2} \qquad (28)$$

For a unit load at the crown, the basic influence ordinate is

$$H = \frac{\int_0^l x\,y\,dx}{\int_0^L y^2\,dx} = \frac{3\,\pi - 4}{32}\,\frac{L}{h} = 0.1695\,\frac{L}{h} \qquad (29)$$

In the case of the semi-ellipse, as for the parabola, the influence ordinates are found to be a linear function of the (L/h)-ratio. The basic influence values are also proportional to those for a semicircle $(L/h = 2)$. The basic influence line for the semi-ellipse and influence lines for types 1 to 6 were computed by column analogy and are similar to those for a circle of $L/h = 2$ (see Fig. 9(*c*)).

EFFECT OF VARIATIONS IN CURVE

The comparative curves of the parabolic, circular, and semi-elliptic arches are shown in Fig. 10. An examination of these curves, together with the respective influence lines in Fig. 9 and the data in Table 5, shows that the more the curve departs from a straight line—(1) the lower are the influence values, and (2) the greater is the effect of variation in cross section upon these values.

GENERALIZED CURVES FOR TWO-HINGED ARCHES

Fig. 11 is a comparative diagram of the basic influence lines for the parabolic, circular, and semi-elliptical arch, plotted as fractions of the maximum values. It shows that, for practical purposes, all the basic influence lines have the same relative shape. This is also true for the influence lines for different $\left(\frac{1}{E\,I}\frac{ds}{dx}\right)$-variations. Consequently, using the parabola as a standard, an influence line for any circular or semi-elliptic arch can be determined by multiplying the influence values for the corresponding parabola (basic, A, or B in Fig. 5(*a*)) by the ratio of the respective (L/h)-coefficients. Table 5, line 3, gives the ratios of coefficients for basic influence values.

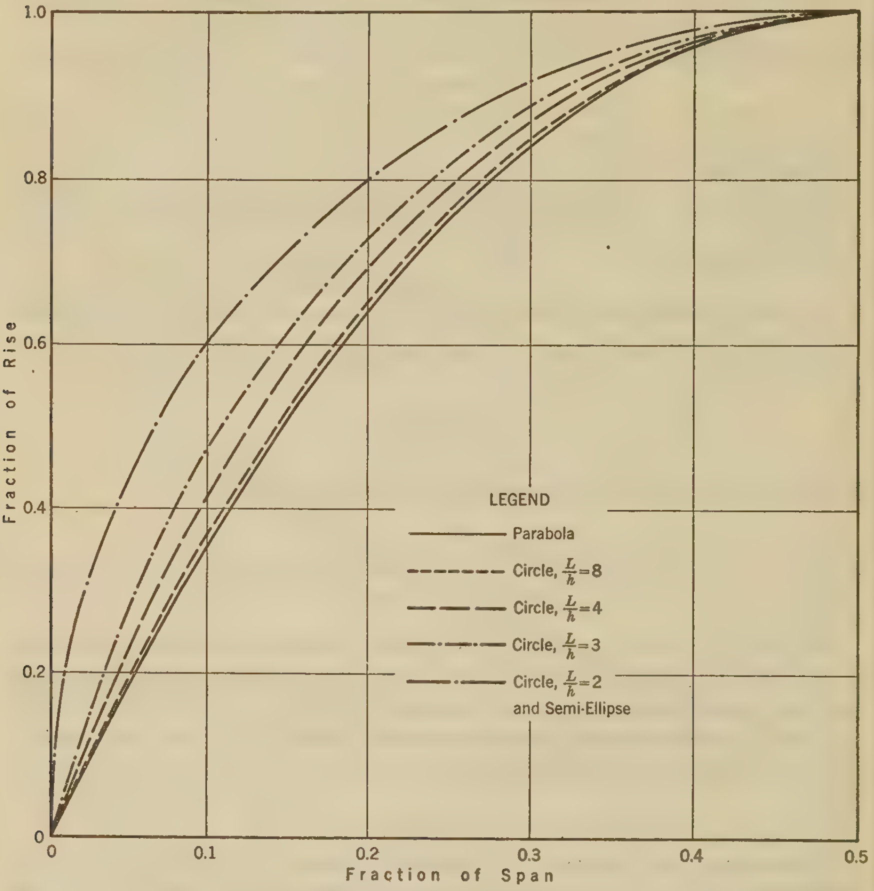

FIG. 10.—COMPARISON OF CURVE SHAPES

Plotting these points gives a reference curve for general use in the solid line in Fig. 12. This is used in conjunction with the basic values for the parabola in Fig. 5(*a*). Thus, for a circular arch of $L/h = 3.5$, the basic influence ordinates are obtained by multiplying the basic influence ordinates of the parabola (Fig. 5(*a*)) by $3.5 \times 0.950 = 3.325$, the factor 0.950 being taken from the basic reference curve in Fig. 12. Two similar average reference curves for the average curves A and B are plotted in Fig. 12 as dotted lines. For other arch forms, such as a multi-centered arch, segment of an ellipse, and others, the comparative curve form can be plotted in Fig. 10, and influence values determined from that curve which most nearly approximates it.

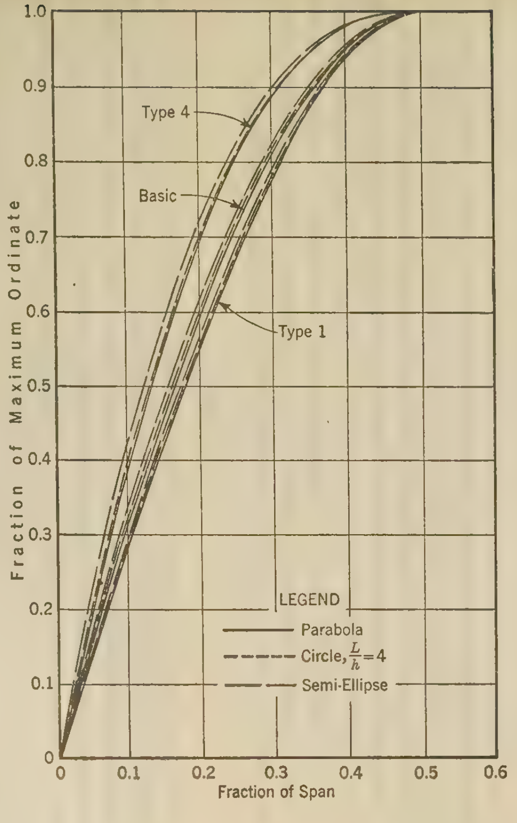

FIG. 11.—COMPARISON OF INFLUENCE LINE SHAPES

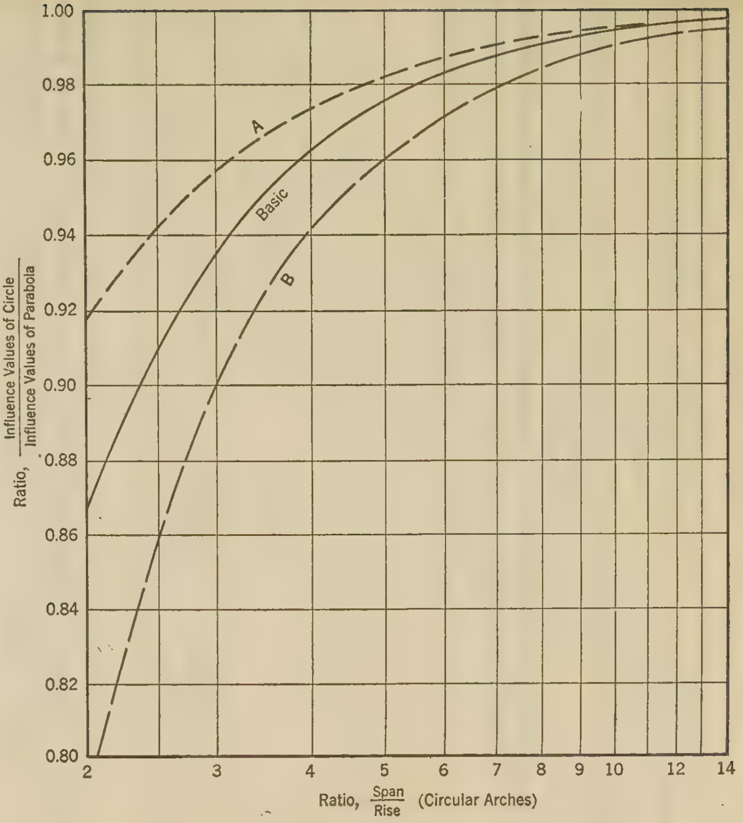

FIG. 12.—REFERENCE CURVES FOR TWO-HINGED ARCHES

ARCH TRUSSES

The reference curves in this paper apply equally well to two-hinged arch trusses. Computations show that the relation between the reduced equation $\frac{\sum \sigma u}{\sum u^2}$ and the classic equation $\frac{\sum \frac{\sigma u L}{A E}}{\sum \frac{u^2 L}{A E}}$ for truss structures is substantially the same as for solid structures.[2] Illustrative data are presented for three framed arches in Table 6. The Tyngsborough arch is parabolic in shape and of constant depth, corresponding to constant $\left(\frac{1}{E I} \frac{ds}{dx}\right)$-values. The Hell Gate and the Cottage Farm arches both have parabolic lower chords and are haunched in shape, the minimum depth being at the crown. The rise in each case is from the hinges to the midpoint between top and bottom chords at the crown. The Hell Gate and Cottage Farm arches are taken as parabolic in Table 6.

TABLE 6.—COMPARATIVE DATA FOR THREE TWO-HINGED ARCHES

No.	Arch	Location	Type	Ratio, span to rise	MAXIMUM INFLUENCE ORDINATE	
					"Reduced"	Actual
1	Tyngsborough	Lowell, Mass.	Basic	5.71	1.113	1.104
2	Cottage Farm	Boston, Mass.	A	4.165	0.852	0.838
3	Hell Gate	New York, N. Y.	A	4.16	0.849	0.841

LIMITATIONS

The accuracy of the reference curves decreases as the arch form becomes more curved, the errors varying from approximately 1% to 3% for the parabola to approximately 5% to 8% for the semi-ellipse, with usual arch shapes that do not have excessive differences in thickness between crown and haunch.

These reference curves will not apply to rigid-framed bents, and other similar structures, solved as two-hinged arches, because of their near-rectangular shape and consequent lack of "correspondence of ordinates." A special study of these shapes is necessary to establish the relationship between the geometry of the bents and the large errors resulting from reducing the equations.

CONCLUSION

The purpose of this paper has been to state a principle and to illustrate its application, but not to present an exhaustive treatise. Consequently the following considerations and many more have been omitted intentionally: Initial selection of the curve and shape of the arch rib or arch truss; rare arch forms of curves falling between a parabola and a straight line; rigid-frame bents and rectangular two-hinged structures; rib shortening; temperature effects; the effect of dissymmetry; and structures statically indeterminate to the second degree and higher. Furthermore, the study of the effect of variations in the thickness of the arch rib has been restricted to a small group of representative sections which is deemed sufficient for the practical application of the results. There would be no end to a "complete" investigation of this effect since there is an infinite number of possible variations.

---

[2] "A Simplified Method for Solving Statically Indeterminate Framed Structures," by Lee H. Johnson, Jr., presented to Harvard Univ., Cambridge, Mass., in May, 1935, in partial fulfilment of the requirements for the degree of Doctor of Science in Civil Engineering.

The basic principle is applicable, however, to the analysis of certain highly indeterminate structures. A simple example is a three-span continuous truss, statically indeterminate to the second degree. The classic equations for the indeterminate reactions, R_1 and R_2, can be written:

$$R_1 \sum \frac{u^2_1\,L}{A\,E} + R_2 \sum \frac{u_1\,u_2\,L}{A\,E} + \sum \frac{\sigma\,u_1\,L}{A\,E} = 0 \quad \text{.........(30}a\text{)}$$

$$R_1 \sum \frac{u_1\,u_2\,L}{A\,E} + R_2 \sum \frac{u^2_2\,L}{A\,E} + \sum \frac{\sigma\,u_2\,L}{A\,E} = 0 \quad \text{.........(30}b\text{)}$$

The reduced equations would be:

$$R_1 \sum u^2_1 + R_2 \sum u_1\,u_2 + \sum \sigma\,u_1 = 0 \quad \text{..............(31}a\text{)}$$

$$R_1 \sum u_1\,u_2 + R_2 \sum u^2_2 + \sum \sigma\,u_2 = 0 \quad \text{..............(31}b\text{)}$$

Computations of continuous trusses in a paper by Albert Haertlein,[3] M. Am. Soc. C. E., show good agreement between the results obtained from the two sets of equations.

The "method of reduced equations" can be used to analyze structures statically indeterminate to the first degree where there is "correspondence of ordinates." It reduces the labor required of the designer and makes possible quicker solutions.

The factors governing the application of the method to the analysis of more highly indeterminate structures are not known to the writer. The development of such applications would be of considerable value to the designing engineer. The few computations the writer has made indicate that, if small deformations or movements of a structure produce large changes in any of its reactions, the method of reduced equations will not necessarily give close approximations to those reactions. The moments at the ends of a stiff, fixed-end arch are such reactions.

APPENDIX

NOTATION

The following letter symbols, used in this paper, conform essentially to American Standard Symbols for Mechanics, Structural Engineering and Testing Materials[4] prepared by a Committee of the American Standards Association and approved by the Association in 1932:

[4] ASA—Z10a—1932.

A = area of the cross section of the arch rib;
a = coefficient; the letters a, b, B, c, and d are used as mathematical coefficients, or arbitrary constants, in the introduction part of this paper (see "Basic Principle"); also a = distance along the span from the nearest support (see Fig. 4);
B = an arbitrary constant (see a);
c = an arbitrary constant (see a);
d = an arbitrary constant (see a);
E = modulus of elasticity;
f = "function of," distinguished by numerical subscripts as in Eq. 4; see also ϵ and η;
G = difference term as defined by Eqs. 2 and 6;
g = substitution factors g_1, g_2, g_3, and g_4, defined by Eqs. 25;
H = horizontal reaction;
h = rise of the arch;
I = moment of inertia of the cross section of the arch rib;
j = a fraction of the half span $l = a/l$ (see Eq. 16a);
k = mathematical multipliers k_1, k_2, $\cdots$, k_n, used to demonstrate the basic principle (see Eq. 1);
L = span length of arch axis = $2\,l$;
l = half the span length = $L/2$;
M = bending moment due to given loads and vertical reactions only;
m = arbitrary constant in the difference terms (Table 2, Col. 3) for arches that taper downward from the support to the center; m' = an arbitrary constant for arches that taper;
n = number of terms, as in Eq. 3;
R = reactions (see Eqs. 30);
s = length of an arch measured along its center line axis; Δs = length of a small segment of arc;
u = total stress in an arch member due to a horizontal force of unity applied at the reaction;
x = abscissa distance to any point x,y;
y = ordinate distance to any point x,y; the rise of the arch at a distance x from the left support;
ϵ = "function of"; $\epsilon(x)$ = a function whose absolute value can be made arbitrarily small; see also f and η;
η = "function of"; see f and ϵ;
σ = total stress in an arch member due to given loads and vertical reactions only.

DISCUSSION

Josef Sorkin,[5] M. Am. Soc. C. E.—The thesis presented in this paper is offered (see "Synopsis") as one that "* * * is useful in simplifying the analysis of certain types of statically indeterminate structures * * *." The paper belongs to the category of a number of others published since 1930, all attempting to simplify the application of the classical elastic theory and nearly all, unfortunately, ending in utter failure. The only notable exception is the "Analysis of Continuous Frames by Distributing Fixed-End Moments,"[6] by Hardy Cross, M. Am. Soc. C. E., in which a radically new approach substitutes simple arithmetic for the solution of simultaneous equations. This statement implies no reflection upon the sincerity of purpose of the other writers.

The simple fact is that most statically indeterminate structures, as encountered in actual practice, do not lend themselves to solution by specific simple mathematical expressions. Various solutions may be devised for any assumed academic cases, but it is impossible to assume enough cases to meet all, or even most, of the conditions encountered in actual design problems. That is primarily the reason why efforts to develop a "cure-all formula" are futile.

The author states clearly that the method proposed does not replace other methods and that it does not apply to all structures. Its primary purpose appears to be simplification of approximations of members preliminary to final design. The design of a statically indeterminate structure by any method requires that the size and the properties of the members must be assumed before proceeding with the stress analysis. It is not clear why the same principle does not apply to the method proposed by the author, regardless of his statement to the contrary. Irrespective of the method used for determining the reactions, the shape of the member originally assumed must finally be checked for stresses. Any part of the structure found to be either deficient or extravagant must be modified correspondingly with suitable readjustment of the reactions and the stresses. In prognosticating the proportions of such a structure, nothing can ever take the place of a designer's judgment based on past experience with similar structures. The question appears to be whether the methods proposed are in fact simpler than other methods available.

In so far as two-hinged arches are concerned, certain rudimentary rules have been in existence for many years. Thus, for the preliminary design of a parabolic arch, it is customary to assume that[7]

$$H = \frac{5}{8}\frac{P\,L}{h}\,(k - 2\,k^3 + k^4) \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which $k\,L$ = distance from support. Incidentally, Eq. 32 is the same as Eq. 16*a*, since $j = 2\,k$. This formula can be employed with only a slight error for the preliminary proportioning of a circular arch of usual proportions.

[6] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[7] "The Theory and Practice of Modern Framed Structures," by J. B. Johnson, C. W. Bryan, and F. E. Turneaure, 9th Ed., John Wiley & Sons, Inc., New York, N. Y., 1910–1916.

That no greater precision is necessary is indicated by the use of Table 6 as illustrated in Table 7. Values for the maximum influence ordinate, as obtained by the use of Eq. 32, are well within the required accuracy for preliminary design, compare favorably with the values obtained by the use of the author's reduced equations, and are more simple to compute. Preliminary determinations within 3% are fairly close. Variation of details may account for greater differences.

TABLE 7.—COMPARISON OF INFLUENCE ORDINATES IN TABLE 6 WITH COMPUTATIONS BY EQ. 32

No.	Arch (see Table 6)	MAXIMUM INFLUENCE ORDINATE			PERCENTAGE ERROR	
		"Reduced"	Actual	Eq. 32	"Reduced"	Eq. 32
1	Tyngsborough	1.113	1.104	1.114	+1.0	+1.0
2	Cottage Farm	0.852	0.838	0.813	+1.7	−3.0
3	Hell Gate	0.849	0.841	0.813	+1.0	−3.4

At its best, the method appears to be directly applicable only to solid concrete ribs of such shapes as the author (see paragraph following Eq. 16*b*) has selected "primarily because of their mathematical simplicity." It is clear that for steel ribs composed of shapes and plates, where changes in sections are abrupt, the mathematics would become so involved as to make the method too cumbersome for practical use. The author claims that the method is also applicable to arch trusses and to three-span continuous trusses; it is yet to be demonstrated, however, just how such application would be useful in any but very simple cases, where any relation to a practical design problem would be purely coincidental.

It may be pertinent to state that the actual time required for the analysis of any usual structure is a very small part of the total time required to prepare designs, plans, and specifications. Hence, the difference between one or two, or even three, trial designs reflects the total effort only in a minor way. Each designer as a rule develops his own peculiar approach to a problem and recognizes "short cuts" as his experience broadens. The quickest design method for any structure is the method that the designer knows and understands best.

Of late entirely too much emphasis seems to have been placed on methods and not enough on the physical meaning of the mechanics of calculations. Thus, as an example, the significance of Eq. 8*a*, for a horizontal reaction of a two-hinged arch, is simply that the horizontal reaction is equal to the horizontal movement of an arch end due to superimposed loads (if the end were free to move) divided by the similar movement caused by a unit load applied at that end. Such a definition is easily understood and the problem then is one of determining these movements of the arch end. Unfortunately, the true meaning of Eq. 8*a* can easily be befogged by bending moments, ordinates, and differential elements—the actual significance of the meaning being lost in the shuffle.

I. Oesterblom,[8] M. Am. Soc. C. E.—It is interesting to note that even the ancient Greek mathematicians have something to add to modern calculus, since the basic formula, Eq. 1, of the paper was set up and used by them in discussions of "proportionality." The development of the idea to assist modern engineers, when infinitesimal differences have to be computed, no doubt will have a much greater scope than Dean Johnson has so modestly shown.

Influence lines for horizontal reactions in arch bridges have been developed before, but never so easily and gracefully. On this account, one may say that the procedure presented in the paper is too late and no longer needed. This is not so, however; there is always room for a more graceful method. Then, there are also the broader needs—better understanding of a type, clearer comparisons of different arches or of loadings (especially unusual loadings) for various designs, comprehension of the stress behavior near the danger limits for unusual loads and for comparative alternates, and knowledge of how to use materials to the best advantage. Engineers can afford to spend more time on all these questions, and they will build better balanced as well as safer structures by doing so.

For the writer, Dean Johnson's method is so far only a dream—but a fine and fair one. He hopes, however, that opportunities will come soon to turn the vision into structural beauty. For the young engineer the paper presents more than a vision; it is a challenge to build always with grace—not only bridges but all kinds of indeterminate structures.

Indeterminate structures often involve small increments, and the method should be applicable to such problems. The writer expressed similar thoughts when Hardy Cross, M. Am. Soc. C. E., first presented his great vision of frame relaxation.[6] How well that idea was justified is now clear. The writer hopes sincerely that his present forecast will be equally justified.

Leon Beskin,[9] Assoc. M. Am. Soc. C. E.—The transformation of crude and well-known rules of the thumb used in preliminary design into a method of analysis for indeterminate structures has been attempted in this paper. It appears to the writer that this effort is misleading, because the examples selected and the internal forces computed are so chosen that they lead to erroneous general conclusions. For the special problem (hinged arches) for which the method has been developed, the charts and tables already available give enough information for preliminary design purposes without resorting to the author's approximations. Among such tables are those prepared by Eduard Winkler and presented in a French manufacturer's catalog and handbook.[10] These tables are computed for two-hinged arches, for built-in arches, and for various ratios of rise to span as well as for differences in moment of inertia along the span. Maximum positive and negative moments are given, as are the corresponding vertical and horizontal components of the force applied at the centroid, under the action of a uniform live load. The fraction of the span along which the live load is distributed is chosen to obtain the maximum moment. Tables of this type have considerable interest for a designer, and the author could have served his stated purpose better by completing existing tables of influence lines for arches of various proportions.

[9] Design Specialist, Consolidated Vultee Aircraft Corp., San Diego, Calif.

[10] *Acitries de Longwy,* Longwy Steel Co., Paris, France, 1928 Ed.

Theoretical Considerations.—The fact that "the basic principle is one of simple arithmetic" (see heading, "Basic Principle") reveals one limitation of the author's development: The designer must assume that factors of the type of $M\,y$ are invariably plus or minus—never both. Otherwise, it is obvious that the value of a fraction such as that on the left-hand side of Eq. 1 (in which a_1 and a_2 have opposite signs) is not represented, to any degree of accuracy, by the fraction on the right-hand side. The two fractions may have opposite signs. Thus, the value of the redundant defined by the first fraction cannot be found by application of the author's method.

It may appear that the method is acceptable when ratios such as a_n/b_n (see Eq. 3) are approximately equal, so that the error G—which the author designates as "difference term"—is small. In this case, however, the method may lead to an even more serious failure than when the error G is great, as may be observed by comparing concentrated loads (large values of G) and distributed loads (small values of G). This fact can be demonstrated theoretically as follows: The values of the thrust computed by the correct formula (H) and by the approximate formula (H'), respectively, are

$$H = \frac{\Sigma M\,y\,\Delta s/I}{\Sigma y^2\,\Delta s/I} \quad\quad (33a)$$

and

$$H' = \frac{\Sigma M\,y\,\Delta s}{\Sigma y^2\,\Delta s} \quad\quad (33b)$$

Introduce the moments M' corresponding to H':

$$M' = M - H'\,y \quad\quad (34)$$

which can be considered as statical moments. Introduced into Eqs. 33, the thrust correction is found to be equal to zero if the approximate formula (Eq. 33b) is used, or to G if the correct formula (Eq. 33a) is used; thus:

$$G = \frac{\Sigma M'\,y\,\Delta s/I}{\Sigma y^2\,\Delta s/I} = \frac{\Sigma M\,y\,\Delta s/I}{\Sigma y^2\,\Delta s/I} - \frac{\Sigma M\,y\,\Delta s}{\Sigma y^2\,\Delta s} \times \frac{\Sigma y^2\,\Delta s/I}{\Sigma y^2\,\Delta s/I} = H - H' \quad (35)$$

The final moment M_0 can be expressed in terms of M' by the relation:

$$M_0 = M - H\,y = M' - G\,y \quad\quad (36)$$

Since M and y are assumed approximately proportional to each other, the quantities M' are very small in comparison with the quantities M. Thus, $G\,y$ and M' are of the same order or magnitude, and the error resulting from the use of H' (leading to M') instead of H (leading to M_0) may yield considerable differences between the moments, although the thrusts are practically equal.

Application to a Two-Hinged Arch.—The significance of the foregoing comments can be applied to the paper under discussion by the analysis of a two-hinged parabolic arch, under two conditions of loading. The following comparison is made between an arch that has a constant value of $E\,I\,dx/ds$ and an arch defined by the formula,

$$\frac{1}{E\,I} = \frac{1}{E\,I_0}\frac{ds}{dx}(1 + \beta\,\xi^2)\ldots\ldots\ldots\ldots\ldots\ldots(37)$$

in which $\xi = \frac{x}{l}$, the distance x being measured from the center line. The constant β may be positive or negative. Eq. 37 defines the arch ribs of types 3 and 6 (Fig. 5(*b*)). The extreme values of m and m' are $+40$ and -0.975 (see Tables 3 and 4), which correspond approximately to $\beta = -0.975$ and $\beta = 40$, since the relation between m (or m') and β is

$$(1 + m)(1 + \beta) = 1\ldots\ldots\ldots\ldots\ldots\ldots\ldots(38)$$

Case (*a*). Two Symmetrically Placed Concentrated Vertical Loads (*P*).—The expression for the thrust is (see Fig. 4, with $\alpha = 1 - a/l$):

$$\frac{H}{P} = \frac{l\int_0^{\alpha}(1-\alpha)(1-\xi^2)\,ds/I + l\int_{\alpha}^{1}(1-\xi)(1-\xi^2)\,ds/I}{h\int_0^{1}(1-\xi^2)^2\,ds/I}\ldots(39a)$$

or

$$\frac{H\,h}{l\,P} = \frac{\int_0^{\alpha}(1-\alpha)(1-\xi^2)(1+\beta\,\xi^2)\,d\xi + \int_{\alpha}^{1}(1-\xi)(1-\xi^2)(1+\beta\,\xi^2)\,d\xi}{\int_{\alpha}^{1}(1-\xi^2)^2(1+\beta\,\xi^2)\,d\xi}\ldots(39b)$$

The final value is:

$$\frac{H\,h}{l\,P} = \frac{5\,(5 - 6\,\alpha^2 + \alpha^4) + \beta\,(3 - 5\,\alpha^4 + 2\,\alpha^6)}{32\,(1 + \beta/7)}\ldots\ldots\ldots\ldots(40)$$

Table 8 contains the coefficients for thrust and moment, resulting from the application of Eq. 40, for various values of α and β. Moments are determined at the points of application of the concentrated loads. Percentage errors in thrust and moment, as related to the "basic arch" ($\beta = 0$), are included for comparison.

TABLE 8.—INFLUENCE VALUES RESULTING FROM EQS. 40 AND 43

Constant β	CASE (*a*)								CASE (*b*)	
	Thrust, $\frac{h\,H}{l\,P}$				Moment, $\frac{M}{l\,P}$				Moment, $\frac{M}{l^2\,w_2}$	
	Computation		Error (%)		Computation		Error (%)		Computation	Error (%)
	$\alpha = 0$	$\alpha = 0.5$	$\alpha = 0$	$\alpha = 0.5$	$\alpha = 0$	$\alpha = 0.5$	$\alpha = 0$	$\alpha = 0.5$		
− 0.975	0.802	0.551	− 3	−1	0.196	0.101	+12	+12	−0.00934	+27
− 0.900	0.800	0.550	− 3	−1	0.200	0.102	+10	+11	−0.00956	+24
0	0.781	0.556	0	0	0.219	0.113	0	0	−0.0119	0
+10	0.708	0.580	+10	+4	0.292	0.160	−25	−29	−0.0212	−44
+40	0.676	0.590	+15	+6	0.325	0.179	−32	−37	−0.0254	−53

In his presentation, Dean Johnson has not shown the errors in moment values, which reach 37%. He has reduced the error in thrust (which reaches

15%) to a fictitious value of 6% (see line 14 preceding Eq. 26) by the use of average arches with varying moments of inertia that have no relation to the basic arches introduced at the beginning of the paper. Since the object of the paper is to establish a method based on the properties of the basic geometric arches, it seems inconsistent to use arches with varying moments of inertia for the evaluation of errors due to the use of the basic arch. The result is an apparent compromise between the actual arch and the basic arch, which the writer cannot accept as tenable.

Case (*b*). A Variable Distributed Load (*w*).—Consider a variable load defined by

$$w = w_0 + w_2\,\xi^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (41)$$

When the ratio w_2/w_0 is small, the load is approximately uniform; and, when the ratio is large, the variation in load is relatively great. Then the formula for thrust is

$$\frac{h\,H}{l^2} = \frac{1}{2}\,w_0 + w_2\,\frac{\int_0^1 (1 - \xi^2)\,(1 = \beta\,\xi^2)\,(1 - \xi^4)\,d\xi}{12 \int^1 (1 - \xi^2)^2\,(1 + \beta\,\xi^2)\,d\xi}$$

$$= \frac{1}{2}\,w_0 + w_2\,\frac{6 + \beta}{9\,(7 + \beta)} \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

and the moment at the crown is:

$$\frac{M}{l^2} = \frac{w_2}{12}\left[1 - \frac{4\,(6 + \beta)}{3\,(7 + \beta)}\right] = -\frac{(3 + \beta)\,w_2}{36\,(7 + \beta)} \ldots\ldots\ldots (43)$$

Values of the moment and of the error resulting from the use of the basic arch for this condition are included in Table 8. They show that errors are greater in the case of distributed loads than in the case of concentrated loads. The relative error in the value of the thrust is a function of the ratio $\rho = w_0/w_2$; thus:

$$\epsilon = \frac{\beta}{7\,[6 + \beta + 9\,\rho\,(7 + \beta)/2]} \ldots\ldots\ldots\ldots\ldots (44)$$

The error is infinite if ρ has the value,

$$\rho = -\frac{2\,(6 + \beta)}{9\,(7 + \beta)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (45)$$

Eq. 45 shows that, with a proper choice of ρ, any arbitrary value of ϵ can be selected. For instance, if $\epsilon = -2$, the approximate value of the thrust is equal and opposite to the actual value.

Loading conditions that lead to such results are not theoretical. For instance, in frames, used to reinforce a shell structure such as an airplane fuselage, it is possible to find cases for which the frame tends to open or close under a given applied load, depending on the distribution of the moments of inertia. Thus, depending on the structure, there may be thrusts of opposite signs—a fact that cannot be shown if basic arches are used.

Incidental Comment.—The author introduces expressions such as "difference term" and "reduced equation" when the expressions, "error" and "approximate equation," are well known and fulfil the same requirements, without obscuring the approximate character of the method. The expression, "correspondence of ordinates," is loosely defined. For instance, in Fig. 1(*c*), there is no reason to assume that the correspondence is stopped precisely at the center line. The concept of "correlation," which has a definite significance in statistics, could be usefully applied, because it would supply a definite quantity to express the "degree of correspondence" between various curves.

The author has devoted too much of his paper to a description of elementary methods of integration and to well-known tricks, such as the use of two symmetrical loads and the expedient of integrating along the half span when determining the thrust due to one load. The distinction between m and m', to separate positive and negative values, leads to the writing of two sets of formulas instead of one.

A difference is claimed between parabolic and circular arches, which actually does not exist. For example, in the sentence following Eq. 27, the author states: "The influence values [for circular arches] * * * are not a linear function of L/h, as in the case of the parabola." This is correct for a true "basic arch"; but, because the author uses a substitute basic arch in the case of a parabolic profile for expediency (in which $I\,dx/ds$ is constant, instead of I), he finds that the thrust is a linear function of L/h. If a similar adjustment is made for circular arches, the property of linearity may be shown to exist for this second case as well as for parabolic arches.

Conclusions.—In recent years, many writers have tried to simplify the analysis of redundant structures. With a few exceptions (which all concerned methods of successive approximations), these attempts have proved failures. This paper, likewise, has failed in its purpose.

JAROSLAV POLIVKA,[11] M. AM. SOC. C. E.—The results of analyses of a two-hinged arch of parabolic, circular, and elliptical shape, with a variable moment of inertia, I, are presented in this excellent paper. Tables and graphs are included showing clearly the effect of the variation of I, and the effect of the shape upon the horizontal reaction H. With this evidence, Dean Johnson arrives at the conclusion that H can be found with sufficient accuracy from three types of average influence lines, referring to three general types of two-hinged arches. The author discusses the correlation of error resulting from average values and the "correspondence of ordinates"; and he expresses this error in a novel manner by means of "difference terms."

Furthermore, the author defines the limitations of the method of using typical average values or reference curves. He states that such reference curves will not apply to rigid-framed bents and other similar structures, solved as two-hinged arches, because of the lack of "correspondence of ordinates." Finally, he concludes that such average reference curves will not necessarily give close approximations to redundant reactions for structures in which small deformations produce large changes in reactions—as, for example, those produced by the moments at the abutments of a restrained arch.

---

[11] Lecturer, Univ. of California Eng. Dept., Cons. Engr., Berkeley, Calif.

The author derives the "reduced equation" (Eq. 10) from the "classic equation" (Eq. 9) by eliminating the variable term $E\,I$. This is possible[12,13] by making $E\,I$ proportional to $\frac{1}{\cos\phi} = \sqrt{1 + \left(\frac{dy}{dx}\right)^2}$, in which $\frac{dy}{dx} = \tan\phi$. Eqs. 16 used to determine the influence line for H in the case of a parabolic arch has been derived by W. Ritter as follows:

$$H = \frac{x\,(L - x)\,(L^2 + L\,x - x^2)}{2\,L^3\,m} \qquad (46)$$

in which

$$m = \frac{4}{5}h\left(+ \frac{3\,I}{2\,A\,h}\right) \qquad (47)$$

The second term in Eq. 47 is an expression of rib shortening; and, for $x = \frac{L}{2}$ (or for $j = 1$ in the paper), Eq. 46 yields:

$$H_{\max} = \frac{25\,L}{128\,h} \qquad (48)$$

The effect of a variation in the thickness of the ribs is obtained by expressing the variation in simple terms which allow easy integration—a procedure which has been proposed by several writers.[14,15] The new version of the reduced equation should be a great help in the design of two-hinged arches with variable moments of inertia because the conventional methods involve a great many cumbersome computations.

LEE H. JOHNSON, JR.,[16] M. AM. SOC. C. E.—The writer is indebted to those who have prepared discussions of this paper. He has been aware of the fact that it presented only an idea, and was prompted to submit it in the hope that others would be stimulated to investigate the possibilities of the idea. In statically indeterminate structures both the geometry and the properties of the cross sections and materials have an influence upon the reactions and the internal forces. It is conceivable that the relation between these two influences may be determined sufficiently to be of value to the designer, at least for some types of structures. The use of reduced equations may provide a method of limited applicability for determining this relation. The possibilities of the method for this purpose were illustrated in the application to two-hinged arches, where it was shown that the influence of cross sections and materials upon reactions was relatively small and could be correlated to the influence of geometry.

Mr. Oesterblom's discussion is a great encouragement to pursue the idea still further. The writer agrees with him that at present the possibilities of

[16] Dean and Prof. of Civ. Eng., School of Eng., Univ. of Mississippi, University, Miss.

the method largely remain to be determined. The writer is indebted to Mr. Polivka for emphasizing the usefulness of the two-hinged arch data in eliminating certain cumbersome computations.

Although Mr. Beskin's mathematical analyses appear to be correct, his criticism comes from misleading inferences which he draws from them. He points out several apparent limitations to the writer's method—one to the basic principle as expressed in Eq. 1, another to the computation of moment values, M_0, in Eq. 36, and a third in the computation of thrust for a variable load in Eq. 45. None of these are actual limitations since they are valid only for values in the neighborhood of zero.

Consider two influence lines whose corresponding ordinates differ by relatively small amounts and which do not cross the horizontal or zero axis at the same point. It is obvious that the relative error becomes infinite at one of the zero points and is very large in the vicinity of that point. The small ordinates to influence lines, moment diagrams, and shear diagrams near the zero points are seldom significant in a design. Mr. Beskin has attempted to make them so, in discussing the writer's two-hinged arch data, by using a combination loading consisting of a uniform load and a load that increases parabolically from the center to the ends of the arch. He finds under this loading that the error in thrust, using the reduced equations, is infinite for a certain ratio of the two load constants, which ratio, it should be noted, is negative. Again it is obvious that if an arch is subjected to two loads, one downward and one upward as is indicated by the negative sign, the thrust on the arch can be made zero by properly balancing the loads, in which case the error in making any approximation to the thrust must be infinite. The stresses computed with a thrust of zero and the stresses computed with a very small thrust would be approximately the same in spite of the fact that the error in thrust is infinite. In a problem of this type where the thrust is zero, or is so close to zero that the approximation may be of the opposite sign, the thrust is not significant in determining the stresses and the arch behaves more as a curved beam with unusual support and loading than as an arch. Contrary to Mr. Beskin's statement, the method of reduced equations can be used to examine loadings of this type, and he, himself, has made a start in this direction.

The comparative values which Mr. Beskin shows in Table 8 are with respect to the basic influence values rather than with respect to curve A or B, Fig. 12; hence the large relative errors. He contends that there is no justification for curves A and B; but the writer is of the opinion that much more justification for these curves can be found in mathematical analyses than can be found for the use of any "allowable stress" in the design of a structure.

The writer made no claim to a difference between parabolic and circular arches such as Mr. Beskin states. He did claim, and still does, that the "basic influence values" for circular arches are not a linear function of the (L/h)-ratio as are those of the parabolic and semi-elliptic arches. The term "basic arch" was not used in the paper.

Mr. Beskin's suggestions about the terminology are noteworthy. The writer agrees that the term "correlation" would have been better than "correspondence" and that "error" would have done as well as "difference term."

He prefers the term "reduced equation," however, as it implies a particular type of approximation. There is a reason to assume that the correspondence in Fig. 1(*c*) is stopped precisely at the center line, for it is precisely there that the slope of curve F changes from positive to negative.

Mr. Sorkin's criticism arises from a misinterpretation of the details of the paper, the significance of the fundamental idea, and of its application to two-hinged arches. Apparently, he denies the possibility of beginning the design of a statically indeterminate structure without first assuming the size and properties of the members. The writer has shown mathematically under what conditions these quantities may be omitted from the first computations.

Mr. Sorkin states that the method is too cumbersome for practical use in the case of steel ribs composed of plates and shapes because of the involved mathematics. The reader should understand that the result of the application of the method to two-hinged arches is a set of three charts, Figs. 5, 10, and 12, which apply to steel girder ribs and to truss ribs as well as to solid concrete ribs. In the paper the writer did not give the tabular data for plotting the basic influence line, curve A, and curve B in Fig. 5. These data are given in Table 9.

TABLE 9.—ORDINATES FOR INFLUENCE LINES FOR PARABOLA (SEE FIG. 5)

(Values Are in Terms of L/h)

Fraction of span	Curve A	Basic influence line	Curve B
0.05	0.028	0.031	0.036
0.10	0.058	0.061	0.069
0.15	0.085	0.090	0.100
0.20	0.112	0.116	0.124
0.25	0.136	0.139	0.144
0.30	0.159	0.159	0.159
0.35	0.177	0.175	0.169
0.40	0.192	0.186	0.176
0.45	0.201	0.193	0.179
0.50	0.204	0.195	0.180

The parabolic formula, Eq. 32, which Mr. Sorkin mentions, can be used with small errors only for parabolic arches, and for circular arches of the higher (L/h)-ratios—say greater than 6. It will not give accurate results for these arches in cases where the crown thickness is much greater than the thickness at the haunch. The writer's data give closer approximations in all cases than the parabolic formula and also apply to any other arch form within the limits of the data in Figs. 10 and 12. The writer does not agree with Mr. Sorkin's implication that since "the difference between one or two, or even three, trial designs reflects the total effort only in a minor way," no attempt should be made to improve this phase of the work in the creation of a structure.

COLUMN FORMULAS

By William R. Osgood,[1] M. Am. Soc. C. E.

With Discussion by Messrs. L. E. Grinter, George Winter, Jonathan Jones, Edward Godfrey, Ralph E. Spaulding, James H. Cissel, Leon Beskin, Louis Balog, and William R. Osgood.

Synopsis

An empirical column formula should be one that expresses theoretically possible relations. The prime requisites of any column formula or formulas are that the average stress be a continuous, monotonically decreasing function of the ratio of slenderness and that it approach the Euler value as the ratio of slenderness becomes infinite. Another desirable requisite is that the first derivative of the average stress with respect to the ratio of slenderness be continuous. These requirements impose certain restrictions on the constants in empirical formulas, and these restrictions are considered for a number of well-known and less well-known column formulas.

Introduction

Column formulas are a convenience, not a necessity, for relating the strength of a column to its dimensions. It would be quite possible to plot the results of tests, determine a curve from the plot, and select design values from this curve or from a table of values read from the curve. When a formula is used, however, as it usually is, there is some virtue in having it of correct form, if only because the designer may have to extrapolate beyond the values on which the formula is based. If, for example, at large ratios of slenderness a formula covering all ratios of slenderness leads to values of average stress that are known to be impossible, the formula will lead at less large ratios of slenderness to values that are likely to be impossible. Therefore it is desirable not to preclude extrapolation. Is it not at least slightly better to know that extrapolated values may be right than to know that they probably are wrong?

There have been numerous and elaborate attempts to devise formulas based on elastic theory for the design of centrally loaded columns in the plastic range.

Note.—Published in December, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Materials Engr., National Bureau of Standards, Washington, D. C.

Before the development of the double-modulus theory toward the end of the past century these attempts were consonant with good engineering practice. Today, however, it should be realized how futile such attempts must be. It would be possible to design by means of the double-modulus theory, given the compressive stress-strain curve of the material; but the best testing technique results in wider discrepancies between theoretical and experimental values in the plastic range than in the elastic range, and most engineers would undoubtedly prefer to use an empirical formula based on tests. An empirical formula, however, should be one that expresses theoretically possible relations. Besides being of correct form, the formula should contain separately one constant of the structure, implicitly or explicitly, and one or more constants related to the material. It would be very hard to justify more than two constants of the material in any practical column formula.

As to the form, the prime requisites of any column formula or formulas are that the average stress be a continuous, monotonically decreasing function of the ratio of slenderness and that it approach the Euler value as the ratio of slenderness becomes infinite. Another desirable requisite is that the first derivative of the average stress with respect to the ratio of slenderness be continuous.

It is proposed to present a number of formulas in their most general forms to satisfy the requirements of the preceding paragraph. For comparative purposes the formulas will all be written in terms of the two non-dimensional variables, λ_o (the reduced ratio of slenderness) and σ (the reduced average stress):

$$\lambda_o = \frac{1}{\pi}\frac{l_o}{i}\sqrt{\frac{S}{E}} \quad \text{(1a)}$$

and

$$\sigma = \frac{P}{A\,S} \quad \text{(1b)}$$

as well as in terms of the customary variables—the average stress P/A, and the ratio of slenderness l_o/i. The free length is:

$$l_o = k\,l \quad \text{(2)}$$

l being the actual length (panel-point length) of the column and k being the constant of the structure—namely, the factor depending on end conditions by which l must be reduced or increased to obtain the distance, l_o, between successive points of inflection. For simply supported ends, $k = 1$; for fixed ends, $k = \frac{1}{2}$; for one end free and the other end fixed, $k = 2$; etc. In Eqs. 1, E is the modulus of elasticity of the material, and S is an arbitrary constant of the dimensions of stress. In analyzing column-test data, S should be taken as a compressive secant yield strength. (The secant yield strength is the stress at the intersection with the stress-strain curve of a line through the origin having a slope $m\,E$, where $0 < m < 1$.)

The most general forms of some well-known and other, less well-known formulas will now be given. The dimensionless constants β, γ, and n, and the constants B and C that appear are arbitrary, subject to the conditions stated in each case. They are constants related to the material. The load, P, is to be considered the maximum load, and after assigning values to the constants, P is to be taken as the working load multiplied by a factor of safety.

The only formula containing but one arbitrary constant that will be considered is the Rankine formula. This formula is used extensively. The justification for it is that at low and at high ratios of slenderness it fits test results well, and at intermediate ratios of slenderness, where the scatter in test results is relatively large, the formula gives lower values of the average stress than the mean of the average stresses found in tests of most materials. The formula applies for all values of ratio of slenderness.

I. The Rankine Formula

The Rankine formula is expressed by

$$\sigma = \frac{1}{\beta + \lambda^2_o}; \qquad \beta \geqq 0 \ldots\ldots (3a)$$

or

$$\frac{P}{A} = \frac{\pi^2 E}{B + \left(\frac{l_o}{i}\right)^2}; \qquad B \geqq 0 \ldots\ldots (3b)$$

When $\beta = B = 0$, Eqs. 3 reduce to the Euler formula,

$$\sigma = \frac{1}{\lambda^2_o} \ldots\ldots (4a)$$

or

$$\frac{P}{A} = \frac{\pi^2 E}{\left(\frac{l_o}{i}\right)^2} \ldots\ldots (4b)$$

It is easy to determine β from a series of observed values of σ and λ_o by plotting $\sigma \lambda^2_o$ against σ, for

$$\sigma \lambda^2_o = -\beta \sigma + 1 \ldots\ldots (5)$$

and $-\beta$ is the slope of the resulting straight line (if one results!) through the point $\sigma = 0$, $\sigma \lambda^2_o = 1$. Alternatively, since

$$\beta = \frac{1}{\sigma} - \lambda^2_o \ldots\ldots (6)$$

β may be taken as the average of the values of $\frac{1}{\sigma} - \lambda^2_o$.

There are several formulas containing two arbitrary constants, and one of them, and often more than one, can be made to fit almost any column-test data that it may be desired to fit. First will be considered formulas covering the entire range of ratios of slenderness.

II. The Secant Formula

The secant formula is expressed by:

$$\lambda_o = \frac{2}{\pi \sqrt{\sigma}} \sec^{-1}\left(\frac{1}{\beta \sigma} + C\right); \qquad \beta \geqq 0, \qquad C \leqq 1 \ldots\ldots (7a)$$

or

$$\frac{l_o}{i} = \frac{2\sqrt{E}}{\sqrt{\frac{P}{A}}}\sec^{-1}\left(\frac{1}{B\frac{P}{A}} + C\right); \qquad B \geqq 0, \qquad C \leqq 1 \ldots\ldots\ldots (7b)$$

When $\beta = B = 0$, Eqs. 7 reduce to Euler's formula.

The constants β and C may be determined by plotting $\sec\frac{\pi}{2}\lambda_o\sqrt{\sigma}$ against $1/\sigma$, for

$$\sec\frac{\pi}{2}\lambda_o\sqrt{\sigma} = \frac{1}{\beta\,\sigma} + C \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

and $\frac{1}{\beta}$ and C are the slope and intercept, respectively, of what may turn out to be a straight line.

III. AARFLOT'S FORMULA

A column formula due to M. G. Aarflot[2] is:

$$\sigma = \frac{1}{C\lambda^2_o + (1 - C)\sqrt{\lambda^4_o + \beta}}; \qquad \beta \geqq 0, \qquad 0 \leqq C \leqq 1 \ldots\ldots (9a)$$

or

$$\frac{P}{A} = \frac{\pi^2 E}{C\left(\frac{l_o}{i}\right)^2 + (1 - C)\sqrt{\left(\frac{l_o}{i}\right)^4 + B}}; \qquad B \geqq 0, \qquad 0 \leqq C \leqq 1 \ldots (9b)$$

When $\beta = B = 0$, or $C = 1$, Eqs. 9 reduce to Euler's formula.

The constants β and C may be determined from a series of observed values of σ and λ_o by plotting $\frac{1}{\sigma^2} - \lambda^4_o$ against $\lambda^2_o\left(\frac{1}{\sigma} - \lambda^2_o\right)$, for

$$\frac{1}{\sigma^2} - \lambda^4_o = 2\,C\lambda^2_o\left(\frac{1}{\sigma} - \lambda^2_o\right) + \beta\,(1 - C)^2 \ldots\ldots\ldots\ldots (10)$$

and $2\,C$ and $\beta\,(1 - C)^2$ are the slope and intercept, respectively, of the straight line represented by Eq. 10.

IV. YLINEN'S FORMULA

A column formula due to A. A. J. Ylinen[3] is:

$$\lambda_o = \sqrt{\frac{1 - \beta\sigma^n}{\sigma}}; \qquad \beta \geqq 0, \qquad n > 0 \ldots\ldots\ldots\ldots (11a)$$

---

[2] "A New Column Formula," by Martin G. Aarflot, *Bulletin*, Am. Soc. of Swedish Engrs., Vol. 26, February, 1931, p. 7.

[3] "Keskeisesti Puristetun Sauvan Nurjahtamisesta Suhteellisuusrajan Yläpuolella," by Arvo A. J. Ylinen, *Teknillinen Aikakauslehti*, Vol. 21, 1931, p. 95.

or

$$\frac{l_o}{i} = \pi\sqrt{E}\sqrt{\frac{1 - B\left(\frac{P}{A}\right)^n}{\frac{P}{A}}}; \qquad B \geqq 0, \qquad n > 0 \ldots\ldots (11b)$$

When $\beta = B = 0$, Eqs. 11 reduce to Euler's formula, and when $\beta > 0$, $B > 0$, and $n = 1$, they reduce to Rankine's formula.

It is easy to determine whether the formula is a good fit to test data and to determine the constants if it is, for

$$\log (1 - \lambda^2_o \sigma) = n \log \sigma + \log \beta \ldots\ldots\ldots\ldots\ldots (12)$$

and it is only necessary to plot observed values of $1 - \lambda^2_o \sigma$ against σ on logarithmic paper. If the plotted points fall on a straight line, the constants may be obtained from the slope and intercepts of this line.

V. FORMULAS PROPOSED BY THE WRITER

A formula proposed by the writer is:

$$\sigma = \frac{1}{\beta + \gamma\lambda_o + \lambda^2_o}; \qquad \beta \geqq 0, \qquad \gamma \geqq 0 \ldots\ldots\ldots\ldots (13a)$$

or

$$\frac{P}{A} = \frac{\pi^2 E}{B + C\frac{l_o}{i} + \left(\frac{l_o}{i}\right)^2}; \qquad B \geqq 0, \qquad C \geqq 0 \ldots\ldots\ldots (13b)$$

When $\beta = \gamma = B = C = 0$, Eqs. 13 reduce to Euler's formula, and, when $\beta > 0$, $B > 0$, and $\gamma = C = 0$, they reduce to Rankine's formula.

The constants β and γ may be determined by plotting $\frac{1}{\sigma} - \lambda^2_o$ against λ_o, for

$$\frac{1}{\sigma} - \lambda^2_o = \gamma\lambda_o + \beta \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

and, if the resulting plot is approximately a straight line, γ and β are its slope and intercept, respectively. If a straight line does not result, Eqs. 13 are inapplicable. (Eqs. 13 may not be new, and the writer would appreciate having a reference to them if any reader knows of one.)

Another suggestion by the writer is:

$$\lambda_o = \frac{1}{\sqrt{\sigma + \beta\sigma^n}}; \qquad \beta \geqq 0, \qquad n > 1 \ldots\ldots\ldots\ldots (15a)$$

or

$$\frac{l_o}{i} = \frac{\pi\sqrt{E}}{\sqrt{\frac{P}{A} + B\left(\frac{P}{A}\right)^n}}; \qquad B \geqq 0, \qquad n > 1 \ldots\ldots\ldots (15b)$$

When $\beta = B = 0$, Eqs. 15 reduce to Euler's formula. As $n \to \infty$, Eq. 15*a* approaches a broken curve consisting of the axis of σ down to $\sigma = 1$, the line $\sigma = 1$ between $\lambda_o = 0$ and $\lambda_o = 1$, and the reduced Euler curve beyond $\lambda_o = 1$.

As in the case of Eqs. 11 it is easy to determine whether Eq. 15*a* represents a good fit to test data, and to determine the constants if it does, for

$$\log\left(\frac{1}{\lambda^2_o} - \sigma\right) = n \log \sigma + \log \beta \text{................} (16)$$

Eqs. 15 are derived by the double-modulus theory from a stress-strain curve having the equation,

$$e = \frac{P}{A\,E} + K\left(\frac{P}{A\,E}\right)^n \text{....................} (17)$$

in which K and n are empirical constants.

A third suggestion by the writer is:

$$\lambda_o = \frac{2}{\sqrt{\sigma} + \sqrt{\sigma + \beta\,\sigma^n}}; \qquad \beta \geqq 0, \qquad n > 1 \text{.........} (18a)$$

or

$$\frac{l_o}{i} = \frac{2\,\pi\,\sqrt{E}}{\sqrt{\frac{P}{A}} + \sqrt{\frac{P}{A} + B\left(\frac{P}{A}\right)^n}}; \qquad B \geqq 0, \qquad n > 1 \text{......} (18b)$$

When $\beta = B = 0$, Eqs. 18 reduce to Euler's formula. Like Eq. 15*a*, as $n \to \infty$, Eq. 18*a* approaches a broken curve consisting of the axis of σ down to $\sigma = 1$, the line $\sigma = 1$ between $\lambda_o = 0$ and $\lambda_o = 1$, and the reduced Euler curve beyond $\lambda_o = 1$. Also, like Eqs. 15, Eqs. 18 are derived by the double-modulus theory from a stress-strain curve of the form of Eq. 17.

As in the case of Eqs. 11 the constants in Eqs. 18 may be determined easily and accurately, for

$$\log \frac{4}{\lambda_o}\left(\frac{1}{\lambda_o} - \sqrt{\sigma}\right) = n \log \sigma + \log \beta \text{..............} (19)$$

The next two formulas (Eqs. 20 and 21) contain two arbitrary constants each, but the formulas are intended for use only above the limiting average stresses indicated. The curves they represent are tangent to the Euler curve, and for stresses below the point of tangency the Euler formula, Eqs. 4, should be used.

VI. The Parabolic-Type or Hyperbolic-Type Formula

The following formula is of a parabolic or a hyperbolic type:[4]

$$\sigma = \beta\left[1 - \frac{2}{n+2}\left(\frac{n\,\beta}{n+2}\right)^{n/2} \lambda^n_o\right];$$

$$\beta > 0, \qquad n > 0, \qquad \sigma \geqq \frac{n\,\beta}{n+2} \text{..............} (20a)$$

---

[4] "Column Curves and Stress-Strain Diagrams," by William R. Osgood, *Journal of Research*, National Bureau of Standards, Vol. 9, October, 1932, p. 571.

or

$$\frac{P}{A} = B\left\{1 - \frac{2}{n+2}\left[\frac{n\,B}{(n+2)\,E}\right]^{n/2}\frac{1}{\pi^n}\left(\frac{l_o}{i}\right)^n\right\};$$

$$B > 0, \qquad n > 0, \qquad \frac{P}{A} \geqq \frac{n\,B}{n+2} \ldots\ldots\ldots\ldots\ldots (20b)$$

When $n = 1$, Eqs. 20 become the straight-line formula; and when $n = 2$, they become the Johnson parabolic formula.

VII. KREÜGER'S FORMULA

A formula due to H. Kreüger[5] is

$$\sigma = \frac{\beta - \lambda^2_o}{\frac{1}{4}(\beta - \gamma)^2 + \gamma\,\lambda^2_o}; \quad \beta > 0, \qquad -\beta \leqq \gamma \leqq \beta, \qquad \sigma \geqq \frac{2}{\beta - \gamma} \ldots (21a)$$

or

$$\frac{P}{A} = \frac{\pi^2\,E\,B - \left(\frac{l_o}{i}\right)^2}{\frac{1}{4}\,\pi^2\,E\,(B - C)^2 + C\left(\frac{l_o}{i}\right)^2};$$

$$B > 0, \qquad -B \leqq C \leqq B, \qquad \frac{P}{A} \geqq \frac{2}{B - C} \ldots\ldots\ldots\ldots (21b)$$

When $\gamma = C = 0$, Eqs. 21 reduce to the Johnson parabola.

SUMMARY

There is little to be said for a formula on the grounds of its simplicity, for any formula can be plotted to as large a scale as desired and values read from the graph, or it may be tabulated with increments in the argument as small as desired. On the other hand, there is no point in using a formula that is applicable only down to a given value of the average stress, or up to a given value of the ratio of slenderness, beyond which the Euler formula must be used. The column formulas in Sections II to V, inclusive, apply for all values of the ratio of slenderness, and one or all of them can almost be guaranteed to fit adequately any reasonable column-test data it may be desired to fit.

[5] "Bidrag till frågån om sträfvors knäckning," by H. Kreüger, *Teknisk Tidskrift*, Väg- och Vattenbyggnadskonst, Vol. 45, September 15, 1915, p. 101.

DISCUSSION

L. E. GRINTER,[6] M. AM. SOC. C. E.—Since the column is probably the most critical structural member, it is well for the structural engineer to review, at intervals, the background of procedures for column design. Design of columns has long been associated with the use of a "column formula" and, therefore, the author's excellent paper again stimulates the profession to re-examine its methods.

Test results for columns of varying slenderness, when plotted on a graph of failure stress versus slenderness ratio, do not fall along a single line but represent a broad band even when the tests were all performed in one laboratory. This is true because of the virtual impossibility of producing a centered load or a perfectly homogeneous column, particularly if it must be fabricated from parts. No doubt the spread of failure loads would be much greater for columns in actual structures where soil movements, temperature movements, and strains of fabrication have an influence upon resistance to failure.

The choice of a column formula, therefore, is something of a psychological or philosophical matter rather than a strictly scientific decision. A straight line, a broken line, a parabola, or a reversed curve can each be chosen to represent test results, probably with equal satisfaction and accuracy, within the common working range of slenderness ratios. If this is true, then the choice of a formula should be influenced by another consideration: What column formula will produce the best results in terms of design when placed in the hands of the ordinary designer who is not always a highly competent structural engineer?

There are two mistakes that can be made in the use of a column formula. The formula itself may be misinterpreted; and this mistake will become more probable as the formula becomes more complex. For this reason either the Kreüger formula or the Aarflot formula mentioned by the author could become a source of errors in design. The second mistake is in extending the use of the formula beyond its specified range. This can be counteracted by emphasizing the necessary limitations on the formula or by selecting a formula of the kind recommended by the author for which extrapolation beyond test results will give reasonably safe results.

Perhaps it is unfortunate, but, nevertheless, much design work is actually performed by persons of limited competency in structural design. For them the straight-line formula or the Rankine formula is the reasonable limit of useful complexity. Since no greater accuracy can be obtained by use of a more complex formula, the advantage of adding terms is not very clear. The best form of printed specification and one which would meet all objections would be a complete statement of the design formula to cover each range of slenderness ratio. The only mistake that has been common in specification writing has been to cover only the normal range and simply to neglect entirely the upper and lower ranges with resulting confusion in the minds of many persons who must, and do, perform design work.

---

[6] Vice-Pres. and Dean, Graduate School, Illinois Inst. of Technology, Chicago, Ill.

George Winter,[7] M. Am. Soc. C. E.—Until a decade or two ago practical column formulas were exclusively of the empirical type. Mathematical expressions were simply chosen to approximate, as closely as possible, the results of a greater or smaller number of column tests. Little attention was paid to the physical significance of these formulas, to correct representation of end fixities, manufacturing peculiarities, and sometimes even to physical characteristics of the material. Since then the development has been along more rational lines. Methods were developed to account for column strength by considering, in a rigorous analytical way, properties of material, end fixity, initial shape of the member, manner of load application, etc. Two types of such methods have evolved:

(*a*) The one designated by the author as double-modulus theory which takes account of the deviation from the straight line of the stress-strain curves, particularly at higher stresses. This method proved rather cumbersome in its application and, as the author states, is of only limited practical consequence.

(*b*) The other takes account of the fact that the strength of a column depends to a great extent on its initial shape and the manner of load application. Initial deviations from straightness, eccentricities of loading, and other factors which might be termed imperfections were found to decrease the strength of columns considerably, particularly in the range of low and medium slenderness ratios. The secant formula is of this latter type as is the method proposed by D. H. Young[8] in 1934.

The great advantage of methods (*b*) consists in the fact that any term entering such a column formula has a definite physical significance and the entire formula is based on rigorous elastic theory rather than merely representing a necessarily limited number of test results. In the hands of a discriminating designer such a formula can be adapted to almost any set of particular circumstances, such as eccentricities of loading, imperfections of shaping, etc., which is entirely impossible with the purely empirical type of formula. Too much reliance on the latter actually may lead to unsafe design, inasmuch as a column, with larger amounts of eccentricity or crookedness than were inherent in the test specimens, actually fails at loads often considerably below those given by the empirical formula. After many years of extensive experimental research the Society's Special Committee on Steel Column Research[9] recommended a formula of this rational type—the secant formula—as the basis for design specifications. It found this formula not only to be rational and definite in the physical significance of its mathematical terms, but also established its excellent agreement with the results of an unusually large number of tests. The formula is directly adaptable to any given properties of material, eccentricity of loading, imperfection of initial shape, factor of safety, and other special conditions. The design specifications for railway bridges of the American Railway Engineering Association (A.R.E.A.) are presently based on this formula and, taking advantage of its versatility, are adapted not only to standard structural steel but also to a number of special steels used in bridges.

[8] "Rational Design of Steel Columns," by D. H. Young, *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 422.

[9] *Ibid.*, Vol. 98 (1933), p. 1376.

The author's proposed formulas are exclusively of the first, purely empirical type and, therefore, in the writer's opinion, represent a definite step backward in the direction of formal expressions merely adapted to a given set of tests but devoid of fundamental physical meaning. Therefore they are not applicable to any structures except those which duplicate the test setup in all significant details. They are purely mathematical expressions representing S-shaped curves with zero slope at the lower end and zero asymptote for large values of l/i; that is, they merely have the formal mathematical characteristics of all column curves without being capable of physical interpretation.

In the writer's opinion the desirable development in this field lies in the direction of rational column formulas of the type mentioned. For standard design conditions the way a column curve was originally determined may be of little consequence. Under nonstandard circumstances—such as columns of unusual alloys, special loading conditions (eccentricities), and particular fabricating methods—which may involve either larger or smaller imperfections of shape than are commonly met with, formulas of the rational type give considerable guidance to the designer even without, or with very limited, test evidence. The author's formulas, to be applicable, would require elaborate tests in each of these special cases. It is precisely for this reason (to take care of unusual situations) that the A.R.E.A., in an appendix to its specifications, included the complete secant formula with the physical significance of all its terms explicitly stated. From his own design experience with structures of nonstandard material and nonstandard but at least approximately known imperfections, the writer can testify to the reliability of this method which, in some cases he dealt with, was very succesfully verified by a small number of full-scale confirmatory tests.

The secant formula, and others of the same type, permit the engineer to predict the maximum fiber stress under a given load for a column of any material provided the following characteristics are known with reasonable accuracy: Properties of material, end conditions, eccentricities of loading, and initial deviations from straightness (crookedness). By equating this maximum fiber stress to some stress considered as dangerous (such as the yield point for steel) and by applying a suitable factor of safety, a practical column formula is immediately derived which covers the entire range of slenderness ratios. The reason that, despite these advantages, the explicit secant formula has not become too popular with designers lies in the fact that it is rather unwieldly mathematically. It requires the use of trigonometric tables and cannot be solved explicitly for the working stress for a given slenderness ratio; that is, it necessitates in each case the drawing of a complete column curve. This practical difficulty is easily overcome by developing general column formulas of the standard familiar type (Rankine and Johnson formulas), which are made to fit very closely the values of the exact secant formula.

The general form of the secant formula is

$$\left(\frac{P}{A}\right)_w = \frac{\dfrac{\sigma_y}{\eta}}{1 + a \sec\left[\dfrac{k\,l}{2\,i}\sqrt{\dfrac{\eta}{E}\left(\dfrac{P}{A}\right)_w}\,\right]} \quad\ldots\ldots\ldots\ldots(22)$$

in which (supplementing the notation of the paper): $\left(\frac{P}{A}\right)_w$ = working stress in compression; σ_y = limiting (that is, dangerous) value of extreme fiber stress, generally the yield point of the material; η = factor of safety; and a = "degree of imperfection"; that is—

$$a = \frac{(e + d)\,c}{i^2} \quad\ldots\ldots\ldots\ldots(23)$$

in which e = eccentricity of loading; d = maximum deviation from straightness (crookedness) of column; and c = distance from center of gravity to outer fiber of cross section.

Accepted values for these constants are: η = 1.7 to 1.8 for bridges and 1.5 to 1.6 for buildings; a = 0.25 for standard manufacturing conditions and centered connections; and k = 0.75 for riveted and welded connections and 0.875 for pin connections.

A very close approximation of the values of the secant formula in the low and medium range of l/i is obtained by the expression

$$\left(\frac{P}{A}\right)_w = \frac{\sigma_y}{n_s} - \frac{\sigma^2_y\,k^2}{4\,n_s\,\pi^2\,E}\left(\frac{l}{i}\right)^2 \quad\ldots\ldots\ldots\ldots(24)$$

in which

$$n_s = \eta\,(1 + a) \quad\ldots\ldots\ldots\ldots(25)$$

Eq. 24 is of the Johnson parabolic type familiar to designing engineers. Most column specifications, such as those of the American Institute of Steel Construction (A.I.S.C.) and the American Railway Engineering Association (A.R.E.A.), are written in terms of the Johnson formula for the low and medium range of l/i. The values obtained from Eq. 24 are extremely close to those of the secant formula, Eq. 22, for all values of the working stress down to

$$\left(\frac{P}{A}\right)_w = 0.5\left(\frac{P}{A}\right)'_w = 0.5\,\frac{\sigma_y}{n_s} \quad\ldots\ldots\ldots\ldots(26)$$

in which $\frac{\sigma_y}{n_s}$ is the working stress at $l/i = 0$. The limiting value of l/i at which $\left(\frac{P}{A}\right)_w = 0.5\left(\frac{P}{A}\right)'_w$ is

$$\left(\frac{l}{i}\right)_{\text{limit}} = \frac{\pi}{k}\sqrt{\frac{2\,E}{\sigma_y}} \quad\ldots\ldots\ldots\ldots(27)$$

For values of l/i larger than those given by Eq. 27, the Johnson curve deviates increasingly from the secant curve and, therefore, should no longer be used for design purposes. It will be found that for structurally useful alloys the value of $\left(\frac{l}{i}\right)_{\text{limit}}$ ranges from about 80 to 160, depending on mechanical properties. (The use of 0.5 $\left(\frac{P}{A}\right)'_w$ as the end point for the Johnson formulas was first suggested to the writer by Prof. J. H. Cissel, M. Am. Soc. C. E., of the University of Michigan, Ann Arbor, in a discussion concerning general questions of column design.)

For slenderness ratios larger than $\left(\frac{l}{i}\right)_{\text{limit}}$ a very close approximation of the secant formula is obtained by the expression,

$$\left(\frac{P}{A}\right)_w = \frac{B}{1 + \frac{1}{C}\left(\frac{l}{i}\right)^2} \quad \text{.....................(28)}$$

in which

$$C = \frac{500{,}000\,\pi^2\,E\,\eta\,a}{250{,}000\,k^2\,\eta\,\sigma_y - 2\,n_s\,\pi^2\,E} \quad \text{...............(29a)}$$

and

$$B = \frac{\sigma_y}{2\,n_s} + \frac{1}{C}\,\frac{\pi^2\,E}{k^2\,n_s} \quad \text{.....................(29b)}$$

Eq. 28 is adjusted to give working stresses extremely close to those of the secant curve up to values of $l/i = 400$ and even higher. This was achieved by making the value of $\left(\frac{P}{A}\right)_w$ from Eq. 28 equal to (Euler value)/η at $l/i = 500$. At such large slendernesses the values of the secant formula are almost identical with those of the Euler equation which results in the close approximation of Eq. 28 with the secant values.

It is seen that Eqs. 24 and 28 are given in the same general terms as is the secant formula (σ_y, E, η, k, a) and result in column formulas of the type familiar to the designer, that is, the Johnson formula for small and medium slenderness ratios and the Rankine formula for large slenderness ratios. Thus, for a given material and given conditions, design formulas, Eqs. 24 and 28, are computed once and for all by substituting appropriate values for the constants. The resulting formulas are then used in the same simple manner as any standard column formula in current codes. In fact, they are of the same form as those used in the A.I.S.C. specifications. In this manner the use of the arithmetically cumbersome secant formula is entirely eliminated, whereas all the advantages are retained. The formulas are adaptable to any type of material of known mechanical properties, which is likely to become advantageous with the increasing use of various ferrous and nonferrous alloys for structural purposes. The approximation is extremely close for all values of a from 0.1 to about 0.6; that is, in the practically important range.

The use of these formulas and the excellent approximation they furnish to the values of the secant formula are illustrated in the following two examples:

Example 1.—Consider a column of structural grade steel, under the following design conditions: $\sigma_y = 33{,}000$ lb per sq in.; $E = 29{,}500{,}000$ lb per sq in.; $\eta = 1.76$; $a = 0.25$; and $k = 0.875$. These data are precisely the same as those assumed for pin-ended members in the A.R.E.A. Specifications for Steel Railway Bridges, 1941 (see Appendix A). Substitution of the foregoing values in Eqs. 24 to 29 gives the following working formulas: For $l/i = 0$ to $l/i = 152$—

$$\left(\frac{P}{A}\right)_w = 15{,}000 - 0.323\left(\frac{l}{i}\right)^2 \qquad (30a)$$

and, for l/i larger than 152—

$$\left(\frac{P}{A}\right)_w = \frac{34{,}000}{1 + \frac{1}{6{,}510}\left(\frac{l}{i}\right)^2} \qquad (30b)$$

Eq. 30*a* is almost identical with that of the A.R.E.A. Bridge Specifications (Section III) for slenderness ratios as great as 140:

$$\left(\frac{P}{A}\right)_w = 15{,}000 - \frac{1}{3}\left(\frac{l}{i}\right)^2 \qquad (31)$$

For a greater slenderness ratio the A.R.E.A. specifications suggest the direct use of the secant formula. It is thought that the use of the more convenient Eq. 30*b*, instead of the secant formula, is preferable in a practical way.

The exact secant curve (solid curve), as well as the approximating working curves (dotted curves), is shown in Fig. 1(*a*). The close approximation obtained is immediately evident.

Example 2.—Consider a column of high-strength, corrosion-resisting steel under the following design conditions: $\sigma_y = 65{,}000$ lb per sq in.; $E = 29{,}500{,}000$ lb per sq in.; $\eta = 1.55$; $a = 0.35$; and $k = 0.75$. Substitution of these values in Eqs. 24 to 29 gives the following working formulas: For $l/i = 0$ to $l/i = 126$—

$$\left(\frac{P}{A}\right)_w = 31{,}000 - 0.971\left(\frac{l}{i}\right)^2 \qquad (32a)$$

and, for l/i larger than 126—

$$\left(\frac{P}{A}\right)_w = \frac{55{,}700}{1 + \frac{1}{6{,}140}\left(\frac{l}{i}\right)^2} \qquad (32b)$$

The curves for high-strength steel corresponding to Eqs. 32*a* and 32*b* and to the secant formula are given in Fig. 1(*b*).

Examples 1 and 2 demonstrate the adaptability of the writer's proposal, the simple form of the resulting working formulas, and the good degree of approximation as compared with the values of the secant formula.

For each of his nine formulas the author has indicated how they can be made to fit a particular series of tests. The same can be accomplished by the secant formula, as was actually done in the Society's column investigation.[9] Whereas fitting an empirical formula to a series of tests consists in the adjustment of arbitrary coefficients, the rational way to coordinate the secant formula with test results is to determine experimentally the degree of imperfection entering the formula. To establish the magnitude of this quantity it is only necessary to know $e + d$; that is, eccentricity plus crookedness (compare Eq. 23).

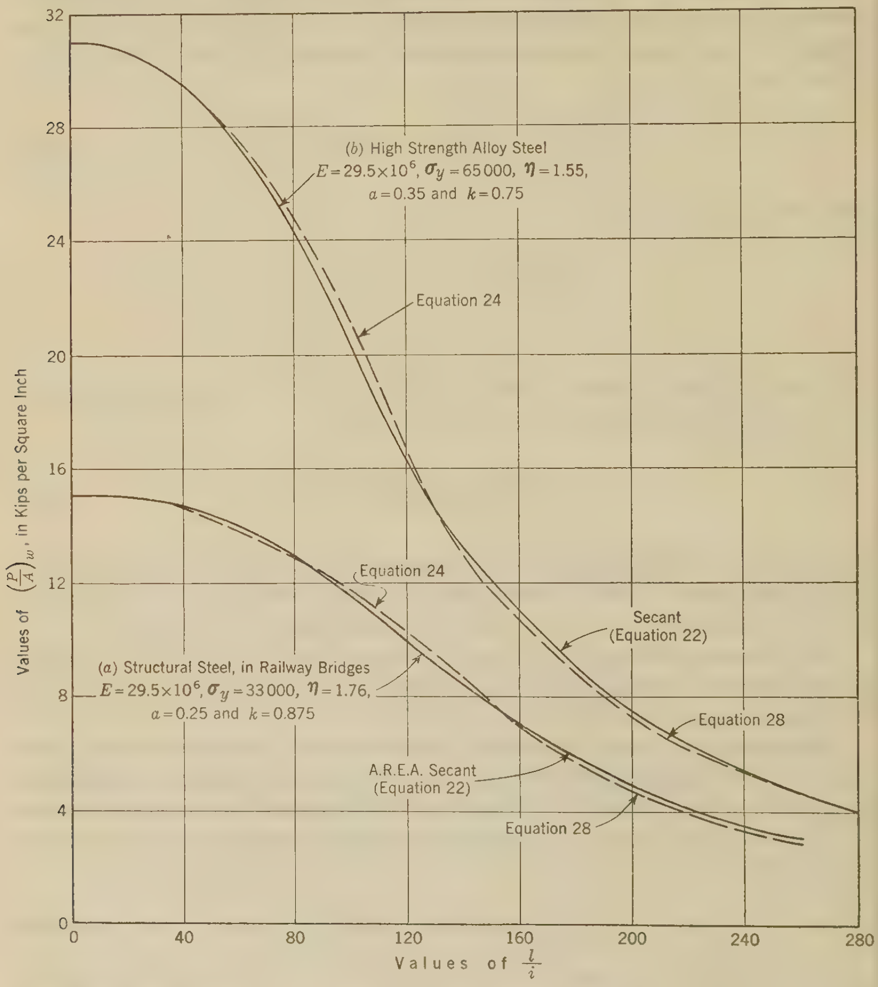

FIG. 1.—DESIGN CURVES FOR STEEL COLUMNS

The effect of these two factors is known to be almost identical; that is, an eccentricity of given amount has the same effect as a deviation from straightness of the same amount. For this reason it is superfluous to determine e and d separately, since only their sum enters the secant formula (and Eqs. 24 and 28). This quantity $(e + d)$ is easily determined in standard ways by the well-known Southwell method.[10] By this method it is even possible to determine the degree of imperfection without loading the element to destruction, which is of considerable advantage in the case of complicated special structures. Once this quantity and the physical characteristics of the material are known, the secant formula and the corresponding simplified expressions, Eqs. 24 and 28, can be applied directly.

It is quite possible that one of the author's several formulas can be made to fit the secant equation equally as well as Eqs. 24 and 28. The writer has chosen these particular formulas because they are of a form familiar to designers and widely used in design codes. Experience has shown that there is no particular disadvantage in using two different formulas for different ranges of l/i. The main point the writer wishes to convey is that, in his opinion, analytically rigorous formulas which lend themselves to complete physical interpretation are vastly preferable to empirical expressions of a purely formal, mathematical character.

A discussion by the author of the full significance of his arbitrary constant S, referred to as the secant yield strength, would contribute to a better understanding of this paper.

Jonathan Jones,[11] M. Am. Soc. C. E.—This paper is of a philosophical nature, comprising a discussion of how various curves, each defined by a formula, can be made to fit the data derived from a large number, and wide variety, of tests made on columns. It is of no assistance to a practicing engineer in what is considered "structural" work, because it proceeds, as expressed by the author in the "Synopsis" and in the "Summary," from postulates which, from the viewpoint of such an engineer, are untrue or unimportant.

The "Synopsis" states that a prime requisite of any column formula is that the average stress "approach the Euler value as the ratio of slenderness becomes infinite." As the Euler value at that ratio is zero, and as the column formulas in practical use do approach zero as the ratio of slenderness becomes infinite, this statement seems of little importance. However, it is here implied, and elsewhere stated, that a desirable property of a column formula is that it shall be susceptible to extrapolation. The practicing engineer is not concerned with extrapolation (as to values of slenderness ratio), as his entire work is within a range of slenderness ratios defined by specification.

The "Synopsis" further states that a desirable requisite is that "the first derivative of the average stress with respect to the ratio of slenderness be continuous." This condition certainly does not present itself as a necessity to the practicing engineer. Why is it stated as axiomatic?

---

[10] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1936, p. 177.

[11] Chf. Engr., Fabricated Steel Constr., Bethlehem Steel Co., Bethlehem, Pa.

It is stated in the "Summary" that "there is no point in using a formula that is applicable only * * * up to a given value of the ratio of slenderness * * *." As a matter of fact, almost all of the critical work done by the structural designer is in a range up to a given value of the ratio of slenderness, and a formula that is applicable within that range is exactly what is needed.

It is stated in the "Summary" that

> "There is little to be said for a formula on the grounds of its simplicity, for any formula can be plotted to as large a scale as desired and values read from the graph, or it may be tabulated with increments in the argument as small as desired."

As a matter of fact, a practicing engineer will be confronted frequently with a need for an estimate of column capacity, at a time and place where neither graphs nor tables are available; the writer is certain that he has made such estimates, in the course of his experience, thousands of times, by the simple application of mental arithmetic, either at a saving of effort as compared with looking up a graph or a table, or when neither was at hand. It is very largely for this reason that the practicing engineer is so fond of "straight-line" or "Johnson's parabola" formulas, which lend themselves to quick, mental solution.

The attitude of the structural engineer toward column formulas has undoubtedly been oversimplified; but the correct approach for him to take is entirely different from the path marked out in this paper.

The theory leading to the "secant formula" is as valid a piece of mechanical reasoning as that leading to the customary beam theory, the "theorem of three moments," and other tools of the structural engineer. Furthermore, the secant formula has been shown to conform well to tests, where the tests have been controlled with respect to the variables entering into the formula. The point which the structural engineer must remember, however, is that, in order to use the secant formula, there must be established not only the properties of the material and the radius of gyration of the column but also an effective length (between points of contraflexure) and a constant representing the possible external moment applied through frame action, eccentricity of end loading, and crookedness resulting from fabrication, shipment, or erection. If practical column formulas need to be rendered more precise and, therefore, more complicated, the need is to recognize that these moments vary quite considerably over the entire column field. They may be safely estimated for one category of columns, and again safely estimated for some other category of columns; but it is probably useless to attempt what has been tried in the past—namely, to estimate them once and for all over the entire field.

It would appear to the writer that the most fruitful field of inquiry now open to the structural engineer is to determine, for each different type of column (compression members in framed trusses, columns in mill buildings, columns in story buildings, derrick masts, etc.), the most reasonable allowances for free length and for applied moments that should be inserted in the general secant formula, to safely and economically meet the probable loading conditions in that particular category of columns.

Having established these several allowances for moment, there can be written down, for steel of any one yield-point strength, a secant formula expressing the average unit stress at that load which causes a yield-point stress on the most severely stressed fiber. For a series of other steels, having other yield points, all these formulas can again be written, and the difference of yield point will make them all different, in detail only, from the corresponding members of the first series.

It is reasonable to believe, from the work already reported by a committee of the Society, that each of these formulas would quite reasonably represent the maximum loads that would be obtained from a series of tests, introducing in each particular case the material and the moments postulated in setting up the formulas.

The structural engineer would then affect each of these formulas by a factor of safety, representing the number of times (usually between 1.50 and 2), by which the anticipated total load could be assumed to be safely multiplied before the extreme fiber stress would reach the yield point in question. These then would be a set of safe-load formulas, all based upon the same reasonable premises, and each safe for practical use. However, one serious practical difficulty would remain—that the secant formula does not lend itself readily to arithmetical solution. It therefore would remain to be seen whether it would be possible to substitute, for the safe-load formulas thus in hand, simpler formulas, easier to handle, and not departing unduly from the secant series.

In the case of compression members in railroad bridge trusses, it is common knowledge that the American Railway Engineering Association (A.R.E.A.) has found such a substitution possible—

$$P = 15{,}000 - 0.25\left(\frac{l}{i}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots (33a)$$

—for values of slenderness ratio up to 140. The American Institute of Steel Construction (A.I.S.C.) has established a similar parabola—

$$P = 17{,}000 - 0.485\left(\frac{l}{i}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots (33b)$$

—for columns in buildings, up to a slenderness ratio of 120. Beyond these slenderness ratios it has been found, by these specification-writing bodies, that the secant curve and the second-degree parabola depart from each other rapidly. They have accordingly adopted other curves for slenderness ratios greater than those just stated—A.R.E.A. choosing the secant formula itself, and A.I.S.C. choosing the Rankine-Gordon type, as a reasonable equivalent.

In actual bridge and building practice, inasmuch as columns of greater slenderness ratios than those to which the second-degree parabola can be applied either are extremely rare, or are relegated by the specifications to non-critical elements of the structure, it would seem to the writer to be fully justifiable to adopt, for simplicity, for the second portion or end of each curve, a curve of the Euler form—namely, some easily remembered constant number in the numerator and the familiar $\left(\frac{l}{r}\right)^2$ in the denominator (the author's

$\left(\frac{l}{i}\right)^2\bigg)$; or an inverted parabola, which also can be kept simple in form and easy to solve.

The writer would not wish it to be inferred that he considers any of the foregoing remarks to be applicable outside the field of usual columns of structural steel, in bridges, buildings, and like structures; in that field, however, he feels that the discussion of column formulas should be entirely uninfluenced by the hypotheses and developments of the present paper.

Edward Godfrey,[12] M. Am. Soc. C. E.—The subject of this paper is of great importance to designers. With the exception of the Euler formula, rational column formulas are conspicuously absent from engineering works. The Euler formula is the one rational formula in common use, but it is applicable to slender columns only and has no meaning when applied to columns with a slenderness ratio usually specified as proper in ordinary structural work. Furthermore, column formulas in common use give totally false unit values when used for columns with slenderness ratios to which the Euler formula is applicable.

In spite of statements in column-design literature, the Euler load, instead of being the load a column can sustain in equilibrium, is the absolute maximum load—the load at which the column is certain to fail. The proof of this statement is quite simple. Assume that a column is in the shape of a bow with a finite versed sine or offset. The Euler load, by its derivation, will double that offset. It will not stop there, however. The column is still a bow with an offset and that offset will be increased again for the same reason that the first increase occurred. This process will continue indefinitely, or until the column has failed completely, since the increments are not decreasing. If the load adds one half to the original bow, the final bow will be only twice the original bow or offset. When $x = \frac{1}{2}$, the infinite series $1 + x + x^2 + x^3 + \cdots$, etc., is 2.

In the "Summary," Mr. Osgood disparages the use of one formula for short columns and another for slender columns. The writer does not agree with this opinion since it is on this very point that he has always differed with standard theories on the subject.

The criterion for shorter columns—those in structures such as bridges and buildings where the ratio of slenderness is properly restricted—is stress per square inch on the extreme fibers of the section. Based on the strength of the material of the column, the stress must not exceed certain values which are limited by a factor of safety. The criterion for slender columns—those outside the limit of the slenderness ratio permitted by specifications—is not in any sense the compressive strength of the material of the column, since only the modulus of elasticity (a property nearly constant for the various grades of steel) is needed for the derivation of the formula.

There are two distinct phases to be considered in determining the strength of a compression member. Failure to appreciate this fact has caused much misapprehension. Formulas have been derived, and accepted, that attempt to combine the two phases of the strength of columns in utter disregard of the distinction between the two.

---

[12] Structural Engr., Robert W. Hunt Co., Pittsburgh, Pa.

Every column of elastic material is a spring or bow as well as a shaft subject to endwise compression, and the strength of a column considered as a spring is independent of the ultimate or elastic strength of the material. In addition, the formula showing this strength is quite distinct from any formula based on ultimate strength of the material. The Gordon-Rankine formula has limited application. This formula is fraught with danger, if it is used in the range of slender columns.

That the straight-line formula for the strength of a column can be substantiated, rationally and theoretically, has been demonstrated elsewhere by the writer.[13]

In former years at least, European engineers used the Euler formula with a factor of safety of five. There is no reason for so high a factor of safety in the region where the Euler formula is applicable. The Euler formula is never applicable to short columns. A factor of safety of two, or even less, is ample for use in the Euler load, if the Euler formula is applicable, because the condition that causes failure is not reached until the load approaches the Euler value. Also, columns not in the slender bracket are likely to fail at the first observable sidewise deflection.

In tests described by C. P. Buchanan,[14] the deflection due to the load did not exceed 0.2 in. within the elastic value of the column for any column tested, and at the ultimate load, in many cases, this deflection did not increase.

In his previously cited work,[13] the writer shows the locus of an exceedingly complex formula and comparison with the Euler load in the slender range (with a factor of safety of two). The complex formula referred to is completely rational. It is based on the simple assumption that a column is bowed with an offset 1/300 of its length. The compressive load increases the bow by an infinite series of decreasing terms. The bow is not "frozen," as in the derivation of the Gordon-Rankine formula.

The formula is too cumbersome to use in practice, but the locus, up to 90 radii, is a straight line, and beyond this it deviates but little from a straight line in the range of structurally permitted columns. In the "slender" range it almost coincides with the Euler value with a factor of safety of two, which is ample for slender columns.

However, instead of being a reason for the use of one formula for both slender and short columns, it is a sound reason for the use of the ordinary straight-line formula for bridge and building columns and the Euler load for light struts, such as are used in transmission and radio towers.

Ralph E. Spaulding,[15] M. Am. Soc. C. E.—In the study of column formulas it is not generally recognized that the Euler formula,

$$\frac{P}{A} = \frac{K\,\pi^2\,E}{(L/i)^2} \quad \text{.......................} (34)$$

---

[13] "Steel Designing" (Book Three of a Series on Structural Engineering), by Edward Godfrey, 1913, Chapter X, pp. 152–162.

[14] "A Series of Failure Tests of Full-Size Compression Members, Made for the Pennsylvania Lines West of Pittsburg," by C. P. Buchanan, *Engineering News*, December 26, 1907, p. 685.

[15] Cons. Engr., Jacksonville, Fla.

gives true theoretical values of P/A for all values of L/i from zero to infinity when, and only when, the yield strength is equal to the modulus of elasticity ($\sigma_y = E$). Since this relationship does not exist in metals, it is necessary to modify, or complete, the Euler formula in order to adapt it to any required use. This may be done by introducing the yield-strength factor into the Euler formula; thus:

$$\frac{P}{A} = \frac{K\,\pi^2\,E}{(L/i)^2} \times \frac{\dfrac{K\,\pi^2\,E}{(L/i)^2} + \dfrac{\sigma_y\,(L/i)^2}{K\,\pi^2} + (E + \sigma_y)}{\left[\dfrac{K\,\pi^2\,E}{(L/i)^2} \times \dfrac{E}{\sigma_y}\right] + \dfrac{\sigma_y\,(L/i)^2}{K\,\pi^2} + (E + \sigma_y)} \ldots\ldots (35)$$

Eq. 35 can be applied to any metal that follows Hooke's law by simply inserting the respective values of σ_y, E, and the end condition factor K. When σ_y becomes equal to E, Eq. 35 reverts to the Euler formula.

It is interesting to test this formula in connection with available data concerning the values of σ_y and E. In Fig. 2(a), the writer has plotted Eq. 35 for values of L/i as high as 400, for three metals with different characteristics. Apparently, this formula fulfils all the desirable requisites for a column formula as enumerated in this paper.

If the yield strength and the modulus of elasticity are known, the values may be inserted in Eq. 35 and the resultant values of P/A may be determined with reasonably dependable accuracy for all values of the ratio of slenderness.

There is a distinction between the column formulas proposed for the determination of allowable stresses in columns as built in engineering structures and formulas that reflect the probable ultimate load on columns at failure under laboratory conditions. Probably the author did not intend to open for discussion the relative merits of these many formulas. The column behavior under laboratory conditions can be predicted with reasonable accuracy; but, because of unexpected eccentricities and undetected defects in manufacture and erection, the design of columns for practical use becomes more a matter of judgment and experience aided by theory based on observed laboratory tests. The laboratory tests indicate the maximum limits beyond which the working formula cannot go.

Hundreds of formulas have been devised, and used, for the determination of the working stresses in columns. The writer takes the liberty of suggesting one more.

In columns, as built into structures (in contrast with columns tested under perfect laboratory conditions), the end condition factor, K, is a variable rather than a constant. For example, in a flat end column this factor would be 4 when the column was very short; but, as the column became relatively longer and the effects of manufacturing defects, residual stresses, etc., began to have more influence on the ultimate strength, the factor should be reduced. Reduction in accordance with the following formula is suggested—

$$K \text{ (effective)} = K \text{ (initial)} \times \frac{\sigma_y}{\sigma_y + (L/i)^2} \ldots\ldots\ldots\ldots (36)$$

A somewhat simplified and closely approximate form of Eq. 35 with the factor

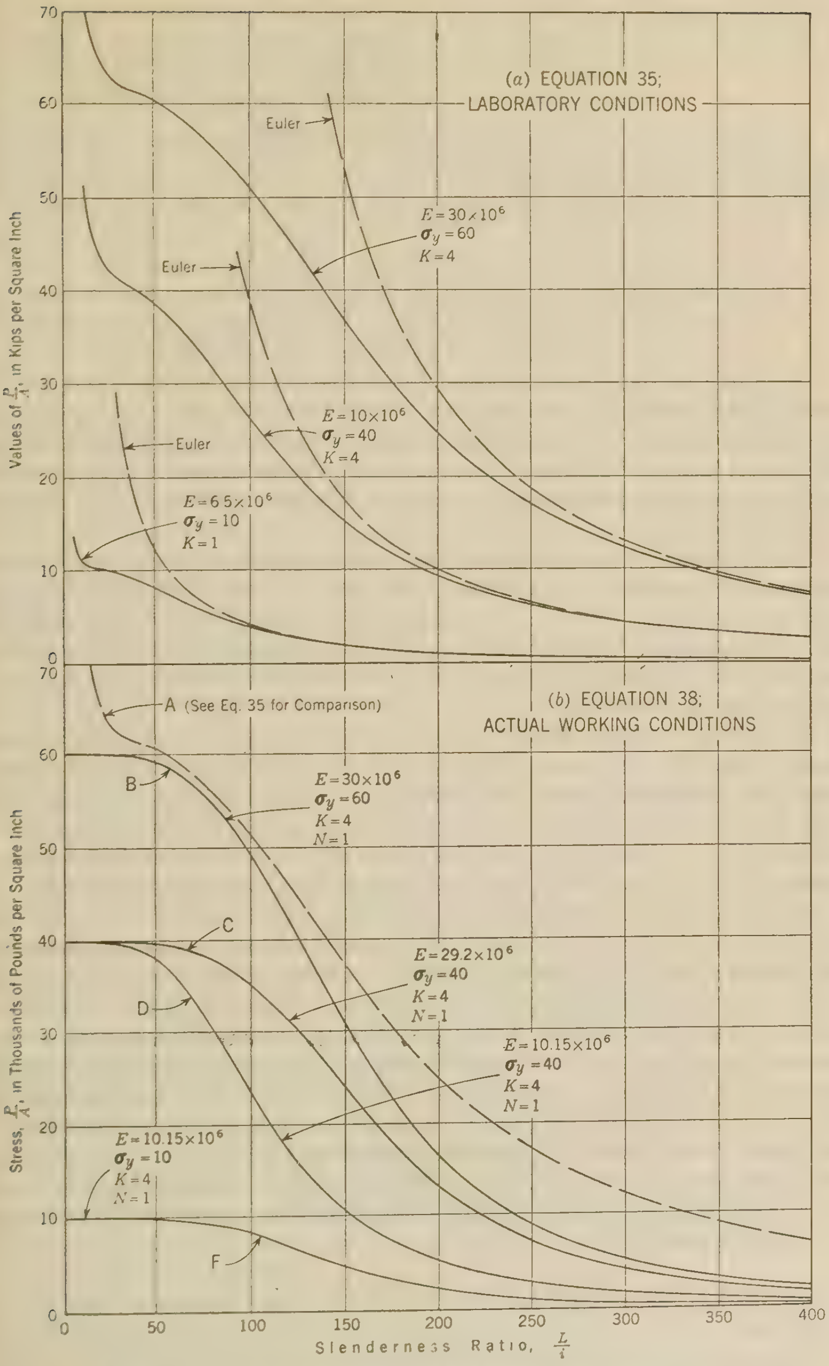

FIG. 2.—COMPARISON OF COLUMN FORMULAS FOR STEELS WITH VARIOUS PROPERTIES

of safety, N, added is—

$$\frac{P}{A} = \frac{\sigma_y}{N} \times \frac{1 + \dfrac{K\pi^2 E}{\sigma_y (L/i)^2}}{1 + \dfrac{K \pi^2 E}{\sigma_y (L/i)^2} + \dfrac{\sigma_y (L/i)^2}{K \pi^2 E}} \dots\dots\dots\dots (37)$$

and, by inserting the value of K proposed by Eq. 36 for the K-value in Eq. 37—

$$\frac{P}{A} = \frac{\sigma_y}{N} \times \frac{1 + \dfrac{K \pi^2 E}{\sigma_y (L/i)^2 + (L/i)^4}}{1 + \dfrac{K \pi^2 E}{\sigma_y (L/i)^2 + (L/i)^4} + \dfrac{\sigma_y (L/i)^2 + (L/i)^4}{K \pi^2 E}} \dots\dots (38)$$

which is the writer's suggested column formula for allowable working stresses in columns as built. The value of the end condition factor, K, still remains to be inserted in accordance with the actual initial end condition. The factor of safety can best be determined by judgment of existing conditions and requirements.

Eq. 38, like Eq. 35, is applicable to any metal or alloy that follows Hooke's law and for any value of the ratio of slenderness—in contrast to many formulas that are applicable only to one metal and often only within a narrow range of L/i. Although Eq. 38 is not quite as simple as some others that do not have such universal applicability, it is a reasonably simple formula, having only one variable together with its reciprocal.

In Fig. 2(*b*), curves are plotted from Eq. 38. Curve A (the only curve plotted from Eq. 35) shows the probable ultimate column strength under laboratory conditions for an alloy with the properties indicated in Fig. 2(*b*), whereas curve B for the same metal, and for actual working conditions, gives the suggested maximum design stress before application of a desired factor of safety. Curves C, D, and F (Fig. 2(*b*)) are of the same type as curve B.

Curves C and D illustrate the comparison in column strength between two metals having the same yield strength but very different moduli of elasticity; and curves D and F illustrate the difference between two metals having the same modulus of elasticity but quite different yield strengths. When the ratio of slenderness is from about 120 to 140, column C has an allowable working stress equal to twice that of column D although the respective yield strengths of the columns are the same. Column D has an allowable working stress only twice that of column F, whereas the yield strength of metal D is four times that of metal F. This relationship may be verified by reference to actual test data. In other words, as has always been known, except for very short columns, a high elastic modulus is of greater economic importance than a high yield strength.

JAMES H. CISSEL,[16] M. AM. SOC. C. E.—In the "Synopsis," the author states that

---

[16] Prof., Structural Eng., Asst. to Director of Eng. Research, Univ. of Michigan, Ann Arbor, Mich.

> "The * * * requisites of any column formula * * * are that the average stress be a continuous, monotonically decreasing function of the ratio of slenderness and that it approach the Euler value as the ratio of slenderness becomes infinite."

It may be questioned whether this requirement in itself is an objective of formulas for compression members. The main purpose of any column formula should be to express, in convenient form, the behavior of a column in terms of dimensions and critical load.

The "Summary" states that "There is little to be said for a formula on the grounds of its simplicity * * *." This viewpoint completely ignores the need of the practicing engineer for a procedure of estimating the capacity of a given member quickly and accurately.

Any acceptable column formula must correctly appraise the probable ultimate axial load on a column by proper consideration of any combination of the following four possible modes of failure: (1) Compressive failure by crushing the material; (2) column failure or bending over the unsupported length of the member (in this type of action, the cross sections are translated laterally in the direction of least resistance of the member); (3) torsional failure in which the cross sections are rotated with respect to the longitudinal axis of the member; and (4) plate buckling or local failure of elements of the section by wrinkling over a limited length of member.

Failure (1) is the type that would occur in a very short member (l/i less than, say, 20) with elements or walls of such ratios of width to thickness as are necessary to preclude local wrinkles or buckles. Current specifications such as those of the American Railway Engineering Association (A.R.E.A.) or the American Institute of Steel Construction prescribe minimum thickness and maximum values of width to thickness for plates and elements; and, hence, short members complying with such specifications will not fail until the yield stress in the material has been developed by an axial load.

Failure (2) implies bending over the length of the column induced by eccentricity of loading and crookedness of member. If the thickness of elements is sufficient to prevent local wrinkling, failure will not occur until the stress on the extreme fiber due to direct stress and bending has reached the yield stress of the material. The appraisal of this action is the general purpose of column formulas, and the unstated assumption incorporated in the commonly used equation is that the elements of the section are elastically stable for unit stresses up to the yield stress of the material.

Failure (3) represents a twisting of the section with respect to the longitudinal axis, and is particularly likely to occur in members lacking torsional resistance, or subject to eccentric loads. It does not appear to have great practical importance for members with the proportions usually found in average structures, but may become significant for unsymmetrical sections or for long, slender members.

Failure (4) is sometimes called local failure by buckling of elements comprising the section. Current specifications attempt to eliminate this type of failure from consideration by specifying minimum thicknesses and proportions of parts, such as outstanding legs of flange angles. Such limitations merely prevent the use of thin-walled members, which may, in fact, be perfectly satisfactory and economical for a given purpose.

As a result of its extensive study of steel columns, the Society's Special Committee on Steel Column Research[9] recommends the secant formula as best interpreting the test results. Allowing for adaptation to the author's notation, this formula is commonly expressed in the form:

$$\sigma_w = \frac{P}{A\,\eta} = \frac{\dfrac{\sigma_y}{\eta}}{1 + a \sec \dfrac{l'}{2\,i}\sqrt{\dfrac{P\,\eta}{A\,E}}} \qquad (39)$$

in which σ_w is the allowable working stress; η is the safety factor equal to unity for ultimate load; P is the ultimate axial load; σ_y is the yield strength of material; A is the cross-sectional area; a is equal to $e\,c/i^2$ equal to the eccentric ratio; i is the radius of gyration of section; l' is the free length between inflection points; and E is the modulus of elasticity.

The validity of the secant formula has been proved repeatedly by test, and probably is as rational an equation as can be developed for expressing the ultimate axial load on columns that fail in accordance with failures (1) and (2). It cannot be safely applied in the form expressed in Eq. 39 to thin-walled sections or to members that are critical as regards torsional resistance. Moreover, since it is difficult in practical cases to determine precisely the value of the eccentric ratio expressed by the term a in Eq. 39, the use of a is inconvenient for practical design purposes. In recognizing the latter objection, the Society's committee recommended[9] the use of an average value of 0.25 for a, and a parabolic equation for values of l'/i to 160. In following this recommendation, the A.R.E.A. permits the use of the following formula for allowable working stress on structural grade steel columns:

$$\sigma_w = 15{,}000 - 0.33\left(\frac{l}{i}\right)^2 \qquad (40)$$

Eq. 40 gives a close approximation of values obtained from Eq. 39, when $\sigma_y = 33{,}000$, $a = 0.25$, $l' = 7/8\,l$, and $\eta = 1.76$. It should be observed that Eq. 40 will produce results consistent with those obtained by the secant formula, only when $a = 0.25$. This value, set by the Society's committee after a comprehensive study of the tests, provides an allowance for eccentricity of loading and eccentricity due to crookedness of member, as follows:

Eccentricity of applied loading $= 0.15\,i^2/c$
Eccentricity due to crookedness $= 0.10\,i^2/c$

Thus, for a cross section whose radius of gyration is 0.8 c, the load is assumed to be applied at a distance of 0.096 c from the axis, and the deviation of the axis from an absolute straight line is assumed to be 0.064 c, regardless of the length of the member. Also, the allowance for crookedness was based on a tolerance of $\frac{1}{1{,}200}\,l$ for a member with length $l = 100\,i$, and with a radius of gyration $i = 0.8\,c$. The effect of the eccentric ratio in producing variation in values of P/A is shown diagrammatically in Fig. 3.

Considering the fact that, in nearly all actual cases, the allowances for eccentricity in the secant formula are mere guesses, the writer prefers the Johnson formula as a means of estimating column capacity. This formula expresses the behavior as a parabolic curve tangent to the Euler curve when $P/A = 1/2\,\sigma_y$. Thus:

$$\sigma_w = \frac{P}{A\,\eta} = \frac{\sigma_y}{\eta} - \frac{\frac{\sigma^2{}_y}{\eta}}{4\,C\,\pi^2\,E}\left(\frac{l}{i}\right)^2 \dots\dots\dots\dots\dots\dots (41)$$

in which l is the unbraced length of member and C is a factor determined by the conditions of end restraint affecting the member (1.0 for hinged ends and 4.0 for fixed ends).

When $\frac{P}{A} = \frac{1}{2}\,\sigma_y$, $\frac{l}{i} = 4.44\sqrt{\frac{C\,E}{\sigma_y}}$; and, for greater values of $\frac{l}{i}$, the Euler formula is used, in which

$$\frac{P}{A} = \frac{C\,\pi^2\,E}{(l/i)^2} \dots\dots\dots\dots\dots\dots\dots\dots (42)$$

A comparison of the Johnson-Euler curves with those obtained from the secant formula is shown in Fig. 4.

Since Eqs. 39 to 42 apply only to cases where failure is of the types described herein as failures (1) and (2), they cannot be used without modification for thin-walled sections where width:thickness ratios of elements are outside the limits set by such specifications as those of the A.R.E.A. For sections outside such width:thickness limitations, the ultimate resistance is less than the yield strength of the material, and is determined by the elastic stability of the elements composing the section. The maximum critical load on such sections is that load which will induce the average critical buckling stress in the elements comprising the section, and Eqs. 39 to 42 will not be effective for loads greater than this value. The approximate value of the critical buckling stress for a section composed of rectangular-shaped elements of area can be determined by application of the Bryan-Timoshenko formula for critical stress in the following manner:

(*a*) Assume the sections to be divided into rectangular elements, or plates, attached to other similar elements at one or both edges.

(*b*) Compute the value of the critical stress for each such element from the Bryan-Timoshenko formula, and designate the ratio of this value to the yield stress of the material as the *z*-factor for the element. The Bryan-Timoshenko formula for the local crippling stress in rectangular plates may be written in the form:

$$z = \frac{\sigma_{cr}}{\sigma_y} = \frac{K\,\pi^2\,E}{12\,\sigma_y\,(1 - \mu^2)}\left(\frac{t}{b}\right)^2 \dots\dots\dots\dots\dots\dots (43)$$

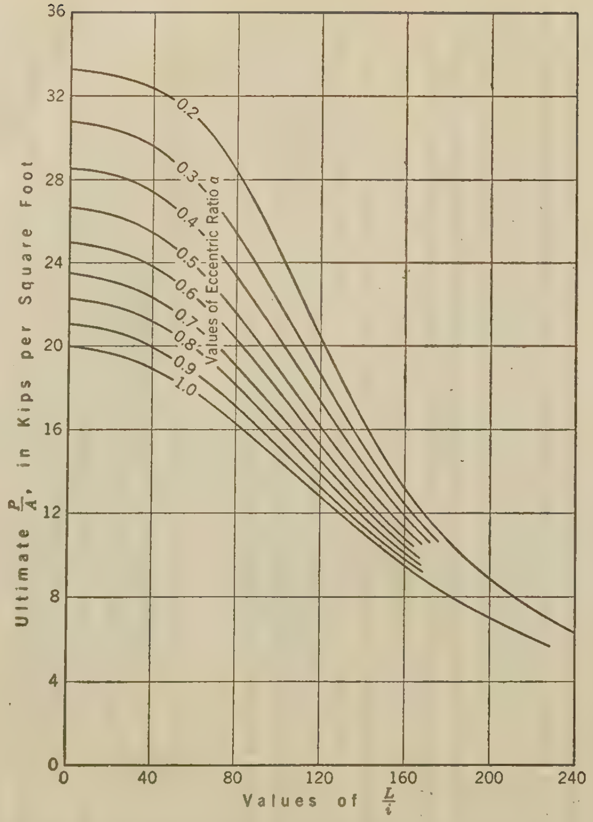

FIG. 3.—ULTIMATE AXIAL LOADS BY THE SECANT FORMULA, EQ. 39 (σ_y = 40 KIPS PER SQ IN., $\eta = 1$, $l' = \frac{7}{8} l$ FOR PIN ENDS, AND $E = 29.4 \times 10^6$)

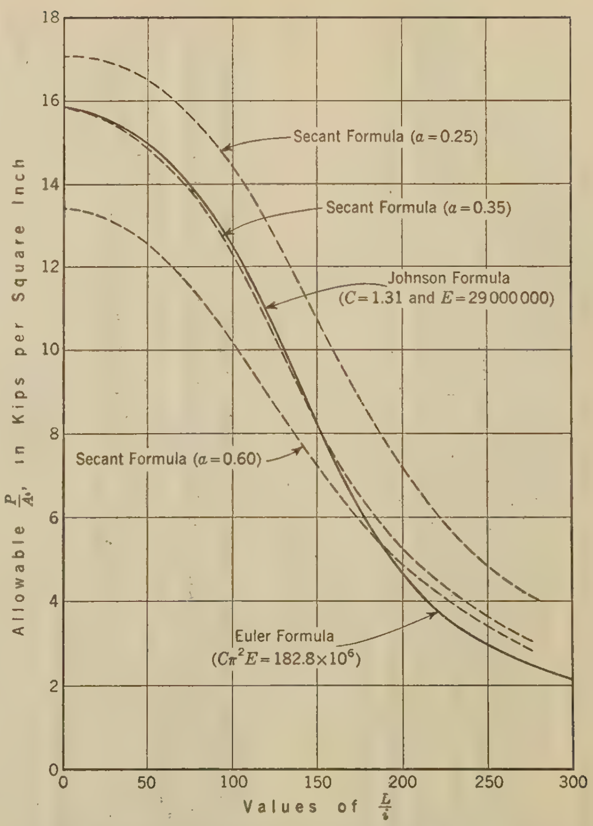

FIG. 4.—COMPARISON OF SECANT FORMULA, EQ. 39 ($\eta = 1.55$ AND σ_y = 33 KIPS PER SQ IN.), WITH JOHNSON FORMULA, EQ. 41 ($\eta = 2.09$ AND σ_y = 33 KIPS PER SQ. IN.)

in which σ_{cr} is the critical unit stress; t is the thickness of plate; b is the width of plate; μ is Poisson's ratio (0.3 for steel); and K is a coefficient determined primarily by the condition of edge support and restraint. It should be noted that, in Eq. 43, z must not be taken greater than unity.

(c) Compute the value of the form factor F for the entire section as the ratio:

$$F = \frac{\Sigma k\, b'\, t'}{\Sigma b'\, t'} \qquad (44)$$

in which b' is the width of any element and t' is the thickness of any element. The form factor, F, represents the approximate ratio of the average critical stress on the section to the yield stress of the material, and the limiting value of P/A is therefore $F\,\sigma_y$.

Since the formulas presented in this paper provide no limitation based on crippling stress, they should not be used without proper modification for sections whose form factor is less than unity.

Leon Beskin,[17] Assoc. M. Am. Soc. C. E.—That a column formula may be used as a curve on a graph, a set of precomputed values in a table, or as an algebraic expression, solved mathematically for each case that occurs in practice, is obvious. Nearly all structural designing departments plot column formulas instead of using them in their mathematical form, even if specifications give column strengths in terms of a mathematical expression. The author makes the point that, if this is so, an otherwise acceptable formula should not be rejected merely on the ground that it is complicated, since a graph of the formula is as easy to apply as the most elementary empirical expression. This seems to imply that the author proposes first to adjust a formula to fit experimental results and then to plot the resulting expression. This proposal seems to eliminate all interest in the formula since it is more straightforward to use an averaged curve of experimental results, directly without bothering with its mathematical expression.

Mathematical column formulas may be useful, however, when materials with different characteristics (such as aluminum alloys or concrete) are being considered. Graphical representation of a formula then involves a set of curves that can be applied to any material of the group. In this case it may be convenient to derive a formula in which the strength or the modulus of elasticity, or both, appear explicitly. Given the material to be used, it is then a simple matter to plot an acceptable column curve. In about 1934 the French Air Department introduced the following expression:

$$\sigma = \frac{1 + \frac{3\sqrt{3}}{2}\lambda^3_o}{1 + \lambda^2_o\left(1 + \frac{3\sqrt{3}}{2}\lambda^3_o\right)} \qquad (45)$$

---

[17] Structures Engr., Consolidated Vultee Aircraft Corp., San Diego, Calif.

Eq. 45 is valid for $\lambda^2_o > \frac{1}{3}$, whereas, for $\lambda^2_o < \frac{1}{3}$, σ is assumed equal to unity. The value of σ is asymptotic to the Euler value $\sigma = \frac{1}{\lambda^2_o}$ for infinite values of λ_o, is equal to 1, and has a derivative equal to zero, for $\lambda^2_o = \frac{1}{3}$, so that the conditions of continuity, monotony, and continuity of the derivative are satisfied. The same result is obtained when, for a wide class of aluminum alloys, a straight line or a Johnson parabola, tangent to the Euler curve and corresponding to the block strength for $\lambda_o = 0$, is used.

The curves resulting from Eq. 45 do not satisfy the author's condition of extrapolation, and it is not necessary that they do so since the Euler curve in one case and the limiting value $\sigma = 1$ in the other are so defined that errors in extrapolation are normally avoided. There seems no doubt that the condition of possible extrapolation is unnecessary if the entire range of possible slenderness ratios is covered by a formula (or by several formulas). One such limitation may be defined as the Euler formula, whereas, for small slenderness ratios, a "cutoff" constant value may be used.

Furthermore, a system of several formulas satisfying the conditions of continuity, monotony, and continuity of the derivative as a whole can always be replaced, either exactly, or within the desired degree of accuracy, by a unique formula satisfying the same conditions so that the condition of a unique formula has no mathematical significance. Consequently, there is no practical, mathematical, or logical objection to the use of a limited number of simple formulas, instead of one complicated formula covering the entire range of possible slenderness ratios. An engineer can memorize simple formulas and compute allowable stresses on the slide rule, or by any other method best suited to his immediate needs, whereas a complicated formula leaves the practical engineer no choice but to plot a graph. Since that is his only choice, the best possible graph is that plotted directly from test data.

The writer cannot sense the importance of the condition stated in the "Introduction" that "An empirical [column] formula * * * should be one that expresses theoretically possible relations." The "theoretically possible relations" referred to by the author seem limited exclusively to the condition defined by the Euler formula. If a given empirical formula is claimed to be valid only for stresses less than the Euler values, that formula is absolutely legitimate as soon as it has been shown to fit the experimental results. In addition, if the formula is represented by a curve tangent to the Euler curve, it satisfies the condition of continuity of the derivative; but this condition is not important, since the stress-strain curve is never considered necessary to satisfy it. Since the column curve is a function of the stress-strain curve, it is possible that none of these curves satisfies the condition of continuity.

Thus, of all the conditions expressed by the author, the condition of monotony appears to be the only justifiable one. Incidentally, a decreasing function is always a monotonically decreasing function, because the concept of monotony is broader than the concept of the decreasing function. Mathematically, the word "monotonic" means "not decreasing or not increasing as the independent variable increases."[18] When Mr. Osgood refers to a "monotonically decreasing function" in the "Synopsis," it is understood to mean that the dependent variable "stress" does not increase as the independent variable "slenderness ratio" increases.

As stated by the author, the derivation of a column formula from a stress-strain curve is a difficult task. The double-modulus theory, which has been used for a long time, involves a basic error in theory, in that it presupposes a theoretically straight column. When a column with some initial curvature or eccentricity is considered, the double-modulus theory cannot be applied, and then the single-modulus theory appears to be more representative of both the theoretical picture and the actual facts.

A so-called "theoretical" formula, derived from an empirical stress-strain curve, cannot be considered theoretical, according to the precise meaning of the word as used by physicists. A formula of "correct form" (see "Introduction") cannot be devised without introducing at least one observed constant of the structure, and one observed constant related to the material. A formula of correct form should contain at least the slenderness ratio and one constant related to the strength of the material in compression (for a slenderness ratio of zero). In addition, since the author's opinion is that the "correct form" implies that the curve must be asymptotic to that of the Euler formula, the modulus of elasticity of the material must appear explicitly in the formula.

In the "Introduction," the author declares that "It would be very hard to justify more than two constants of the material in any practical column formula." All the formulas that he indicates, with the sole exception of the Rankine formula, contain two dimensionless constants. If only two constants of the material, one of them being the modulus of elasticity, were to be used, a single dimensionless constant, related to the ratio between the yield point (or the ultimate strength) and the modulus of elasticity, would be sufficient to define a column formula. The occurrence of two dimensionless constants in nearly all formulas shows that at least three constants of the material must be considered. Possibly, these constants could be taken as the average modulus of elasticity before the yield point, the average modulus of elasticity after the yield point, and the yield strength of the material. In the relation between free length and actual length (Eq. 2), the constant k may be different from the theoretical values such as $k = \frac{1}{2}$ for fixed ends, when the material is not in the elastic range, because of the important effect of initial eccentricities. In addition, when the ends are restrained elastically, the constant k is a function of the moduli of elasticity of both the support and the beam, and varies with the load when the column is not in the Euler range.

In the text following Eq. 2, the author states that the arbitrary constant S "* * * should be taken as a compressive secant yield strength." A yield strength defined by an arbitrary value of the permanent strain could be used as well as the secant yield strength. It would be interesting to learn if the author has a definite reason for using the secant yield strength rather than some other constant of the same nature.

---

[18] "Webster's New International Dictionary of the English Language," G. & C. Merriam Co., Springfield, Mass., 2d Ed. (unabridged), 1939, Vol. I, p. 1588.

A better choice for the constant S seems to be the intercept, S_o, of the column curve with the axis, σ. This choice eliminates one constant from all the dimensionless equations summarized by the author, with the exception of the two formulas (Eqs. 15 and 18) derived by means of the double-modulus theory. Eqs. 15 and 18 are not practical since they give an infinite column load for a slenderness ratio of zero. When the value of S is assumed equal to that of S_o, the various nondimensionless equations are transformed as follows:
The Rankine formula (Eq. 3*a*)—

$$\sigma = \frac{1}{1 + \lambda^2_o} \quad \text{(46)}$$

the secant formula (Eq. 7*a*)—

$$\cos \frac{\lambda_o \pi \sigma}{2} = \frac{1}{\frac{1 - C}{\sigma} + C} \quad \text{(47)}$$

the Aarflot formula (Eq. 9*a*)—

$$\sigma = \frac{1}{C \lambda^2_o + \sqrt{1 + (1 - C)^2 \lambda^4_o}} \quad \text{(48)}$$

the Ylinen formula (Eq. 11*a*)—

$$\lambda^2_o = \frac{1 - \sigma^n}{\sigma} \quad \text{(49)}$$

the author's formula (Eq. 13*a*)—

$$\sigma = \frac{1}{1 + C \lambda_o + \lambda^2_o} \quad \text{(50)}$$

the parabolic formula (Eq. 20*a*)—

$$\sigma = 1 - \frac{1}{n + 1} \left(\frac{n}{n + 1} \right)^n \lambda^{2n}_o \quad \text{(51)}$$

and the Kreüger formula (Eq. 21*a*)—

$$\sigma = \frac{1 - \lambda^2_o C^2}{1 + (1 - 2 C) \lambda^2_o} \quad \text{(52)}$$

Experiments show that, when the shape of the cross section of a column is modified for a constant value of the slenderness ratio, the ultimate load is also changed. The constants which appear in the formulas are thus shown to be related to the shape of the cross section, as well as to the material—a fact that is easily explained when the influence of an initial curvature or eccentricity is considered.

Regrettably, the dimensions of the constants in Eqs. 3 to 21 are not the same throughout all the formulas. In the following tabulation, dimensionless constants are denoted by zero, and S represents a constant of the dimension of a stress:

Constant	B	C
The Rankine formula, Eq. 3	0	....
The secant formula, Eq. 7	$1/S$	0
The Aarflot formula, Eq. 9	0	0
The Ylinen formula, Eq. 11	$(1/S)^n$	....
The author's formula, Eq. 13	0	0
The author's formula, Eq. 15	$(1/S)^{n-1}$	....
The author's formula, Eq. 18	$(1/S)^{n-1}$	....
The hyperbolic formula, Eq. 20	S	....
The Kreüger formula, Eq. 21	$1/S$	$1/S$

In the "Summary," the author indicates that "The column formulas in Sections II to V, inclusive, apply for all values of the ratio of slenderness * * *." For very small slenderness ratios, Eqs. 15 and 18 are exceptions to this statement. When these formulas are used, a "cutoff" must be made for the strength corresponding to very short columns, which violates the author's principle that column formulas must be valid for all slenderness ratios. Incidentally, it would be interesting to know how two column equations have been derived from the same basic assumptions; that is (see paragraph containing Eqs. 18), "* * * derived by the double-modulus theory from a stress-strain curve of the form of Eq. 17."

Both the secant formula, when $C > 0$, and Eq. 13 give values less than those of the Rankine formula. This indicates that these formulas have only a limited usefulness, since, as noted by the author in the "Introduction," "* * * the [Rankine] formula gives lower values of the average stress than the mean of the average stresses found in tests of most materials." This fact disqualifies all column curves below the Rankine curve.

Both the secant formula and the Ylinen formula are extremely difficult to apply since the stresses are not given explicitly in terms of the slenderness ratio. Consequently, since the formulas cannot be used directly, tables must be compiled for the computation, which makes these formulas impractical.

From the foregoing, it can be stated that only the Rankine, Aarflot, parabolic (including the Johnson parabolas and the straight line), and Kreüger formulas are of practical value in the design of columns. The remaining formulas cannot be recommended, because they do not fit experimental results, and because they do not define the strength as an explicit function of the slenderness ratio.

LOUIS BALOG,[19] ESQ.—Imperfections in technical processes, and economic considerations, limit the precision attained in making and shaping of metals and in fabricating and erecting structural members. Homogeneity and physical properties of materials, the geometric accuracy of members and structures, the conformity to the contemplated points of application, and the character of the calculated forces depend on practices that must be justified economically for various types of structures. Since all these circumstances influence the carrying capacity of a compression member, the derivation of empirical column formulas, of universal validity, is impossible.

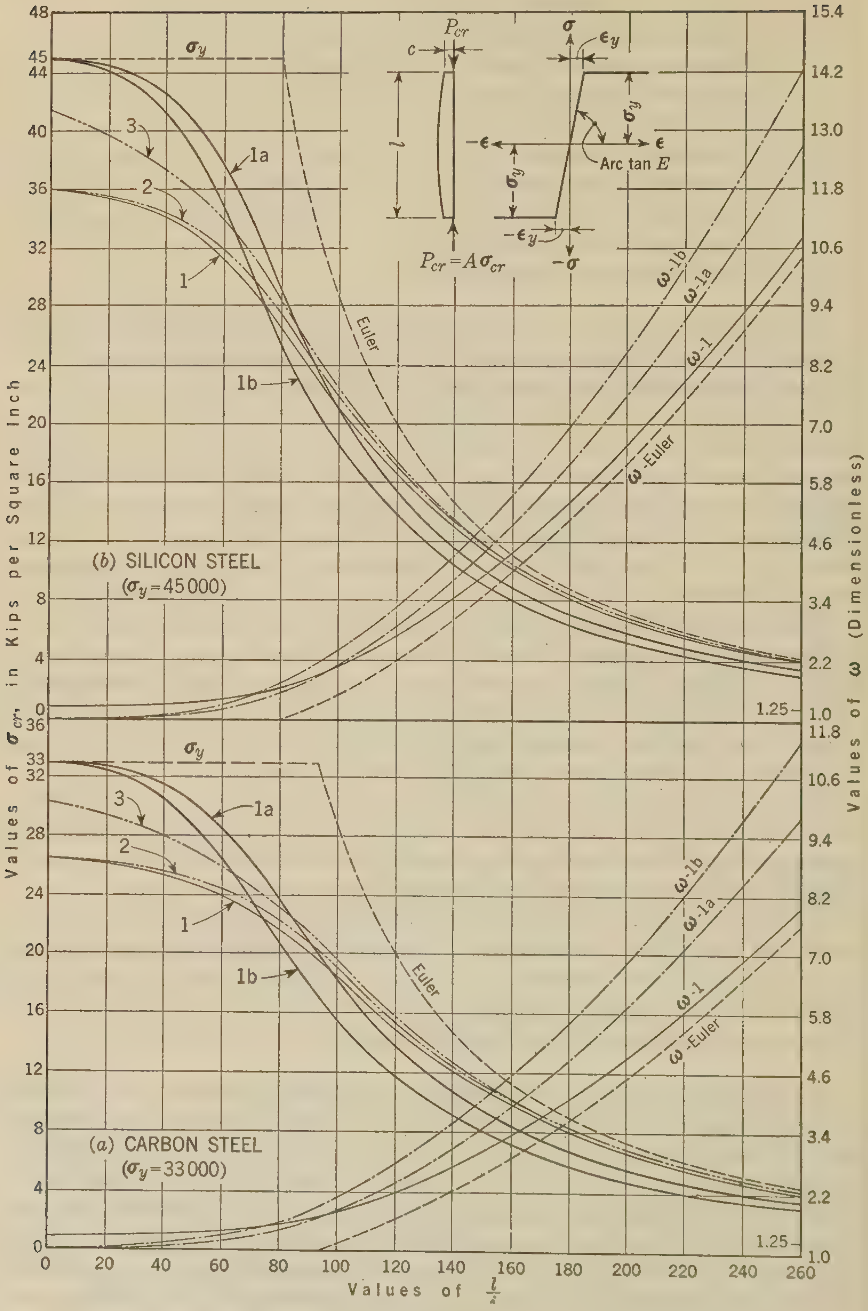

FIG. 5.—COLUMN CURVES FOR CARBON-STEEL AND SILICON-STEEL STRUCTURES (E = 29,400,000 Lb per Sq In.)

For absolutely ideal conditions the $\left(\sigma_{cr} - \frac{l}{i}\right)$-curve is composed of Euler's hyperbola and of a horizontal line $\sigma_{cr} = \sigma_y$, as shown in Fig. 5. The most exacting laboratory tests have failed to conform to this curve, due to the sensitivity of columns to deviations from ideal conditions. Study of the effects of tolerances in metal and of rolled shape characteristics, and experience with the accuracy of statical calculations and with that of shop and erection work, lead to the reduction of the theoretically ideal curve to curves shown below it in Fig. 5, which curves indicate the practical carrying capacity of carbon-steel and silicon-steel columns in bridge and structural work. The deviations between the ideal and actual conditions are so great in this case that the mathematical criteria, set up by the author for establishing the shape of column curves, seem to be of little practical consequence.

The practical validity of the formulas in the paper depends not so much on the primary requisites defined by Mr. Osgood as on the selection of the arbitrary constants they contain. These constants can indeed be so selected that the formulas will approximate special conditions more or less satisfactorily; but the restrictions on the constants, to obtain curves representing monotonically decreasing functions (the first derivatives of which are continuous) are irrelevant requirements from point of view of practical design.

Although columns have been designed by the use of empirical formulas, the general requirements of engineering practice could never be met with such formulas. This alone would be a sufficient reason for their rejection; but empirical formulas also hinder progress in design. The problem, therefore, is not to fit a formula adequately to a series of column tests (which seldom represent actual structural conditions), but to fit a theory to reality. Rational theories, by which the effects of varying all characteristics that enter into the problem can be measured, should be the basis of design.

In the "Introduction" the author states that

> "It would be possible to design by means of the double-modulus theory * * * but * * * most engineers would undoubtedly prefer to use an empirical formula based on tests."

Bridge and structural design practice does not support this opinion. Empirical formulas, based on tests, have been abandoned and theoretical formulas, in the derivation of which the modulus variation is neglected, are in general use. No other conclusion can be drawn from the widely scattering results of column tests than that only theoretical formulas are rational. Tests have failed to furnish data for the basic constants of the theoretical formulas—the eccentric ratio a and the reduced length l_o (Eq. 2)—on which two factors the validity of any practical column formula depends. Values for both of them can be determined, however, from the characteristics of actual structures and from theoretical considerations. It is quite certain that imperfections in testing procedure render such experiments useless. Extremely careful tests of small specimens, to determine the limits of validity of some basic theoretical assumption, constitute the reasonable experimental investigation.

Inasmuch as axially loaded columns do not exist in an ideal sense, only eccentric loading needs to be considered. A distinction must be made between small eccentricities ($a < 0.01$) and large eccentricities ($a > 0.1$); and actual structural columns belong in the latter category.

Numerous difficulties hinder the mathematical expression of the yielding process; and therefore the actual stress-strain relation and the actual shape of the deflection line can be considered only in graphic-analytic solutions of the problem.[20,21,22,23,24,25] The labor involved in these methods restricts their practical use to the most unusual investigations. The same is true of the approximate methods in which some assumption is made for the deflection line and in which the stress-strain relation is replaced by a combination of straight and parabolic lines.[26,27,28,29,30,31,32,33] In spite of their limited practicability of direct application in design these theoretical investigations are of much greater practical value than the tests made to determine empirical column formulas.

Diagrams containing the curves representing the functional relations,

$$\frac{l}{i} = f(\sigma_{cr}, a) \qquad \text{(53)}$$

arranged according to parameter a (see Fig. 6), facilitate the clear visualization of the behavior of compression members as influenced by the characteristics of the metal and by geometric relations. The upper limit of such a group of curves is $a = 0$ in Fig. 6, or the case of ideal axial load. This curve consists of Euler's hyperbola for slenderness ratios larger than that corresponding to the proportional limit; it consists of the Engesser-Kármán (double-modulus) line for slenderness ratios that correspond to the range between the point of strain hardening and proportional limit, and, for smaller slenderness ratios, it consists of a rapidly ascending line. Since structural steels have a long yield range, the limit of hardening will be smaller than 15; or it will be always smaller than the practical minimum slenderness ratio, which is about 25. Therefore, actual compression members would reach their ultimate carrying capacity

before strain hardening can set in, even if they could be loaded axially. The region of hardening, therefore, has no practical significance.

The shape of the Engesser-Kármán (double-modulus) line depends on the shape of the stress-strain diagram between the proportional limit and yield stress. An infinite variety of double-modulus curves is possible between these two values for the same steel. This indicates that a reasonably assumed shape for this curve is just as close to reality as any of those which correspond to a certain actual stress-strain diagram. Comparative examinations of the effect of the variations of the double-modulus curve on the values of the carrying capacity of columns, of the effects of the practically unavoidable eccentricities of the load ($a > 0.1$), and of the fluctuation in the values of σ_p and σ_y, indicate that the double-modulus theory has no practical significance in bridge design or in structural design generally. Therefore, it is not only the simplest procedure, but also the most reasonable, to base structural column formulas on the ideal stress-strain relation.

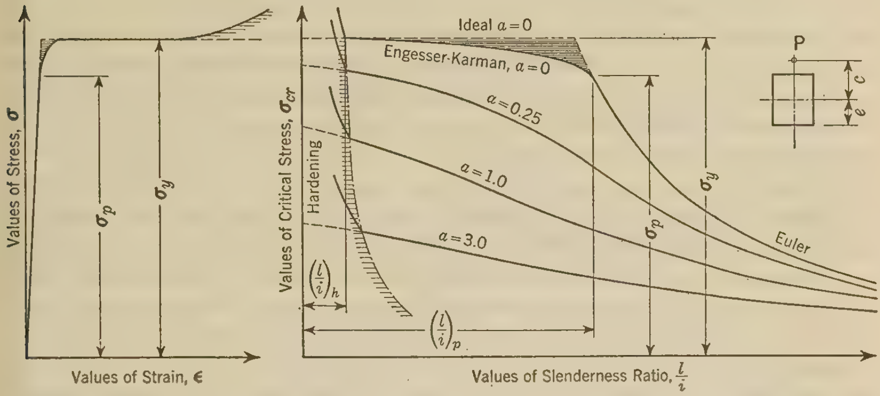

FIG. 6.—RELATION BETWEEN STRESS-STRAIN CURVES AND $\left(\sigma_{cr} - \frac{l}{i}\right)$-DIAGRAMS

The ideal stress-strain variation (see stress-strain diagram in Fig. 5), and the validity of the classical theory of the yielding process, are the fundamental assumptions of practical column investigations. It is assumed that yielding begins when the stress in the extreme fiber of the section reaches the yield stress of the tension-test specimen subjected to the standard tension test, and extends continuously with continuously increasing load.

Actually the stress-strain diagram is different for tension and compression, for increasing and decreasing load. It is also curved beyond the proportional limit, and the yielding process is characterized by the formation of flow layers caused by the superimposed bending stresses resulting from the unavoidable eccentricity of the loading.[34] Yielding, therefore, does not progress continuously with an increasing load but in layers, and this fact influences the stress distribution in the section and brings the shape of the section into play. The consideration of flow layers is generally neglected in present-day structural design. The curved portion of the stress-strain diagram between the proportional limit and yield stress is short for structural steels. The fluctuation of σ_y for specimens of the same steel is often larger than the length of this region. The consideration of these conditions indicates that, for structural steel columns, the foregoing idealizing simplifications are justified. Based on them, and on Bernoulli's hypothesis that originally plain sections remain plain and normal to the longitudinal column fibers after bending, the carrying capacity of compression members is adaptable to a theoretic evaluation that is entirely satisfactory for structural design.

---

[34] "Plasticity," by A. Nadai, McGraw-Hill Book Co., Inc., New York, N. Y., 1931, p. 104.

In view of the foregoing simplifying assumptions, three different stress conditions are possible in a rectangular column section: (*a*) The condition corresponding to purely elastic deformation; (*b*) the stress pattern when there is a plastic area at the compression side; and (*c*) the stress pattern when there is a plastic area at both compression and tension sides. ("Compression side" or "tension side" denotes that side of the section in which the stress due to bending alone is compression or tension—quantities referring to these sides will be designated by subscripts *c* and *t* herein.) For the three different stress conditions of the center section (*a*), (*b*), and (*c*), the following formulas give the carrying capacity:[35,36]

Case (*a*)—

$$\left(\frac{l}{i}\right)^2 = \frac{\pi^2 E}{\sigma_{cr}}\left(1 - \frac{a\,\sigma_{cr}}{\sigma_y - \sigma_{cr}}\right) \qquad (54a)$$

Case (*b*)—

$$\left(\frac{l}{i}\right)^2 = \frac{\pi^2 E}{\sigma_{cr}}\left[1 - \frac{a\,\sigma_{cr}}{3\,(\sigma_y - \sigma_{cr})}\right]^3 \qquad (54b)$$

Case (*c*)—

$$\left(\frac{l}{i}\right)^2 = \frac{\pi^2 E}{\sigma_{cr}}\sqrt{\frac{\sigma_{cr}}{\sigma_y}\left(\frac{\sigma_y}{\sigma_{cr}} - \frac{\sigma_{cr}}{\sigma_y} - \frac{2\,a}{3}\right)^3} \qquad (54c)$$

For the solution of Eqs. 54 only the values of E and σ_y are necessary. These formulas apply to any kind of structural steel. Eq. 54*a* is valid until the yield stress in the extreme fiber is reached; Eq. 54*b* is valid until $a \leqq 3\left(1 - \frac{\sigma_{cr}}{\sigma_y}\right)$; and Eq. 54*c* is valid until $a \geqq 3\left(1 - \frac{\sigma_{cr}}{\sigma_y}\right)$.

The practical carrying capacity, or the lower limit of the carrying capacity of columns, is defined by the load at which the yield stress is reached in the extreme fiber. Eq. 54*a* gives this lower limit on which design is usually based. It is valid for any shape of section and gives practically identical results with the "secant formula":

$$\sigma_{cr} = \frac{\sigma_y}{1 + a \sec \frac{l}{2\,i}\sqrt{\frac{\sigma_{cr}}{E}}} \qquad (55a)$$

---

[35] "Näherungsberechrung der Tragkraft exzentrisch gedrückter Stahlstäbe," by Karl Ježek, *Der Stahlbau*, Vol. 8, 1935, p. 89.

[36] "Die Festigheit von Druckstäben aus Stahl," by Karl Ježek, Julius Springer, Wien, 1937, p. 79.

Eq. 55*a* must be solved by the cumbersome trial-and-error method; but, transformed into the form,

$$\frac{l}{i} = 2\sqrt{\frac{E}{\sigma_{cr}}}\,\text{arc cos}\,\frac{a\,\sigma_{cr}}{\sigma_y - \sigma_{cr}} \quad \ldots\ldots\ldots\ldots\ldots (55b)$$

it is convenient for calculations because tables for circular cosines for radian arguments are readily available; the arc of the cosine can be read from such tables, and Eq. 55*b* can be solved directly.

The upper limit of the carrying capacity is defined by the load that produces the critical equilibrium condition. Eqs. 54*b* and 54*c* give these values for rectangular section.

Rigorous investigations[37] have shown that the upper limit of the carrying capacity is appreciably influenced by certain cross-sectional shapes. A formula by which the sectional form can be considered is:[38,39]

$$\left(\frac{l}{i}\right)^2 = \frac{\pi^2 E}{\sigma_{cr}}\left(1 - \mu_1\frac{a\,\sigma_{cr}}{\sigma_y - \sigma_{cr}}\right)\left(1 - \mu_2\frac{a\,\sigma_{cr}}{\sigma_y - \sigma_{cr}}\right) \ldots\ldots (56)$$

Values of μ_1 and μ_2 for use in Eq. 56 are given in Table 1. Eq. 56 has unlimited validity for each of these sections except sections (d) and (e), for which it is valid, provided

$$\frac{\sigma_{cr}}{\sigma_y} \geqq \frac{S_c - S_t}{S_c + S_t} \ldots\ldots\ldots\ldots\ldots (57)$$

in which S_c and S_t are the section moduli at the compression and tension sides, respectively. If the relation defined by Eq. 57 does not exist, failure occurs at the tension side and the ultimate carrying capacity becomes

$$\left(\frac{l}{i}\right)^2 = \frac{\pi^2 E}{\sigma_{cr}}\left[1 - \mu_1\frac{S_c\,a\,\sigma_{cr}}{S_t\,(\sigma_y + \sigma_{cr})}\right]\left[1 - \mu_2\frac{S_c\,a\,\sigma_{cr}}{S_t\,(\sigma_y + \sigma_{cr})}\right] \ldots (58)$$

As the eccentricity ratio decreases (that is, as *a* approaches zero), the influence of the shape of the section diminishes.

TABLE 1.—VALUES OF μ FOR THE SOLUTION OF EQ. 56

μ	 (*a*)	 (*b*)	 (*c*)	 (*d*)	 (*e*)	 (*f*)	 (*g*)	 (*h*)	 (*i*)
μ_1	0.5	0.5	0.5	0.8	0.8	0.4	0.4	0.9	0.9
μ_2	0.5	0.5	0.5	0.2	0.2	0.4	0.4	0.1	0.1

[37] "Der Einfluss der Querschnittsform auf das Tragvermögen aussermittig gedrückter Bausthalstäbe," by Ernst Chwalla, *Der Stahlbau*, Vol. 8, 1935, p. 193.

[38] "Die Festigkeit aussermittig gedrückter Stahlstäbe beliebiger Querschnittsform," by Karl Ježek, *Der Bauingenieur*, Vol. 17, 1936, p. 306.

[39] "Die Festigheit von Druckstäben aus Stahl," by Karl Ježek, Julius Springer, Wien, 1937, p. 213.

It is possible to base column formulas on the ratio of the yield and critical stresses, or, for design purposes, on the ratio of a constant allowed stress and the critical stresses which correspond to the various $\frac{l}{i}$-ratios. In this case the force to which the column is subjected will be multiplied by this ratio (the dimensionless parameter $\omega \geqq 1$) and it is required that the resulting axial unit stress shall not exceed the constant allowed stress value. An exceedingly practical column formula of this type,[40] in the derivation of which the center deflection was not approximated by $y_m = \frac{c\,\sigma_E}{\sigma_E - \sigma_a}$ (which corresponds to the sine curve assumption of Eq. 54*a*) but by the more exact expression,[41]

$$y_m = \frac{c}{\sigma_E - \sigma_a}\left(\sigma_E - 0.25\,\sigma_a\right) \qquad (59)$$

is as follows:

$$\omega = \tfrac{1}{2}\left[\varphi\left(\frac{l}{i}\right)^2 + a + 1\right]\left\{1 + \sqrt{1 - \frac{4\,\varphi\left(\frac{l}{i}\right)^2 (1 - 0.25\,a)}{\left[\varphi\left(\frac{l}{i}\right)^2 + a + 1\right]^2}}\right\} \qquad (60)$$

in which: $\sigma_E = \frac{\pi^2 E}{\left(\frac{l}{i}\right)^2}$; $\sigma_a = \frac{P}{A}$; and $\varphi = \frac{\sigma_y}{\pi^2 E}$. The critical stress becomes

$$\sigma_{cr} = \frac{\sigma_y}{\omega} \qquad (61)$$

Eq. 60 can be solved directly for any $\frac{l}{i}$-ratio; and for any variation of *a* it gives practically identical results with Eqs. 55.

All imperfections of the column in the structure are translated in column formulas to a single factor representing a certain equivalent eccentricity of the load. The functional relation between the eccentricity and the stress condition of the center section makes such a summary consideration of the imperfections possible. The practical validity of a column formula depends greatly on the assumption of the magnitude and variation of this measure of the degree of imperfection, expressed by the eccentricity ratio *a*.

The column formulas specified by the American Railway Engineering Association (A.R.E.A.; see Eq. 33*a*) and the American Association of State Highway Officials (A.A.S.H.O.) approximate the "secant formula," Eqs. 55 and 61 in which $a = 0.25$ $\left(\text{that is, } c = 0.25\,\frac{i^2}{e} \text{ has been assumed}\right)$. For the same symmetrical column section $\frac{i^2}{e}$ is constant and therefore the value of c remains constant for any l/i-ratio. This results in an increasing reduction of the calculated carrying capacity, or allowed unit stress, as the slenderness decreases. In actual structures $\frac{i^2}{e}$ is not constant; it increases with a decreasing l/i-ratio, and therefore the assumption of $a = 0.25 =$ constant results in increasingly more severe sectional requirements for compression members as the slenderness ratio decreases. The correctness of this statement will be demonstrated by an investigation of actual structures.

---

[40] "Vorschlage zur wirtschaftlichen Bemessung gedrückter Baustahlstäbe," by Ernst Chwalla, *Deutscher Stahlbau-Verband*, Berlin, Ernst, 1939, p. 18.

[41] "The Imperfect Strut and the Arch," by R. H. W. Hawken, *Proceedings*, World Eng. Cong., Tokyo, 1929, Vol. III, Pt. 1, pp. 73–114.

In Fig. 7 the $\frac{i^2}{e}$-values (or, for unsymmetrical sections, the average value) of the core radii $\frac{1}{2}\left(\frac{i^2}{e_t} + \frac{i^2}{e_c}\right)$ of main and bracing sections of several highway and railway bridges are plotted against the $\frac{l}{i}$-value of the members. These bridges have been built since 1920 and include long-span truss bridges, stiffening trusses of large suspension bridges, and other smaller structures. The indicated curve represents the average of scattering points. It appears from this curve that the variation of the actual $\frac{i^2}{e}$-values is hyperbolic in bridge structures, the product $\frac{i^2}{e} \times \frac{l}{i}$ being nearly constant. In addition to the ordinates $\frac{i^2}{e}$, Fig. 7 gives the values of c, the unavoidable eccentricities, on which the specification column formulas are based. The sensitivity of compression members to eccentric loads in the small $\frac{l}{i}$-region, in which rapidly increasing eccentricities are specified, indicates that, in bridge design, it is not reasonable to base a column formula on the assumption that $a = 0.25$ is a constant eccentricity ratio, because it results, unjustifiably, in an increasing factor of safety as $\frac{l}{i}$ decreases. A more uniform factor of safety will be obtained by assuming a linear increase of the unavoidable eccentricities c, with increasing $\frac{l}{i}$. In view of the hyperbolic variation of the actual $\frac{i^2}{e}$-values, this assumption results in an eccentricity,

$$c = \kappa \frac{1}{2}\left(\frac{i^2}{e_t} + \frac{i^2}{e_c}\right)\left(\frac{l}{100\,i}\right)^2 \qquad \text{.................. (62)}$$

By Eq. 62 the design eccentricity becomes a function of the structural, sectional and dimensional characteristics of the compression member, and the expression of the eccentric ratio becomes:

$$a = \frac{\kappa}{2}\left(1 + \frac{e_c}{e_t}\right)\left(\frac{l}{100\,i}\right)^2 \dots\dots\dots\dots\dots\dots\dots (63)$$

With present-day structural imperfections the value of the constant κ, for bridges and structures, is 0.25. The most unfavorable section actually in use is that composed of two angles, back to back. If the load produces compression in the extreme fibers of the legs in contact, the ratio of the distances from the center of gravity to the extreme compression and tension fibers is $e_c/e_t = 2.5$, for such sections. If the load is at the other side of the section e_t/e_c must be introduced into Eq. 63 and the yield stress in this case will occur at the tension side of the section. For symmetrical sections these ratios become unity, and for $\frac{l}{i} = 100$, Eq. 63 reduces to the present specification value of $a = 0.25$.

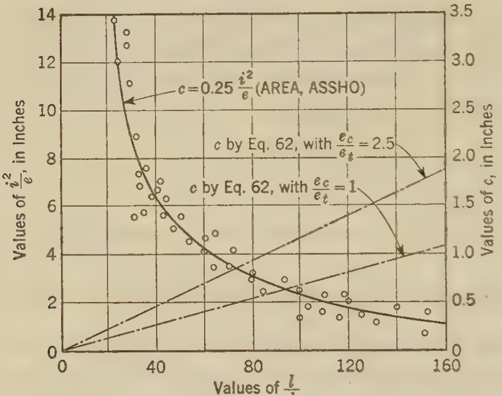

FIG. 7.—VARIATION OF THE RATIO $\frac{i^2}{e}$ WITH THE SLENDERNESS RATIO $\frac{l}{i}$ IN ACTUAL BRIDGES

Fig. 5 is an evaluation of Eqs. 54*a*, 54*b*, 55, 56, 60, and 61 for carbon steel and silicon steel. Curves 1 correspond to Eqs. 55 and 61 with $a = 0.25$; and curves 1a and 1b correspond to the same formulas with $a = \frac{0.25}{2}(1 + 1)\left(\frac{l}{100\,i}\right)^2$ and $a = \frac{0.25}{2}(1 + 2.5)\left(\frac{l}{100\,i}\right)^2$, respectively. Curves 2 correspond to Eq. 54*a* with $a = 0.25$. The critical stress, σ_{cr}, given by curves 1, 1a, 1b, and 2, is the axial, or average, stress at which the yield stress is reached in the extreme compression fiber, and $P_{cr} = A\,\sigma_{cr}$ is the lower limit, or design, carrying capacity of the column. Curves 3, Fig. 5, correspond to Eq. 54*b* and give the upper limit, or ultimate carrying capacity $P_{cr} = A\,\sigma_{cr}$ of a column with a rectangular section based on the classical theory of the yielding process and on the assumption that $a = 0.25$ is a constant eccentricity ratio.

The $\left(\omega = \frac{\sigma_y}{\sigma_{cr}}\right)$-curves are also given in Fig. 5. Examination of these curves reveals that they can be approximated by simple parabolic power relations, or, by means of these ω-curves, doubly curved cubic-hyperbolic $\left(\sigma_{cr} - \frac{l}{i}\right)$-curves, corresponding to eccentricity ratios which vary with $\frac{l}{i}$, can easily be represented.

Comparison of curves 1 with 1a and 1b in Fig. 5 indicates that, for a given value of E and σ_y, the magnitude and variation of the eccentric ratio a has a much greater effect on the values of the critical stresses and on the shape of the column curves than the other variables entering into the design of compression members.

In 1932 the Society's Special Committee on Steel Column Research concluded its 10-yr investigations with the statement that:[42] "A rational column formula can best be constructed on the basis of the theoretical formula for eccentrically loaded columns * * *." This statement is in agreement with the findings of numerous valuable investigations presented since 1926. Progress in the design of compression members, during the intervening years, is characterized by the adoption of the theoretical formula as evidenced also by both the A.R.E.A. and A.A.S.H.O. specifications which have been in force since before 1935. Improvements on the A.R.E.A. formulas and the A.A.S.H.O. formulas so that they will conform to actual structural conditions of eccentricity and the use of proper reduced lengths, constitute the criteria for their usefulness, rather than the formal requirements suggested by Mr. Osgood.

The determination of the reduced length should be based on consistent assumptions. Inasmuch as the design of the members is based on the condition of yield stress in the extreme fiber it is reasonable to consider the reduced lengths which correspond to this condition of the structure. This indicates that such summary assumptions for the buckling lengths as those made by Mr. Osgood and those involved in the A.R.E.A. and A.A.S.H.O. column formulas are neither reasonable nor tenable. The variation of the stress and rigidity of members adjacent to the same panel point, the character of the intermediate supports of members in various truss systems, and other factors influence the buckling length. For all members and conditions the specification formulas assume 0.75 l if the connections are riveted. This fact, combined with the assumed constant eccentricity ratio, makes the design value of these fundamentally correct formulas no greater than rules of thumb.

The critical stresses represented by curves 1a and 1b in Fig. 5—in combination with reduced lengths obtained from the yield stress in the extreme-fiber condition of the members in the structure and correspondence between the allowed stress in tension and compression—are more likely to result in a homogeneous factor of safety at economic advantage than the prevailing specification column formulas which are not fitted to the characteristics of actual structures.

The writer has attempted to explain in the foregoing why there is no need for the application of the double-modulus theory in structural design. The difference between the Engesser-Kármán (double-modulus) line and the line of the ideal buckling stresses is greatest where the Euler hyperbola intersects the horizontal of σ_y (Fig. 6). Assuming this difference to be as great as 10% of σ_y, introducing this value into Eq. 54a, and solving, $a = 0.01$. Inasmuch as the design value of a for actual members in this region is between 0.25 and 0.6, the carrying capacity resulting from the assumption of the ideal stress-strain diagram is only from 1.5% to 4% different from that obtained by the use of the double-modulus line in the extreme case.

---

[42] "Final Report of the Special Committee on Steel Column Research," *Transactions*, Am. Soc. C. E., Vol. 98 (1933), Conclusion 5, p. 1460.

The problem in design is to ascertain a desired structural performance with the greatest economy. The comparison of various structural schemes is equitable only if their factors of safety are the same. Empirical equations, and the prevailing specification formulas, do not result in useful comparisons because their deviations from structural reality affect members of different proportions in different ways. It can generally be stated that the most frequent stress condition—compression combined with bending—is not being given proper attention in design. Laborious calculations, by which internal forces and moments are often determined, usually end in taking the summation of the divisions of force by area and moment by section modulus. The result is not indicative for the factor of safety of the members unless the critical stress that corresponds to the loading condition is known.

The writer agrees with the statements made by Mr. Osgood in the "Summary." There is no point to approximating a correct formula by substituting another of limited validity. It is practical to prepare tables computed from a formula which will apply correctly to the case under consideration in design specifications. Such a method, however, is not applicable directly to many of the infinitely varying complex problems of engineering practice. The simplification of such problems to manageable form requires judgment ripened by thorough structural knowledge, and it requires the study of analytic and experimental investigations in the entire field of stability phenomena.

William R. Osgood,[43] M. Am. Soc. C. E.—Although the paper seems to have been written so that it could be understood, it evidently was not written so that it could not be misunderstood.

The paper contemplates only column failure as distinct from local failure and from crushing of the material, and it contemplates only central loading. Before account can be taken of accidental eccentricities, initial curvatures, and that sort of thing, it seems desirable to eliminate the effects of these disturbing factors so far as possible. When a resulting basic column curve has been obtained, the effects of accidental imperfections in modifying the curve may be considered.

Some of the discussers consider the secant formula to be a rational one. The secant formula is simply the familiar formula,

$$f = \frac{P}{A} + \frac{M c}{I} \qquad \text{(64}a\text{)}$$

written for columns,

$$f = \frac{P}{A} + \frac{P\, e \sec \dfrac{l}{2\,i}\sqrt{\dfrac{P}{E\,A}}}{I}\, c \qquad \text{(64}b\text{)}$$

Eqs. 64 express accurately the relations between the variables that enter so long as Hooke's law applies. For slight departures from Hooke's law, there will be slight inaccuracies. At failure, of either a beam or a column of ordinary structural material, Hooke's law no longer applies even approximately; the inaccuracies are great, and a rational basis can no longer be claimed for the formulas. The computed value of f at failure has no physical meaning whatsoever. In the case of a simple beam ($P = 0$ in Eq. 64a), the computed value of f will vary widely with the shape of the cross section, for the same material. In the case of a column, the computed value of f will vary widely with the shape of the cross section, with the eccentricity, and with the length. Likewise, with a given value of f, the computed values of $\frac{P}{A}$ will bear little relation to the actual values of $\frac{P}{A}$ at failure of columns of different lengths, eccentricities, and shapes of cross section, but of the same material. An unknown, variable factor of safety results when design is based on Eq. 64b with a constant f.

---

[43] Materials Engr., National Bureau of Standards, Washington, D. C.

The view that the secant formula is rational seems similar to maintaining that Rankine's formula is rational, as was often done in the past. Frequently, the assumptions of a theory are not ideally satisfied; but, for the theory to be rational, the assumptions must be reasonably well satisfied. The assumptions underlying the secant formula, considered as a rational one, are not reasonable, and the formula does not and cannot in general produce results in agreement with tests. For example, a series of tests made recently has shown that, for eccentricity ratios of $\rho = \frac{e\,c}{i^2}$ up to 1, the formula,

$$\lambda = \frac{\lambda_o}{1 + 4\,\rho\,\sigma^2} \qquad \text{(65}a\text{)}$$

fits the test results well. In Eq. 65a,

$$\lambda = \frac{1}{\pi}\frac{l}{i}\sqrt{\frac{S}{E}} \qquad \text{(65}b\text{)}$$

in which l is the length of the eccentrically loaded column. In the secant formula,

$$\lambda = \frac{2}{\pi\sqrt{\sigma}}\sec^{-1}\left(\frac{1}{\beta\,\sigma} + C\right) \qquad \text{(65}c\text{)}$$

β and C cannot be determined to fit these test results at all accurately, except possibly for a narrow range. Much less are β and C related to properties of the material. The only rational consideration of the strength of eccentrically loaded columns is along the lines pursued by some of the authors cited by Mr. Balog, notably Karl Ježek and E. Chwalla.

All this does not infer that a formula of the secant type may not be useful, considered as an empirical formula.

A quick and easy formula is demanded by some of the discussers. In comment the writer would quote Mr. Beskin:

> "* * * there is no practical * * * objection to the use of a limited number of simple formulas, instead of one complicated formula covering the entire range of possible slenderness ratios."

To cover the entire range accurately with one or even two simple formulas is asking a lot. It will rarely be possible, depending, of course, on one's ideas of simplicity.

Some object to a formula, like the secant formula, that expresses the ratio of slenderness explicitly as a function of the stress, rather than the stress as a function of the ratio of slenderness. In practice both the load and the length are given. In a formula is it important which one is expressed in terms of the other?

Dean Grinter's criticism indicates the real problem—on the one hand, the need for re-examining methods from time to time, and, on the other hand, the need for keeping them sufficiently simple for use by the ordinary designer. Dean Grinter raises a practical question that must be faced when he says that "* * * much design work is actually performed by persons of limited competency in structural design." The final answer might be to increase the competence of designers! Whether the immediate answer is to confine the use of column formulas to the Rankine formula and the straight-line formula the writer does not know, especially in view of some of the complicated formulas in use by structural designers in the field of aircraft.

Professor Winter and Mr. Beskin suggest that a discussion of the secant yield strength, S, would be of interest. This question has been raised before. It has been answered partially, in reference to beams, in another paper.[44] To answer it for columns, one may write the double-modulus column formula,

$$\sigma = \frac{1}{\lambda^2_o} \frac{\bar{E}}{E} \qquad (66)$$

and ask under what conditions Eq. 66 represents the same reduced column curve for different materials. In Eq. 66,

$$\bar{E} = \frac{E' I' + E I}{I_g} \qquad (67)$$

in which:

E' is the tangent modulus of elasticity of the material at the stress $s = P/A$;

I' is the moment of inertia about the axis of average stress of the part of the cross-sectional area that is subjected to an increase of stress at the instant of failure of the column;

I is the moment of inertia about the axis of average stress of the part of the cross-sectional area that is subjected to a decrease of stress at the instant of failure; and

I_g is the moment of inertia of the cross-sectional area about a gravity axis parallel to the axis of average stress.

The position of the axis of average stress is defined by the relation $E' Q' = E Q$, in which Q' and Q are the statical moments about the axis of average stress of the two parts of the cross-sectional area just mentioned.

---

[44] "A Rational Definition of Yield Strength," by William R. Osgood, *Journal of Applied Mechanics*, Vol. 7, June, 1940, p. A-61.

If, now, for two materials, Nos. 1 and 2, and for geometrically similar cross sections, the column curves are defined by:

$$\sigma_1 = \frac{1}{\lambda^2_1}\frac{\bar{E}_1}{E_1} \quad \text{(68a)}$$

and

$$\sigma_2 = \frac{1}{\lambda^2_2}\frac{\bar{E}_2}{E_2} \quad \text{(68b)}$$

—what conditions are required to make these two curves the same? For any value of $\sigma_1 = \sigma_2$, the corresponding value of λ_1 is equal to λ_2 if $\bar{E}_1/E_1 = \bar{E}_2/E_2$. From the definition of $\bar{E}$, and the axis of average stress, this is the same as requiring that $E'_1/E_1 = E'_2/E_2$; or

$$\frac{1}{E_1}\frac{ds_1}{de_1} = \frac{1}{E_2}\frac{ds_2}{de_2} \quad \text{(69)}$$

in which e is the compressive strain at the stress s. Since $\sigma_1 = \sigma_2$,

$$\frac{s_1}{S_1} = \frac{s_2}{S_2} \quad \text{(70)}$$

and

$$\frac{1}{E_1}\frac{ds_1}{de_1} = \frac{1}{E_2}\frac{S_2}{S_1}\frac{ds_1}{de_2} \quad \text{(71)}$$

or, upon integration,

$$\frac{E_1\,e_1}{S_1} = \frac{E_2\,e_2}{S_2} \quad \text{(72)}$$

The stresses and strains of the two materials must be related as expressed by Eqs. 70 and 72.

Eqs. 70 and 72 must apply in particular when $\sigma_1 = \sigma_2 = 1$—that is, when s_1 and s_2 are equal to the yield strengths of the two materials. If e_{11} and e_{22} denote the strains corresponding to the yield strengths, Eq. 72 becomes, for this case:

$$\frac{S_1/e_{11}}{S_2/e_{22}} = \frac{E_1}{E_2} \quad \text{(73)}$$

which states that the slopes of the lines through both the origins and the yield strengths of the stress-strain curves must be proportional to the moduli of elasticity of the two materials. This requires that the yield strengths of the two materials be determined as the stresses at the intersections with the stress-strain curves of secants through the origin having slopes equal to $m\,E_1$ and $m\,E_2$, in which m is an arbitrary constant $0 < m < 1$—hence, the name "secant yield strength" for yield strengths so determined.

(In a conversation with the writer, Nathan M. Newmark, M. Am. Soc. C. E., has pointed out that, since $E'_1/E_1 = E'_2/E_2$, at the yield strength, $E'_{11}/E_1 = E'_{22}/E_2$ and therefore the yield strengths may be determined as the stresses at which the slopes of the stress-strain curve are $n E_1$ and $n E_2$, with $0 < n < 1$. This is probably the first time that "Johnson's elastic limit" has been justified on any rational basis. Since it is the slope of the stress-strain curve that is particularly significant in compression members, it may be that Johnson's elastic limit is a better measure of the yield strength than the secant yield strength. However, Johnson's elastic limit does require greater care in its determination than does the secant yield strength.)

The necessary and sufficient conditions, therefore, that Eqs. 68 represent the same curve are that Eqs. 70 and 72 be satisfied at every point and that S_1 and S_2 be secant yield strengths determined with the same value of m. It will always be possible to determine S_1 and S_2 as required. Whether Eqs. 70 and 72 are satisfied at every point depends on the materials considered. Many tests have shown, however, that, for nominally similar materials, such as materials complying with a given specification, Eqs. 70 and 72 are in fact satisfied to a high degree of approximation, even when the yield strengths differ widely.

Finally, the generalization from two materials to any number of materials is obvious, the practical point being that the yield strengths must be determined as secant yield strengths with slopes of the secants equal to $m E$, in which m is the same constant for all the materials being considered and E is the modulus of elasticity of each individual material.

Incidentally, whether Eqs. 70 and 72 are satisfied or not, the scatter in the column data can be reduced by plotting σ against λ_o rather than s against l_o/i, provided S is the secant yield strength. Moreover, no other method is likely to give as good results consistently; and no other method can give as good results if Eqs. 70 and 72 are satisfied at every point and if S is the secant yield strength.

In Mr. Godfrey's opinion, "The Gordon-Rankine formula has limited application. This formula is fraught with danger, if it is used in the range of slender columns." One of the objectives of the paper was to call attention to this kind of danger. If the Rankine formula is written in the form of Eq. 3*b*, in which $B \geqq 0$, the average stress can never exceed the Euler value. If B is chosen to give safe values in the range of "medium" ratios of slenderness, safe values will be obtained for slenderer columns also. The writer agrees with Mr. Godfrey that a factor of safety of 5 in the Euler range is excessive. If a variable factor of safety is used (and it probably should be used in some form), it is the opinion of the writer that the factor should be less for short and for long columns than for columns of medium length, for which λ_o is usually about 1, depending on how S is measured.

In its most general, dimensionless form, Mr. Spaulding's first formula, Eq. 35, may be written

$$\sigma = \frac{1}{\lambda^2_o} \frac{\lambda^4_o + \beta \lambda^2_o + \gamma}{\lambda^4_o + \delta \lambda^2_o + \epsilon} \qquad (74a)$$

and his second one, Eq. 37,

$$\sigma = \frac{\beta + \lambda^2_o}{\gamma + \delta \lambda^2_o + \lambda^4_o} \qquad (74b)$$

(Mr. Spaulding's σ_y—a yield strength—is not to be confused with the writer's σ, which is a dimensionless "stress".) Eq. 74*a* contains four arbitrary constants; and Eq. 74*b*, three. These are too many to determine conveniently and more than are necessary. Mr. Spaulding arbitrarily takes $\beta = \gamma + 1 = \delta = \epsilon + 1$ in Eq. 35 and $\beta = \gamma = \delta$ in Eq. 37, thus reducing the number of constants to one in each formula. In terms of λ_o and σ, the solid curves of Fig. 2(*a*) reduce to one curve.

Laboratory conditions differ from conditions in engineering structures primarily in that the former conditions are usually better known than the latter. Undoubtedly, the most troublesome unknown is k. Mr. Spaulding and Mr. Beskin consider this factor a variable rather than a constant. Perhaps it is better called a parameter. It is usually exceedingly difficult (that is, particularly time consuming) to determine k rationally for a given structure. It seems that k must be determined largely by judgment, although the excellent studies of F. Bleich, M. Am. Soc. C. E., may serve as a helpful guide. The writer is of the opinion that conditions such as unintentional eccentricities and initial curvature are best taken care of by the factor of safety.

Professor Cissel lists four possible modes of failure. The first, compressive failure by crushing the material, is important for "brittle" materials—in structural work, primarily for concrete. It was important for cast iron and may become so again for metals, with the development and use of alloy steels, alloys of aluminum, and alloys of magnesium, for example. The formulas of the paper were concerned implicitly with column failure, Mr. Cissel's second mode of failure. His third mode of failure, twisting, is sometimes lost sight of but must definitely be considered; and perhaps the fourth mode, local failure, is the type most likely to occur, certainly in short columns.

The objection to using, instead of a formula, an averaged curve of experimental results (which Mr. Beskin suggests as a possibility) is that such a curve cannot be transferred readily. No two users would be dealing with the same curve, although a sufficient number of corresponding abscissas and ordinates might be read from a master curve and a list of these points published so that practically the same curve would be drawn by everyone.

It is true, as Mr. Beskin states, that a decreasing function is always a monotonically decreasing function; but a monotonically decreasing function is not always everywhere a decreasing function.

The writer disagrees with Mr. Beskin that the double-modulus theory involves a basic error in theory, in that it presupposes a theoretically straight column. In carefully made and carefully centered columns, if the departures from the ideally assumed conditions were small but sufficiently great to give results differing significantly from those predicted by the theory, then the theory would be in error. Actually, no such significant differences in results are obtained. It is presumably the column that is in error, not the theory; that is, the imperfections in the column lead to results not in complete accord with those predicted by the theory.

When the writer stated "It would be very hard to justify more than two constants of the material in any practical column formula," he had in mind the dimensionless constants of the formulas written in terms of λ_o and σ.

As Mr. Beskin states, the formulas in terms of l_o/i and P/A all contain one more constant—namely, E, the modulus of elasticity of the material.

To choose for the constant S the intercept S_o of the column curve with the axis of P/A, as Mr. Beskin would prefer, sounds easier than it is. It is not so easy to determine this intercept. A column of zero length has practically infinite strength; and, if S_o is to be determined by extrapolation, extrapolation of what? If the material tested is all uniform and has the same mechanical properties, and if the cross sections of all specimens are geometrically similar, it may be possible by extrapolation from low values of l_o/i to arrive at a fairly definite value of S_o for that material and that cross section. This value of S_o has no significance for a different, but nominally the same, material and a different shape of cross section.

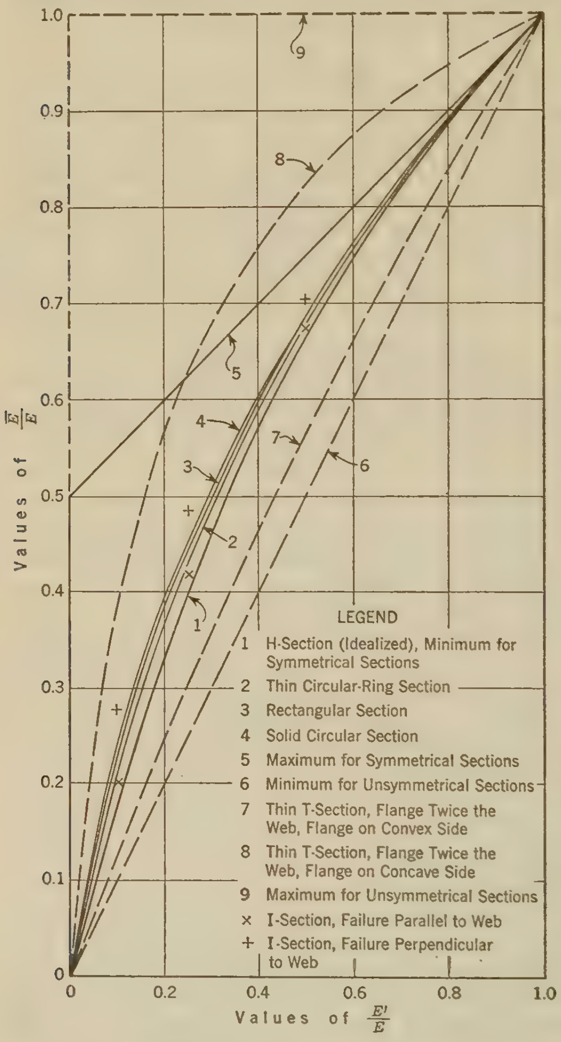

FIG. 8.—THE EFFECT OF THE SHAPE OF THE CROSS SECTION ON THE STRENGTH OF COLUMNS

Mr. Beskin calls attention to the effect of the shape of cross section on column strength. The effect of shape is illustrated in Fig. 8, in which $\bar{E}/E$ is shown as a function of E'/E for a number of cross sections.[4] Since E' is the slope of the stress-strain curve—that is, the tangent modulus at a particular stress—the abscissas also represent stresses to some scale. For a given value of E'/E that is not too small, the spread in $\bar{E}/E$ for practical symmetrical sections is seen not to be excessive. The same is not true of unsymmetrical sections, where large variations in $\bar{E}/E$, and thus in the strength (Eq. 66), may be obtained.

Mr. Beskin regrets that the dimensions of the constants in Eqs. 3 to 21 are not the same throughout all the formulas, but he does not say why. Perhaps he would have liked the dimensionless constants of the first forms, Eqs. 3*a* to 21*a*, to have been retained in the second forms, Eqs. 3*b* to 21*b*; but it seemed to the writer that this would merely clutter up these formulas unnecessarily. The constants are not intended to have the same values in each formula. Thus, whether Eq. 13 gives values less than the Rankine formula depends on the values of B and C in Eq. 13, on the one hand, and on the value of B in Eq. 3 on the other hand. There is no connection between the value of B in Eq. 13 and the value of B in Eq. 3. The writer regrets the confusion that might have been avoided by using different letters for the constants in all the formulas.

As for the necessity for a cutoff when Eqs. 15 and 18 are used, it may be stated in general that any formula may need a cutoff if the material fails at a lower stress than the column stress. Cutoffs may also be needed to take account of crinkling failure without bending of the column as a whole.

Eqs. 15 and 18 were derived by methods published elsewhere.[4] When the column strength is represented by

$$\sigma = \frac{1}{\lambda^2_o} \frac{E'}{E} \qquad \text{(75)}$$

and, when

$$K\,n \left(\frac{S}{E}\right)^{n-1} = \beta \qquad \text{(76a)}$$

Eq. 17 leads to Eq. 15*a*. When the column strength is represented by Eq. 66 with $\bar{E}$ the double modulus for an idealized H-section (negligible web); and, when

$$\frac{1}{2} K\,n \left(\frac{S}{E}\right)^{n-1} = \beta \qquad \text{(76b)}$$

Eq. 17 also leads to Eq. 15*a*. When, in Eq. 66, $\bar{E}$ is the double modulus for a rectangular cross section, and β is defined by Eq. 76*a*, Eq. 17 leads to Eq. 18*a*.

Both Eqs. 15 and 18 were intended to be purely empirical column formulas, with the β's and n's to be determined as the results of tests. On the other hand, Eq. 75 and the resulting formula, Eq. 15*a*, with β in effect given by Eq. 76*a*, have received wide experimental confirmation in ordinary, carefully made laboratory tests for a wide variety of structural materials. The writer would feel much more confident in predicting column strength of a new material from Eq. 75, Eq. 15*a* and Eq. 76*a*, or Eq. 65*a*, than from the secant formula.

Mr. Balog's "ideal conditions" (second paragraph of his discussion), leading to a column curve composed of Euler's curve and a horizontal line (Fig. 5), include of necessity an "ideal" compressive stress-strain curve composed of a modulus line and a horizontal yield line. Most structural materials do not have so simple a stress-strain curve; in particular, they do not have the sharp knee of Mr. Balog's ideal material. The blunter the knee, the wider the gap will be between the "ideal" column curve and the actual column curve.

Mr. Balog writes that an infinite variety of double-modulus curves is possible between the proportional limit and yield stress for the same steel. If the steel is really the same, only one double-modulus curve is possible, and the writer believes Mr. Balog is mistaken, unless he means that an infinite variety is possible depending on the shape of the cross section; but, as noted previously, the column strength does not vary very much with different symmetrical shapes in common use.

The writer was not aware that he made any "summary assumptions for the buckling lengths." The free length, or the buckling length, is one of the most difficult variables, if not the most difficult, to evaluate in the design of columns; and the writer is just as much against summary assumptions in this case as is Mr. Balog.

THE EFFECT OF BLANKETS ON SEEPAGE THROUGH PERVIOUS FOUNDATIONS

BY PRESTON T. BENNETT,[1] ESQ.

WITH DISCUSSION BY MESSRS. REGINALD A. BARRON, V. A. ENDERSBY, HARRY R. CEDERGREN, W. J. TURNBULL, KENNETH S. LANE, AND PRESTON T. BENNETT.

SYNOPSIS

A mathematical analysis of seepage through natural or artificial blankets of relatively impervious soil overlying a pervious foundation is presented in this paper, indicating methods for the application of formulas to the design of earth dams. Since natural foundations rarely if ever approach the simplicity of structure and the uniformity assumed in this analysis, the blanket formulas should not be considered as an accurate means of computing flow conditions, but as an aid to the judgment of the designer.

INTRODUCTION

In the design of earth dams built on pervious foundations, there appears to be a trend toward the control of seepage through the foundation by construction of an upstream blanket connected to the impervious section of the dam, and providing drainage for the downstream section of the dam by horizontal pipe drains or by a system of vertical drainage wells. In dams where the control of seepage is undertaken primarily to increase the stability of the structure, rather than to reduce seepage losses to a minimum, this design offers several advantages over a central impervious section in the dam, and a cutoff through the foundation.

In the latter design, practically all the hydrostatic pressure of the reservoir is exerted on the central core and cutoff, and the downstream half of the dam must have slopes sufficiently flat to withstand the full pressure of the reservoir. If the reservoir head is dissipated through a blanket and upstream impervious section, a much larger portion of the dam is effective in offering resistance to the hydrostatic pressure. Furthermore, the flow of water through the upstream impervious section is almost vertically downward toward the pervious founda-

[1] Engr. (Soil Mechanics), U. S. Engr. Office, Missouri River Div., Omaha, Nebr.

tion, which is maintained at a relatively low hydrostatic potential by the combined action of the upstream blanket and the downstream drainage system. There is little tendency, upon sudden drawdown of the reservoir, for the water saturating the upstream section to flow back into the lowered reservoir, and hence the adverse conditions resulting from drawdown are reduced to a minimum. If an excess of impervious material unsuitable for embankment construction is available, the most important advantage of the blanket lies in the economic use of waste material, rather than in the use of a costly cutoff wall.

Quite commonly the alluvial deposit in a river valley consists of a stratum of sand and gravel overlain by a surface layer of relatively impervious finer soils. It is advantageous to leave such a blanket in place for seepage control, but it may be desirable, on the other hand, to remove a part of it to reduce the haul from upstream borrow pits. If the natural blanket is sufficiently uniform in thickness and permeability to justify the application of blanket design theory, the formulas developed herein may be of assistance to the designer in establishing limits for borrow-pit excavation, which will not reduce the blanketing effect materially.

The mathematical analysis of flow through blankets presented herein is of necessity based on idealized assumptions as to the uniformity of permeability and thickness of the pervious stratum and blanket. As in any other phase of soil mechanics, the validity of any conclusions based on this analysis is limited by the degree to which these idealized conditions are approached in nature, and likewise by the degree of accuracy obtainable in the determination of the permeability of the soils involved.

Since natural deposits of soils cannot be expected to be uniform in thickness or permeability, and since the determination of the permeability of such deposits can result at best only in a good approximation, the formulas in the paper are not intended to represent, accurately, the actual conditions of flow and potential distribution under a dam. Nevertheless, if several values for the permeability and thickness of the blanket and pervious stratum are used, covering the estimated range of variation of these factors, the resulting analytical evaluation of a blanket should be of value as an indication of the probable limits of its effectiveness.

NOTATION

The letter symbols in this paper are defined where they first appear, in the text or by illustration, and are assembled for convenience of reference in Appendix I.

ASSUMPTIONS

The following derivation is applicable only when the ratio of foundation permeability to blanket permeability is large—say 10 to 1 or greater. If the contrast in permeability is small, the assumption that flow is vertical through the blanket and horizontal through the foundation may not be warranted. Furthermore, it has been assumed that the vertical plane through the upstream end of the blanket is an equipotential surface at full reservoir head. Actually, the equipotential plane coincides with the bottom of the reservoir, and in the cases represented subsequently by Eqs. 9*a*, 12*a*, and 18*a*, a small loss of head occurs between the true and assumed equipotential surfaces. However, if the length of the path of flow through the foundation is great as compared to the depth of the foundation, this head loss is negligible as compared to the errors due to nonuniformity of natural soils. The assumptions relative to direction of flow and potential distribution at the boundaries are shown in Fig. 1.

(b) POTENTIAL GRADIENT IN FOUNDATION

Fig. 1.—Assumed Direction of Flow, and Potential Distribution at the Boundaries

General Case

At any point x, under the blanket (Fig. 2), the horizontal flow through the foundation is equal to the flow through the blanket upstream from that point, plus the inflow under the upstream end of the blanket. That is:

$$q_f = \int_0^x dq_b + q_{f0} \qquad (1)$$

The vertical flow dq_b, through a small element of the blanket, of width dx and thickness z_b, varies directly with the head loss h, and inversely with blanket thickness z_b, so that

$$dq_b = \frac{k_b\, h\, dx}{z_b} \qquad (2)$$

In the interval dx, the horizontal flow in the pervious stratum is increased by an amount equal to the vertical inflow dq_b, so that

$$\frac{dq_f}{dx} = \frac{dq_b}{dx} = \frac{k_b\, h}{z_b} \qquad (3)$$

Since

$$q_f = k_f\, z_f \frac{dh}{dx} \qquad (4a)$$

it follows that

$$\frac{dq_f}{dx} = k_f\, z_f \frac{d^2h}{dx^2} \qquad (4b)$$

and, from Eq. 3,

$$\frac{d^2h}{dx^2} = \frac{k_b\, h}{z\, k_f\, z_f} \qquad (4c)$$

Using the notation $a = \sqrt{\dfrac{k_b}{z_b\, k_f\, z_f}}$ for blankets of uniform thickness, and $\alpha = \dfrac{k_b}{k_f\, z_f}$ for blankets of variable thickness, Eq. 4c may be written:

$$\frac{d^2h}{dx^2} = a^2\, h \qquad (5a)$$

or

$$\frac{d^2h}{dx^2} = \frac{\alpha\, h}{z_b} \qquad (5b)$$

For a blanket of constant thickness and infinite horizontal extent, the solution to Eq. 5a is

$$h = h_0\, e^{ax} \qquad (6)$$

in which h_0 is the head loss through the blanket at point $x = 0$, which is taken for convenience in this case at the downstream end of the blanket. This solution is verified by successive differentiation:

Fig. 2.—Relation Between Resistance, Head Loss, and Gradient

$$\frac{dh}{dx} = a\, h_0\, e^{ax} = a\, h \qquad (7a)$$

and

$$\frac{d^2h}{dx^2} = a^2\, h_0\, e^{ax} = a^2\, h \qquad (7b)$$

The resistance x_r is a measure of the efficiency of a blanket. It may be defined as the length of a prism of the foundation material, of thickness z_f and permeability k_f, which, under head loss h, would carry a flow equivalent to the flow which passes the blanket system under the same head loss. The relation between resistance, head loss, and gradient is shown graphically in Fig. 2.

Defined algebraically, $x_r = \frac{h}{\frac{dh}{dx}}$; or, for this case,

$$x_r = \frac{h}{a\,h} = \frac{1}{a} = \sqrt{\frac{z_b\,k_f\,z_f}{k_b}} \qquad (8)$$

Eq. 8 may be used to estimate the effectiveness of a natural surface layer as a blanket when none of the fine material is removed for borrow, and all the seepage enters the substratum by percolation through the blanket.

If part of a natural blanket is removed, the substratum is exposed directly to full reservoir head, and a part of the flow enters the foundation sand at the upper limit of the blanket. For this case, the solution of Eq. 5*a* is

$$h = h_n\,(e^{ax} - e^{-ax}) \qquad (9a)$$

$$\frac{dh}{dx} = a\,h_n\,(e^{ax} + e^{-ax}) \qquad (9b)$$

$$\frac{d^2h}{dx^2} = a^2\,h_n\,(e^{ax} - e^{-ax}) = a^2\,h \qquad (9c)$$

and

$$x_r = \frac{e^{ax} - e^{-ax}}{a\,(e^{ax} + e^{-ax})} = \frac{e^{2ax} - 1}{a\,(e^{2ax} + 1)} \qquad (9d)$$

In Eqs. 9, $x = 0$ at the upstream edge of the blanket, and h_n is a constant depending on the total head loss of the system of which the blanket is a part, and on the ratio of the blanket resistance to the remainder of the system. The value of h_0 in Eq. 7*a* is determined in the same manner. For example, assume a top stratum varying in thickness from 10 ft to 15 ft, overlying a sand foundation 50 ft to 60 ft thick, and assume that the ratio of blanket permeability to foundation permeability varies between 0.005 and 0.01. The extreme values of a, as computed from these dimensions, are 0.00246 and 0.0045, corresponding to resistances of 425 ft and 225 ft. If Δh and x_d (see Fig. 2) are, respectively, 80 ft and 750 ft for the dam in question, and, if 300 ft is adopted as the average resistance of the blanket, the effective total length of the percolation path is 1,050 ft, and the head loss through the blanket is 300/1,050 × 80, or 23 ft. Using $a = 0.0033$, corresponding to $x_r = 300$, and $h_0 = 23$, Eq. 7*a* becomes, in this case,

$$h = 23\,e^{0.0033x} \qquad (10)$$

The value of h_n, in Eq. 9*a*, is determined after computation of a definite value of h at the lower end of the blanket, using the relation between Δh, x_d, and x_r indicated graphically in Fig. 2 and as illustrated in the preceding example.

Ordinarily, for upstream blankets, the pressure distribution under the blanket is not of great interest, and the computation of constants for Eq. 6 or 9*a* need not be made, since the determination of x_r is all that is necessary for the estimation of pressures under the dam, or for computation of the approximate horizontal flow or discharge per linear foot of dam, which is

$$q_f = \frac{k_f\,z_f\,\Delta h}{x_r + x_d} \qquad (11)$$

Under downstream blankets, however, the substratum pressures are of considerable importance, and Eqs. 6 and 9*a* may be used in the design of the downstream drainage system to estimate the pressures that would exist if no drainage were provided, and if the underseepage were forced to find its way to the surface against the resistance of an impervious top stratum. When used for downstream blankets, the head loss h is referred to the ground surface (assumed level) downstream from the dam, or to tailwater elevation if the downstream toe is submerged.

The curves in Fig. 3 give values of x_r computed from x and a by the use of Eq. 9*d*. The curves for x_r and $\frac{z_b\,x}{\alpha}$ are plotted on the a-scale and the x-scale; and the curves for z_b are plotted on the a-scale and the α-scale. Suppose, in the foregoing example, that it is desired to excavate the natural blanket for use as fill material, leaving in place enough to provide a resistance of 200 ft. Using the higher of the limiting values of a (Fig. 3), the curve $x_r = 200$ intersects $a = 0.0045$ at $x = 330$ ft, the length of blanket to be left in place.

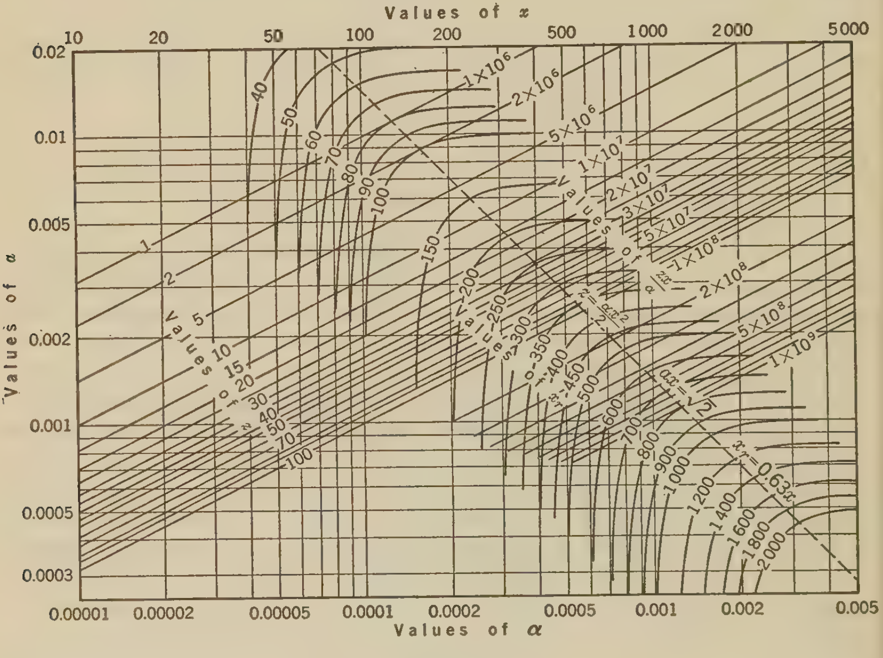

Fig. 3.—Resistance Curves

It is apparent from the curves of Fig. 3 that the ratio of resistance to blanket length, for any value of a, decreases rapidly as the length is extended beyond that indicated by the diagonal line $a\,x = \sqrt{2}$ in Fig. 3, and that very little benefit is to be gained either by leaving a natural blanket in place to great distances above a dam, or by the construction of an artificial blanket of uniform thickness and excessive length. These considerations lead to the conclusion that, if a blanket is to be built, its thickness probably should be reduced at the upstream where the blanket is relatively ineffective, and increased near the dam, interposing an additional thickness of impervious material where the head loss through the blanket is greatest.

This procedure would result in a blanket of triangular section, for which the resistance may be determined by substituting $s\,x$ for z_b in Eq. 5*b*, s being the slope of the blanket surface, and x the blanket length measured from its upstream edge. The solution for this case, as developed by Stanley U. Benscoter, Jun. Am. Soc. C. E., is as follows:

$$h = h_n \left\{ x + \frac{\alpha\,x^2}{2\,s} + \frac{\alpha^2\,x^3}{2!\,3!\,s^2} + \cdots + \frac{\alpha^{(n-1)}\,x^n}{(n-1)!\,n!\,s^{(n-1)}} \right\} \ldots\ldots (12a)$$

$$\frac{dh}{dx} = h_n \left\{ 1 + \frac{\alpha\,x}{s} + \frac{\alpha^2\,x^2}{[2!]^2\,s^2} + \cdots + \frac{\alpha^{(n-1)}\,x^{(n-1)}}{[(n-1)!]^2\,s^{(n-1)}} \right\} \ldots\ldots (12b)$$

and

$$\frac{d^2h}{dx^2} = h_n \left\{ \frac{\alpha}{s} + \frac{\alpha^2\,x}{2\,s^2} + \cdots + \frac{\alpha^{(n-1)}\,x^{(n-2)}}{(n-2)!\,(n-1)!\,s^{(n-1)}} \right\} \ldots\ldots (12c)$$

If Eq. 12*c* is multiplied by $\frac{s\,x}{\alpha}\left(= \frac{z_b}{\alpha}\right)$, the right-hand side becomes identical with the value of h in Eq. 12*a*, and the resulting equation

$$\frac{d^2h}{dx^2}\,\frac{z_b}{\alpha} = h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

verifies Eq. 12*a* as a solution of Eq. 5*b* for the triangular blanket.

The value of x_r, obtained by dividing Eq. 12*a* by Eq. 12*b*, is

$$x_r = x - \frac{\alpha\,x^2}{2\,s} + \frac{\alpha^2\,x^3}{3\,s^2} - \frac{11\,\alpha^3\,x^4}{48\,s^3} + \frac{19\,\alpha^4\,x^5}{120\,s^4} \ldots\ldots\ldots\ldots (14)$$

This series converges very slowly, and is not adapted to numerical computations. Eqs. 12*a* and 12*b* are somewhat better suited to numerical work, and x_r can be obtained from h and $\frac{dh}{dx}$ as computed from these series. Using this method, values of x_r for several triangular sections have been computed, and compared with the resistances of uniform sections of equal end area. From these comparisons, it appears that the resistance of a triangular section is approximately equal to that of a rectangular section of the same end area, if the length of the latter is one half the length of the triangular section.

The numerical difficulties involved in computing the resistance of a triangular section can be avoided by substituting a vertically curved surface profile,

$$z_b = \frac{\alpha\,x^2}{n\,(n-1)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

for the tangent profile $z_b = s\,x$. This substitution is made only to facilitate computations, and it is not recommended that blankets be constructed to fit the curves used for purposes of analysis. For the curved surface indicated by

Eq. 15 the solution to the general formula (Eq. 5*b*) is

$$h = h_n x^n \qquad (16a)$$

$$\frac{dh}{dx} = n\, h_n\, x^{(n-1)} \qquad (16b)$$

and

$$\frac{d^2h}{dx^2} = n\,(n-1)\, h_n\, x^{(n-2)} \qquad (16c)$$

The solution is verified by substituting values of z_b and h from Eqs. 15 and 16*a* in Eq. 16*c*. From Eqs. 16*a* and 16*b* the resistance is

$$x_r = \frac{x}{n} \qquad (17)$$

The use of Eqs. 15 and 17 to approximate the resistance of a triangular section is shown by the following examples, computed for a blanket 500 ft long, which varies uniformly from 0 to 10 ft in thickness, and is built on a pervious stratum 40 ft thick, of such permeability that $\frac{k_b}{k_f} = 0.005$. For these conditions, $\alpha = \frac{k_b}{k_f\, z_f} = 0.000125$ and a curved section conforming to Eq. 15 will have a thickness of 10 ft at $x = 500$ ft when $n\,(n-1) = 3.12$, or $n = 2.34$. The resistance of this section is $500/2.34 = 214$ ft. Another approximation of the triangular section may be made by selecting n (Eq. 15) so that the end area of the parabolic section equals that of the triangular shape. For the preceding example, this gives $n = 2.04$ and $x_r = 245$ ft. Using the assumption that the triangular section 500 ft by 10 ft is equivalent to a uniform section 250 ft by 10 ft, Fig. 3 gives $a = 0.0035$ (for $z_b = 10$ and $\alpha = 0.000125$) and $x_r = 200$ when $x = 250$.

Considering the fact that the basic data used in the computations will be only approximately correct, the foregoing approximate values of the resistance of a triangular section are in sufficiently close agreement to justify the use of either Eq. 9*d* or 17 in estimating the efficiency of this type of blanket. The approximate relationship between rectangular and triangular sections, thus far developed, however, does not furnish any answer to the question raised as to the relative merits of the two sections. Referring again to Fig. 3, it will be seen that the diagonal lines that represent constant blanket thickness, when referred to the α-scale and the a-scale, also represent constant values of the sectional area $z_b\, x$ when referred to the x-scale and the a-scale on which the x_r-curves are plotted. These constant-area curves may be used to estimate the optimum dimensions of a rectangular section if the quantity of blanket material is fixed. For example, suppose that 20,000 cu yd of blanket material per station is available, and that its permeability is such that $\alpha = 0.0001$. The sectional area is then 5,400 sq ft, and $\frac{z_b\, x}{\alpha} = 5.4 \times 10^7$. The maximum resistance (300 ft) is found at $x = 475$, and the corresponding thickness is 11.4 ft. If the blanket material were much more pervious, so that $\alpha = 0.0027$ and $\frac{z_b\, x}{\alpha} = 2 \times 10^6$, the optimum length would be 160 ft, the thickness 34 ft, with a resistance of 100 ft. However, by following the line $\frac{z_b x}{\alpha} = 2 \times 10^6$ to intersect $x_r = 90$ at $x = 105$ and at $x = 250$, it is seen that the optimum length may be reduced by about 34% or increased by about 56% with a loss of only 10% in resistance, if the thickness is correspondingly changed to retain the same sectional area. Since the x_r-curves are spaced to conform to the logarithmic x-scale, the same ratio of loss of resistance to increase or decrease from the optimum value of x holds true for any value of x on the broken line $a x = \sqrt{2}$.

Since Fig. 3 is approximately applicable to triangular sections if the base length is considered to be $2x$, it appears that either the triangular or rectangular shape may be used with equal effectiveness, and that for either section a considerable departure may be made from the theoretical optimum dimensions without great loss of efficiency. It is concluded, therefore, that feasibility of construction should govern the dimensions of a blanket, as long as the extremes of inefficiency represented by the ends of the x_r-curves in Fig. 3 are avoided.

For a combination of natural and artificial blankets, such as is shown in Fig. 4(a), it is again convenient to represent the triangular section by an approximately equivalent parabolic section to simplify the computations. It can be shown analytically that, if $n = 2$ in Eq. 15, the maximum resistance can be obtained from a fixed sectional area. (It is of interest to note that the relationship, between z_b and x for the most favorable ratio of $\frac{x_r}{z_b x}$, is identical

for the curved section as obtained analytically, and for the rectangular section as obtained graphically by the curves in Fig. 3.) The arbitrary use of $n = 2$ simplifies computation, and at the same time permits the development of a formula adapted to use in designing combination blankets. Let the vertical gradient $\frac{h}{z_b}$ be a constant, i. Then

$$z_b = \frac{h}{i} = \frac{\alpha x^2}{2} + \beta x + z_{b0} \qquad (18a)$$

$$\frac{dh}{dx} = i(\alpha x + \beta) \qquad (18b)$$

$$\frac{d^2h}{dx^2} = i\alpha = \frac{\alpha h}{z_b} \qquad (18c)$$

and

$$x_r = \frac{z_b}{\alpha x + \beta} \qquad (18d)$$

At the upstream end of this section $x = 0$, $h = i z_{b0}$, and $\frac{dh}{dx} = i\beta$. If the upstream end adjoins the lower end of another blanket for which the head loss and foundation gradient are numerically equal to $i z_{b0}$ and $i\beta$, there will be no discontinuity in the foundation flow. This condition may be met by choosing values of β and z_{b0} in Eq. 18a such that

$$\frac{z_{b0}}{\beta} = \frac{h}{\frac{dh}{dx}} = x'_r \qquad (19)$$

in which x'_r is the resistance of the upstream blanket.

An application of Eqs. 18 and 19 is shown in Fig. 4, representing an artificial blanket, whose permeability k_{b1} is 0.25 ft per day, constructed on a natural blanket 10 ft thick with a permeability $k_{b2} = 5$ ft per day. The natural blanket may be replaced, for purposes of computation, by one having a thickness of 0.5 ft and a permeability of 0.25 ft per day, equal to that of the artificial section, without changing its resistance, which for infinite length is $\sqrt{\frac{10 \times 300 \times 40}{5}}$ or 155 ft. From the dimensions shown in Fig. 4, the value of α for the artificial blanket is 1/48,000 and z_{b0} is 0.5 ft, the reduced thickness of the natural blanket. Using these constants in Eq. 18a, and $\beta = 0.0032$, computed from Eq. 19,

$$z_b = \frac{x^2}{96{,}000} + 0.0032\,x + 0.5 \qquad (20)$$

in which z_b includes the reduced thickness of the blanket already in place. If the size of the blanket is limited by availability of material to a sectional area of 6,000 sq ft for the case under consideration, the length is found to be about 1,100 ft from Eq. 20, and the corresponding thickness at the dam is 16.2 ft, or 16.7 ft, including the reduced thickness of the original surface layer. From Eq. 18d, the resistance is $\frac{16.7}{0.023 + 0.003}$ or 640 ft, which includes the effect of the natural blanket upstream from the point where no additional material is placed.

From Fig. 4(*a*), the length of the path of flow under the dam is 370 ft, and the resistance of the system 1,165 ft if it is assumed that no seepage takes place through the dam proper. The pressure gradient in the foundation, as determined by these computed resistances, is shown in Fig. 4(*b*). In this example it has been assumed for the sake of simplicity that the entire dam is impervious, and that all the seepage must escape through the downstream blanket. In actual design, foundation drainage would ordinarily be provided in the form of a pervious drainage blanket within the dam, a system of pressure relief wells, or a horizontal pipe drain, and the path of flow or resistance downstream from the blanket would be less than in the example given. A discussion of downstream drainage facilities is outside the scope of this paper, but, since a knowledge of the downstream resistance is necessary in evaluating the effectiveness of a blanket, approximate methods for estimating the path of flow under the dam are included in Appendix II.

As previously stated, the curved section, shown by the dotted line in Fig. 4(*a*), was adopted for purposes of computation only, and would be replaced in actual construction by an equivalent section of similar shape, as indicated. Theoretically, the vertical gradient is constant over the entire length of the curved section, and therefore the curve represents an efficient and well-balanced section which should serve as a good guide in the selection of the actual blanket shape adopted for construction.

Subject to the limitations previously stated as to accuracy of the basic data used in the computations, the formulas for uniformly thick blankets may be used to estimate the substratum pressures downstream from a dam when no drainage is provided, as in the section shown in Fig. 4(*a*). In this example, although the natural blanket has a relatively low resistance, the computations indicate the desirability of a downstream drainage system, and at the same time provide a method whereby the discharge from the system may be estimated.

SUMMARY

The foregoing analysis of flow through blankets is based on assumed conditions which are approached very closely when the ratio of foundation to blanket permeability is large, and when the length of the horizontal path of flow is large as compared to the thickness of the pervious foundation. When these conditions are met, the formulas are mathematically exact for practical purposes.

The difficulty of accurate determination of the permeability of the soils in place, and the nonuniformity of thickness and permeability of natural deposits, constitute the greatest source of error in use of this analysis in design. However, since the same sources of error are present in analysis of flow by models, the analytical method is to be preferred for blanket studies when the foundation may be assumed to consist of a single pervious layer. If the foundation is separated into two or more distinct strata by impervious lenses, a model study would be the better method to investigate the resulting complex flow pattern.

In view of the uncertainties as to the thickness and permeability of natural strata involved, it might first appear that the methods of analysis presented herein are unnecessarily elaborate. The methods have been developed in considerable detail, however, in the belief that the general principles involved, in the design of blankets, could best be presented by a mathematical analysis, and that the application of these principles to blanket problems, although not leading to exact results, will provide, in many cases, an improved method of estimating blanket performance.

APPENDIX I

NOTATION

The following letter symbols, used in this paper, conform essentially with "Soil Mechanics Nomenclature"[2] adopted by the Society's Board of Direction in 1941:

a = an abbreviated notation for $\sqrt{\frac{k_b}{z_b\, k_f\, z_f}}$;

α = an abbreviated notation for $\frac{k_b}{k_f\, z_f}$;

β = a constant, equal to the slope of a curved blanket at $x = 0$;

e = base of natural logarithms;

h = head or potential at any point, x, in the foundation (referred to reservoir potential) and equal to the head loss through the blanket at point x; h_1, h_2, etc. = head at specified points in the foundation:

$\frac{dh}{dx}$ = horizontal potential gradient in the foundation;

$\frac{d^2h}{dx^2}$ = rate of change of $\frac{dh}{dx}$, proportional to inflow through the blanket;

h_n = a constant factor for computing h, determined by the relationship between the blanket and the flow system as a whole;

h_0 = head loss through the blanket at point $x = 0$;

i = vertical potential gradient through blanket, for special case of constant gradient;

k = permeability; k_b = permeability of the blanket material, which influences the vertical seepage path; and k_f = permeability of the foundation material, which influences the horizontal seepage path.

n = an arbitrary constant defining the profile of curved blanket surfaces;

q = flow per unit width; q_1, q_2, q_3, etc. = flow through designated sections of the blanket or foundation;

q_b = vertical flow per unit width, through the blanket; d_{qb} = element of vertical flow through an element dx of the blanket;

q_f = horizontal flow, per unit width, through the foundation;

q_0 = inflow to the foundation under the upstream end of the blanket;

s = z/x, the slope of the surface of a triangular blanket;

x = horizontal distance measured positive in the direction of flow; dx = an element of the distance x;

x_r = resistance of a blanket, being the effective length of the path of flow under the blanket;

---

[2] *Manual of Engineering Practice No. 22*, Am. Soc. C. E., 1941.

z = thickness of a blanket, when the thickness is variable;
z_0 = thickness of blanket at $x = 0$;
z_b = thickness of a blanket when the thickness is constant; and
z_f = thickness of the foundation stratum.

APPENDIX II

Flow Under the Dam Proper

A principle which may be used, in some cases, to estimate the characteristics of flow under the dam itself is illustrated by analogy with the flow under the composite blanket shown in Fig. 4(*a*). Controlling points and slopes on the pressure gradient curve of Fig. 4(*b*) may be obtained without recourse to the equations defining h in terms of x, as follows: Assign any convenient value, say, $h_1 = 1.55$ ft to the head loss through the natural blanket at its junction with the artificial blanket. Under this head, the foundation gradient at this point is $1.55/155 = 0.01$, since the natural blanket resistance is 155 ft, and $q_1 = 0.01\ k_f\ z = 120$ cu ft per day. For this particular case, the vertical gradient through the artificial blanket is constant throughout its length, and is equal to the maximum gradient through the natural blanket. In terms of the reduced thickness of 0.5 ft, the constant vertical gradient is $1.55/0.5 = 3.1$, and the flow through the artificial blanket is $q_2 = 3.1 \times 0.25 \times 1{,}100 = 853$ cu ft per day, making the

total foundation flow at the lower end of the blanket system 973 cu ft per day, with a corresponding horizontal gradient of $\frac{q_1 + q_2}{k_f z_f} = 0.081$. For purposes of computing the head loss at the lower end of the blanket system, the uniform inflow through the artificial blanket may be considered concentrated at its midpoint, and the inflow through the natural blanket as concentrated at a point 155 ft upstream from its lower end. For this assumed condition, the foundation gradient would be two tangents to the actual gradient curve, intersecting at the midpoint of the artificial blanket as shown in Fig. 4(*b*), and the numerical value of $h_2 = 52.5$, corresponding to the assumed value of $h_1 = 1.55$, may be computed from the tangent slopes as indicated in Fig. 5.

In Fig. 5, the blanket is identical with that in Fig. 4, but the dam section consists of an upstream "impervious" section having the same permeability as the blanket, and has a downstream drainage blanket of very high permeability, such that seepage entering it from the foundation will be carried off without appreciable resistance, and the drainage blanket may be assumed to be at tailwater potential. The flow through the impervious upstream section will be principally downward, and the vertical gradient may be roughly estimated as a mean between the value at the lower end of the blanket and the value at the line of saturation, where the vertical gradient for gravity flow may be taken as 1.0. On the basis of these assumptions, the average downward gradient through the dam is 2.0, and over a horizontal distance of 120 ft as shown in Fig. 5, the inflow q_3 is $2 \times 0.25 \times 120 = 60$ cu ft per day. The "center of gravity" of the inflow is somewhat upstream from the center of the 120-ft interval—say 50 ft downstream from the end of the blanket. At this point the hypothetical gradient shown by the broken line in Fig. 5 changes from 0.081 to 0.086 as a result of the increased flow, and the foundation head loss at the upstream end of the drainage blanket is accordingly 66.8 ft. Assuming no back pressure in the drainage blanket of the dam, the resistance of the natural blanket remains 155 ft and in this distance downstream the additional head loss, computed from the gradient of 0.086, is 13.5 ft making a total hypothetical head loss of 79.9 ft resulting from the initial arbitrary assumption of 1.55-ft loss through the upstream natural blanket. Since the actual head on the system is 60 ft, the preliminary head losses and gradient are corrected by the factor 60/79.9 to give the controlling points on the actual head loss profile, as shown by the solid line in Fig. 5. The computed head loss through the blanket system is 39 ft, or two thirds the total loss of the system.

The foregoing example illustrates, in a general way, the methods which may be used for estimating the over-all flow characteristics of a pervious foundation, and which may be modified to take into account toe drainage by longitudinal drains or pressure relief wells. It is to be noted that the effect of horizontal flow in the dam has been neglected entirely in this approximation, and that this method is not applicable where the flow is substantial as compared to the seepage through the foundation.

DISCUSSION

REGINALD A. BARRON,[3] JUN. AM. SOC. C. E.—The efficiency of upstream blankets for dams and dikes has been presented in an interesting manner by Mr. Bennett. The writer agrees with the author as to the effects of variations in extent and physical properties of natural soil deposits, and believes that the simplifying assumptions made in the paper are quite acceptable. The difference in permeability between natural blanket and underlying pervious layer quite easily may be greater than 1 to 10 when the effect of stratification is considered.

The writer has developed and used comparable equations particularly for the study of hydraulic pressures on the lower side of a natural blanket for conditions shown in Fig. 6. In this case an earth embankment with a central impervious core and flanking pervious shells rests upon a natural blanket which in turn rests upon a more pervious deposit in direct contact with the upstream pool. The assumptions are quite similar to those of the author. In the length L_1, it is assumed that the flow is vertically downward in the blanket. In the length $L_2 - L_1$, seepage through the embankment and the underlying blanket is neglected. In the remaining length $L_3 - L_2$, the seepage through the blanket is vertically upward. In the pervious deposit the seepage is considered to occur in a horizontal direction only.

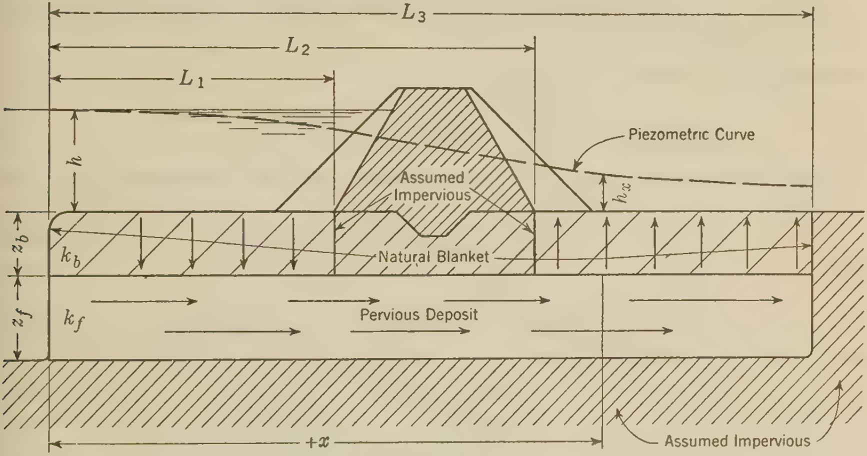

FIG. 6.

The differential equations based upon continuity of flow are: For $0 < x < L_1$,

$$-k_f \frac{d^2h_x}{dx^2} \cdot z_f = +k_b \frac{h - h_x}{z_b} \qquad \text{(21a)}$$

for $L_1 < x < L_2$,

$$-k_f \frac{d^2h_x}{dx^2} \cdot z_f = 0 \qquad \text{(21b)}$$

---

[3] Associate Engr. (Soil Mechanics), U. S. Engr. Office, Providence Dist., Providence, R. I.

and, for $L_2 < x < L_3$,

$$+ k_f \frac{d^2 h_x}{dx^2} \cdot z_f = + k_b \frac{h_x}{z_b} \qquad \text{(21}c\text{)}$$

in which h_x is the elevation of the piezometric height above land-side tailwater.

The boundary conditions are:

1. At $x = 0$, $h_x = h$;
2. At $x = L_1$, h_x obtained from Eq. 21*a* equals h_x obtained from Eq. 21*b*;
3. At $x = L_1$, the gradient, $\frac{dh_x}{dx}$, obtained from Eq. 21*a*, is equal to the gradient, $\frac{dh_x}{dx}$, obtained from Eq. 21*b*;
4. At $x = L_2$, h_x obtained from Eq. 21*b* equals h_x obtained from Eq. 21*c*;
5. At $x = L_2$, the gradient, $\frac{dh_x}{dx}$, obtained from Eq. 21*b*, is equal to the gradient, $\frac{dh_x}{dx}$, obtained from Eq. 21*c*; and
6. At $x = L_3$, horizontal flow ceases—that is, $\frac{dh_x}{dx} = 0$.

The solutions of Eqs. 21, subject to the boundary conditions, are: For $0 < x < L_1$—

$$h_x = h + A \sinh (a\,x) \qquad \text{(22}a\text{)}$$

for $L_1 < x < L_2$—

$$h_x = h + A\,[\sinh (a\,L_1) + a\,(x - L_1) \cosh (a\,L_1)] \qquad \text{(22}b\text{)}$$

and, for $L_2 < x < L_3$—

$$h_x = B\,[e^{ax} + e^{a(2L_3 - x)}] \qquad \text{(22}c\text{)}$$

in which

$$A = B \left\{ \frac{[e^{aL_2} - e^{a(2L_3 - L_2)}]}{\cosh (a\,L_1)} \right\} \qquad \text{(23}a\text{)}$$

$$B = h \div \{[1 - \tanh (a\,L_1) - a\,(L_2 - L_1)]\,e^{aL_2} + [1 + \tanh (a\,L_1) + a\,(L_2 - L_1)]\,e^{a(2L_3 - L_2)}\} \qquad \text{(23}b\text{)}$$

and

$$a = \sqrt{\frac{k_b}{k_f\,z_b\,z_f}} \qquad \text{(23}c\text{)}$$

The seepage rate per unit width at any section in the pervious deposit may then be obtained from:

$$Q_x = -\,k_f \frac{dh_x}{dx} z_f \qquad \text{(24}a\text{)}$$

and the seepage rate per unit width at any point x through the downstream natural blanket may be obtained from

$$Q'_x = k_b \frac{h_x}{z_b} \qquad \text{(24}b\text{)}$$

If the dimension L_3 approaches infinity, Eqs. 22 become: For $0 < x < L_1$—

$$h_x = h \left\{ 1 - \frac{\sinh (a\,x)}{[1 + \tanh (a\,L_1) + a\,(L_2 - L_1)] \cosh (a\,L_1)} \right\} \ldots (25a)$$

for $L_1 < x < L_2$—

$$h_x = h \left[\frac{1 + a\,(L_2 - x)}{1 + \tanh (a\,L_1) + a\,(L_2 - L_1)} \right] \ldots\ldots\ldots\ldots (25b)$$

and, for $L_2 < x$—

$$h_x = \frac{h\, e^{a(L_2 - x)}}{1 + \tanh (a\,L_1) + a\,(L_2 - L_1)} \ldots\ldots\ldots\ldots (25c)$$

If the distance L_1 approaches minus infinity and L_3 approaches plus infinity, then, with the origin at the upstream toe of the impervious core of the earth embankment and with $(L_2 - L_1)$ equal to L, Eqs. 25 further simplify as follows: For $x < 0$—

$$h_x = h \left[1 - \frac{e^{ax}}{2 + a\,L} \right] \ldots\ldots\ldots\ldots (26a)$$

for $0 < x < L$—

$$h_x = h \left[\frac{1 + a\,(L - x)}{2 + a\,L} \right] \ldots\ldots\ldots\ldots (26b)$$

and, for $L < x$—

$$h_x = \frac{h\, e^{a(L - x)}}{2 + a\,L} \ldots\ldots\ldots\ldots (26c)$$

Eqs. 25a and 26a are in agreement with Eqs. 6 and 9a, respectively, when proper consideration is given to the physical constants and boundaries.

The foregoing development neglects the fact that the seepage paths are curved lines in the pervious deposit. Because of this phenomenon, the piezometric heads along the upper part of the pervious deposit will be somewhat less at the river-side toe of the embankment and somewhat greater at the land-side toe, as compared with the piezometric heads obtained from flow-net studies. Since it is possible that the land-side natural blanket may be disrupted by excess water pressure from pervious deposit, this difference in calculated heads is conservative. The neglect of seepage through the embankment and through the natural blanket immediately below reduces the seepage calculated by Eq. 24a as compared with that calculated by flow-net studies. The reduction is not large and is well within the permeability range of natural deposits.

Although the author indicates that the law of diminishing returns applies to an upstream blanket extended beyond certain limiting lengths, the writer would be somewhat reluctant to destroy or weaken any such natural blanket because of the increased water pressures that would occur under the blanket in the downstream area. If upstream borrow pits are used, adequate drainage facilities should be provided at the downstream toe or at adjacent areas to minimize the danger from increased water pressures. Downstream borrow pits, if available, would appear to be more desirable, and might aid in partly controlling any excessive pressures under the blanket between the downstream embankment toe and the borrow pits. However, borrow pits should be excavated so as to minimize the danger from piping or underground erosion which might work back under the natural blanket to the upstream area.

An upstream blanket with variable section is not a new idea but the author has done well to restate the case and to indicate the proper and most beneficial use of available material. A review of a number of dams indicates that blankets with triangular sections have been utilized infrequently. However, triangular-shaped blankets have certain practical limits that should be considered. For instance, it is doubtful that a blanket shaped to a featheredge would be either desirable or practical to construct. For flood control structures that do not have permanent storage, partial loss of imperviousness may occur in an exposed upstream blanket near the surface due to loosening of the blanket by frost action or due to other causes which promote soil expansion.

V. A. Endersby,[4] M. Am. Soc. C. E.—The principle of applying a blanket of low permeability to the dam face and part of the adjacent reservoir bottom is advocated by the author as being preferable to the core and cutoff wall method because more of the dam remains to resist hydrostatic pressure. This procedure has the additional advantage of usually being cheaper; however, it has the disadvantage of not creating as positive a cutoff.

An optimum combination of economy and successful operation should result from blanketing the face of the dam and connecting the blanket with a cutoff at the upstream toe, provided that this location is suitable for a cutoff. The use of an upstream blanket would also permit the cutoff to be placed at some distance from the dam, if such a location were feasible or economical—as may often be the case because of the natural slope of the bedrock. The writer is under the impression that such combinations have not been considered very often.

Of course, the use of such combinations, as well as the use of blankets of considerable area, in general, depends on the cost of blanket construction. A blanket used with a cutoff wall usually would have to be impermeable or almost so. In many cases conservation of water is important.

Mr. Bennett's analysis, favoring a blanket section of variable thickness, also leads to economy of blanket construction where natural, partly pervious materials are being considered. Such materials at the dam usually would be quite thick. If the materials were not already in place, the cost of placing them would justify a comparison with the cost of placing positively impermeable, thin, artificial membranes.

Since 1935 or thereabouts, asphaltic concrete membranes have been used increasingly for canal, flood channel, and reservoir linings. Asphaltic concrete has the advantages of being flexible and plastic, and thus not subject to the cracking due to the ground settlements which usually occur under an impermeable blanket. For this reason, some large dams in Africa were faced several years ago with asphaltic layers under concrete facing.

If an asphalt plant is near by, or if the work is important enough to justify a large portable plant, asphaltic concrete is quite low in cost. Since a 2-in.

---

[4] Research Engr., Shell Development Co., Emeryville, Calif.

blanket, properly sealed, is sufficient for high water heads, asphaltic concrete is in close competition with natural materials.

However, if complete impermeability is required, special sealing treatment for the surface is necessary, unless the mix itself is made impermeable. The latter method requires special proportioning and close control in construction. If sealing treatment is used, requirements for aggregates are less rigid than those for road work, the chief difference being the need for considerably more asphalt in the hydraulic construction.

Asphaltic concrete is suitable for a wide range of gradings and compositions of aggregates, and is free from chemical interaction between binder and aggregate.

The construction of a durable and impermeable asphaltic membrane is highly technical, requiring as much expert supervision as the mixing of Portland cement concrete.

HARRY R. CEDERGREN,[5] JUN. AM. SOC. C. E.—In presenting a mathematical analysis of seepage through impervious blankets, Mr. Bennett has defined one of the major problems encountered in the design of earth dams—the control of underseepage. The author has indicated the trend toward the use of graded filters and vertical drainage wells for the control of seepage and has discussed the value of impervious upstream blankets for reducing seepage quantities through pervious foundations. He has presented a mathematical analysis for determining the head loss through impervious blankets—evaluating the efficiency of the blankets in terms of head loss.

Undoubtedly, the formulas in the paper will find favor among engineers interested in obtaining quick evaluations of the general efficiency of proposed blanket designs. Such analyses should be particularly helpful for preliminary studies in which basic types of treatment and approximate costs of projects are being studied. In some cases, no further analysis may be required; however, in the preparation of final designs, more detailed analysis of the probable development of seepage pressures and gradients is often feasible. For this purpose many engineers make extensive use of the graphical flow-net[6,7] method. Although a moderate amount of study and practice is required for the development of skill in the construction of flow nets, the required effort is not out of proportion to the value. Frequent use of the flow net develops an understanding of seepage that often permits an engineer to detect inadequate designs quickly without detailed analysis, thus saving considerable time and expense. Furthermore, the flow net gives a graphical picture of the probable distribution of seepage pressures and gradients that is an important aid to the engineer in the design of water impounding structures.

As the author has stated, soil deposits are never uniform, and no seepage analysis is more dependable than the degree of accuracy of the conditions assumed in the analysis. Karl Terzaghi, M. Am. Soc. C. E., has stressed this limitation of soil mechanics analyses repeatedly and recommends[8] field observations during construction to determine the degree of safety of structures. Observation wells or piezometers at strategic points in earth dams and in dam foundations will permit the determination of actual pore pressures and thus will reflect the degree of safety of structures, both during and after construction. An adequate system of pore pressure measuring devices should be installed in all important earth dams, and reliable records of pore pressure data, together with pertinent information regarding the installations, should be made available to the engineering profession.

[6] "Seepage Through Dams," by Arthur Casagrande, *Journal*, New England Water Works Assn., June, 1937, pp. 131–172 (also reprinted in *Publication No. 209*, Graduate School of Eng., Harvard Univ., Cambridge, Mass., June, 1937; and in "Contributions to Soil Mechanics, 1925–1940," Boston Soc. of Civ. Engrs., Boston, Mass., 1940).

[7] "Theoretical Soil Mechanics," by Karl Terzaghi, John Wiley & Sons, Inc., New York, N. Y., 1943, pp. 235–247.

In evaluating the performance of an impervious blanket, or any other design feature relating to seepage control, the first consideration should be the safety of the dam. The safety of earth dams on pervious foundations depends in a large measure on uplift pressures in the vicinity of the downstream toe. The author has emphasized the value of downstream drainage systems for the control of uplift pressures downstream from dams, and his two examples (Figs. 4 and 5) show the beneficial influence of a pervious blanket installed beneath the downstream part of the dam. This type of drain increases the degree of safety of the structure but it may not be entirely adequate. Under the assumed condition that the soils are isotropic (horizontal permeabilities (k_{I}) equal to vertical permeabilities (k_{II}), Mr. Bennett's analysis indicates that the escape gradient at the downstream toe is 0.8 for the section in Fig. 4 without drainage and 0.20 for the section in Fig. 5, in which a gravel blanket has been provided beneath the downstream part of the dam. The former condition (Fig. 4) is decidedly unsafe and the latter may be considered barely adequate provided the soils are relatively free of stratification.

Before accepting a blanket design as adequate (for example, the section in Fig. 5), an investigation should be made to determine the probable degree of stratification of the foundation, since natural soil deposits are always more or less stratified and even moderate stratification can have an important influence upon uplift pressures. The effect of stratification can be demonstrated clearly with the aid of the flow net. For example, let it be assumed that all soils in the basic section given in Fig. 5 are moderately stratified and that all the horizontal permeabilities (k_{I}) are nine times the vertical permeabilities (k_{II}). The principal question to be answered is "What effect does this degree of stratification have upon uplift pressures at the downstream toe?" The results of a flow-net analysis of the basic section in Fig. 5, together with a number of modifications, are summarized in Table 1. The section given in Fig. 5 is designated "case 1," and modified sections are designated cases 2, 3, and 4, respectively. All flow nets were constructed by the Forchheimer graphical method.[6,7] To show the influence of stratification, the original section with a 1,100-ft blanket upstream and a drainage blanket under the downstream half of the dam was analyzed for two conditions—namely, all soils homogeneous and isotropic ($k_{\mathrm{I}} = k_{\mathrm{II}}$) and all soils moderately stratified ($k_{\mathrm{I}} = 9\, k_{\mathrm{II}}$). To determine the benefit derived from the blanket, a similar analysis was made with the blanket omitted. This analysis indicated that the blanket reduced the seepage quantity and discharge gradients at the toe approximately 50%. The values obtained from the flow-net analysis of Mr. Bennett's section with homogeneous soils agree substantially with the results obtained from his formulas but indicate a slightly higher discharge gradient of 0.25 at the downstream toe. For the stratified condition, the discharge gradient is increased to 1.0 which represents a critical condition. The magnitude of the discharge gradient in this analysis varies approximately in proportion to the square root of the ratio of k_I to k_{II}; hence, the approximate gradient can be estimated for other degrees of stratification. The original design incorporating the 1,100-ft blanket (case 1, Table 1) may be considered barely adequate, provided the soil is essentially nonstratified, but it is not adequate if any appreciable degree of stratification exists. Omitting the blanket (case 2, Table 1) reduces the degree of safety by approximately 50%; hence, the blanket does definitely contribute to the safety of the structure, even though it may not be entirely adequate.

FIG. 7.—FLOW-NET ANALYSIS; SECTION FROM FIG. 5

Examination of the flow nets for the original section with the 1,100-ft blanket (see Fig. 7) indicates that uplift pressures in the pervious substratum should be relieved by a suitable drainage system such as vertical drainage wells drilled to a substantial depth or a drainage trench excavated to the pervious substratum. The results obtained from flow-net analyses of the latter design are summarized in Table 1 under cases 3 and 4. Case 3 designates the section with a 1,100-ft blanket and with a drain excavated into the pervious substratum; case 4 is identical, except that the upstream blanket has been omitted. Flow nets drawn for the assumed conditions indicate that uplift pressures at the toe have been eliminated by the foundation drain and that the embankment is absolutely safe against blowouts, even with the blanket omitted. The data in Table 1 illustrate that the foundation drain increases the seepage quantity in varying amounts to a maximum of 47%; hence, the value of the lost water (if the structure is to provide storage) and the cost of removing seepage from developed lands on the back side of the structure must be considered in establishing the design.

Where conditions are favorable to the use of a positive cutoff, this alternative may be the most economical long-time solution. In many locations, however, pervious strata are so deep that a cutoff is impracticable; and, in such instances, some other method must be adopted for the control of underseepage. In preliminary studies of embankments incorporating upstream blankets, the method outlined by the author should be a valuable asset. In detailed design studies, many engineers will prefer a more general method that can be adapted to the analysis of a variety of methods of seepage control. For this purpose the graphical flow-net method offers advantages that should not be overlooked by the designing engineer.

W. J. TURNBULL,[9] M. AM. SOC. C. E.—Mr. Bennett should be complimented on his modesty in presenting the mathematical analysis of seepage through natural or artificial blankets as not representing an absolutely concise or correct analysis, but rather furnishing a good estimate on which to base computed seepage flows and to determine required length of blankets.

Of all the assumptions which Mr. Bennett makes in his mathematical treatise, there is no question but that the correct determination of actual soil conditions is the critical one and as a result would be the greatest source contributing to errors. Since the accurate determination of the true soil conditions is very necessary for a reasonably good estimate of blanket length, then it becomes all important that every effort be made to obtain reliable and accurate data as to the soil profile and the soils test applicable for each type of soil in the profile. This can be done only by very careful borings, both disturbed and undisturbed. The undisturbed borings are particularly necessary for the proper determination of density and permeability. In the case of cohesionless materials, such as very coarse silts, sands, and sand gravels, it is impossible, of course, to obtain undisturbed samples by boring, and therefore it is necessary to obtain the best disturbed samples possible, particularly with reference to the finer fractions so that none of them are lost, and a true gradation of the material is determined. It is possible to secure relatively undisturbed samples by means of test pits. However, to collect a sufficient number to determine the true average permeability of the pervious stratum is a costly process. In many cases it may be very desirable to conduct large-scale field pumping tests from which the permeability of the pervious stratum may be obtained. The field permeability test has been used very little by engineers in the past. It is believed, however, that this test will become more and more important and that continued improvement in the technique of the test will result in greater reliability and confidence in the results. There is no question but that such results are much better than laboratory tests on the disturbed material or estimates of permeability made from the grain sizing of the material.

---

[9] Prin. Engr. Executive Asst., U. S. Waterways Experiment Station, Vicksburg, Miss.

Mr. Bennett presents four conditions to be satisfied before his analysis can be applied with a practical degree of accuracy:

(1) The ratio of the permeability of the pervious stratum to the natural or artificial top stratum is at least ten or greater;

(2) The ratio of the length of the path of travel of the seepage water to the thickness of the pervious stratum is relatively great;

(3) There is only a single pervious stratum which is largely responsible for the underseepage flow; and

(4) The horizontal flow through the embankment structure is relatively small as compared with that through the pervious stratum.

All the foregoing criteria will be met by the greater proportion of embankments, thus making them fall within a category to which Mr. Bennett's analysis can be applied.

If the information on the artificial or natural top stratum, and on the semipervious or pervious layers beneath them, is correct, the results of the analysis demonstrated by Mr. Bennett should be regarded with as much confidence as many other soil tests or design features that comprise the over-all design of an embankment and its drainage facilities. A study of existing embankments and their blankets, assuming that accurate original data were available, would be a valuable contribution to the practicability of Mr. Bennett's analysis. With such a study, one could compare the actual performance record with the estimates derived by the methods of the paper.

The analysis presented in this paper is especially important in that it presents a rational means of estimating blanket length and thickness requirements. Such a procedure may be a means of ending arguments that always arise in the design of an embankment as to the proper length of a natural or artificial blanket of a given thickness and permeability. Many engineers are attaching more and more importance to the design of blankets, because it is believed that properly designed blankets may be used to take the place of the conventional sheet-pile cutoff. Many dams now being built include both the sheet-pile cutoff and a blanket, and once engineers learn to design blankets properly and with confidence, proved by satisfactory performance, the older and more costly, and in many cases ineffective (as far as underseepage is concerned), sheet-pile cutoff may be discarded.

KENNETH S. LANE,[10] ASSOC. M. AM. SOC. C. E.—The mathematical analysis presented by Mr. Bennett furnishes a relatively rapid method of studying certain seepage problems—particularly those concerning levees and dams across valley flood plains where the soil profile frequently consists of a relatively impervious top stratum or natural blanket overlying pervious sands and gravels. The equations can be solved for uplift pressure or piezometric head acting on the bottom of the top stratum and caused by seepage through the foundation beneath the structure. This uplift pressure on bottom of the top stratum is of particular interest since it is the pressure that causes flotation in the zone of seepage emergence—whenever the upward pressure equals or exceeds the weight of the overlying soil. In the state of flotation either the soil of the top stratum suffers a great loss of shear strength (acting as a heavy liquid with the soil grains held in suspension by the upward seepage forces which equal or exceed the buoyant weight of the grains) or the top stratum may be slightly lifted bodily, followed by some relief of uplift pressure through cracks in the top stratum. In either case, boils frequently ensue. If these boils are not arrested, eventually they may develop into piping that removes the soil from beneath the structure and causes failure. It has been well stated that flotation is the cause and piping the effect; and, if flotation can be prevented, piping cannot occur.[11] Therefore, these mathematical solutions for investigating the uplift pressure causing flotation are felt to be valuable contributions to the methods of seepage analysis.

In developing a theory for relief wells as a treatment for flotation, W. H. Jervis, Assoc. M. Am. Soc. C. E., has obtained a solution for flow through a blanket of finite length which was published in 1939 for limited distribution in a report of the U. S. Engineer Office, Vicksburg (Miss.) District.[12] Mr. Jervis considered the case of flow to a slot of infinite permeability with the boundary conditions shown in Fig. 8. As converted to the notation of the paper, Mr. Jervis' solution is as follows:

For $0 < x < L_1$

$$h_x = h \left[1 - \frac{\sinh (a\, x)}{\sinh (a\, L_1) + a\, (L_2 - L_1) \cosh (a\, L_1)} \right] \ldots\ldots (27)$$

in which

$$a = \sqrt{\frac{k_b}{k_f\, z_b\, z_f}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

For $L_1 < x < L_2$, the curve of h_x is a straight line falling to zero at $x = L_2$. The author's solution for these boundary conditions is presented in Eq. 9*a*; but, for reasons given subsequently, it is felt that a denominator term in Eq. 9*a* should read as follows, provided h_n has been correctly interpreted to be defined as shown in Fig. 8:

$$h = h_n \frac{e^{ax} - e^{-ax}}{e^{aL_1} - e^{-aL_1}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

---

[10] Head, Soils Laboratory, U. S. Engr. Office, Providence, R. I.

[11] "Uplift and Seepage Under Dams on Sand," by L. F. Harza, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1352.

[12] "Underseepage Studies, Black Bayou Levee," by W. H. Jervis, Rept. to U. S. Engr. Office, Vicksburg Dist., Vicksburg, Miss., June, 1939.

Writing Mr. Jervis' solution in terms of head lost (Δh), as considered by the author:

$$\Delta h = h - h_x = \frac{h \sinh (a\,x)}{\sinh (a\,L_1) + a\,(L_2 - L_1) \cosh (a\,L_1)} \qquad (30)$$

at $x = L_1$—

$$\Delta h_{(x=L_1)} = h_n = \frac{h \sinh (a\,L_1)}{\sinh (a\,L_1) + a\,(L_2 - L_1) \cosh (a\,L_1)} \qquad (31)$$

or

$$h = h_n \frac{\sinh (a\,L_1) + a\,(L_2 - L_1) \cosh (a\,L_1)}{\sinh (a\,L_1)} \qquad (32)$$

Substituting Eq. 32 in Eq. 30:

$$\Delta h = h_n \frac{\sinh (a\,x)}{\sinh (a\,L_1)} \qquad (33a)$$

or

$$\Delta h = h_n \frac{e^{ax} - e^{-ax}}{e^{aL_1} - e^{-aL_1}} \qquad (33b)$$

which is the same case as that covered in Eq. 9a, using $h = \Delta h$ for lost head.

All the foregoing formulas were derived for flow through a two-layer case (impervious top stratum above buried pervious stratum) and are based on the same differential equation to set up which it was necessary to assume that:

1. The flow is vertical through the top stratum and horizontal through the buried pervious stratum; and

2. No flow occurs in the top stratum under the impervious section of the structure; or, expressed otherwise, the impervious section of the structure extends down to the bottom of the top stratum as shown in Fig. 8.

FIG. 12

Actually, the flow paths are somewhat curved in both the top stratum and the underlying pervious layer, and some flow always occurs in the section of the top stratum beneath the structure; but for practical purposes the foregoing assumptions give results sufficiently accurate for analysis considering the variations in soils and their permeability which are encountered in nature and must be handled by replacing nature's conditions with a simplified or generalized section for the purposes of analysis—a condition which the author has well emphasized. Since they are graphically sketched solutions, flow nets are not precise determinations but rather are good approximations for the chosen boundary conditions. Therefore, although the flow nets of Figs. 9 to 12 are not exact, nevertheless, they give good illustrations of the effect of the foregoing two assumptions which were necessary in deriving the formulas.

Fig. 9 exhibits a flow net solved by K. A. Linell, Jun. Am. Soc. C. E. Here the formula gives a value for uplift slightly too low on the upstream side at point e and slightly too high on the downstream side of the structure at point f—largely because of neglecting the flow through the top stratum in the zone cdef, which in this case is less than one twelfth of the total underseepage. However, the formula is conservative in showing slightly too high a value at point f, as this is the point of most interest in computing the uplift causing flotation in the zone of seepage emergence. Divergence of the formula in the zones from $-b$ to $-3b$ and from $+2b$ to $+4b$ is probably caused by neglecting the curvature of the flow lines in the pervious stratum.

The flow net of Fig. 10 has been drawn for a relatively low ratio of foundation permeability to blanket permeability of 4 to 1, which is likely to be much lower than usual cases in nature. Although the author has warned that the formulas may not be applicable for permeability ratios of less than 10 to 1, the agreement in the uplift curves shown by Fig. 10 is still quite good, and again the formula gives slightly high or conservative results at the point of most interest in the emergence zone, point e (Fig. 10). The formula would agree much more closely with the excess uplift pressure measured in the flow net at point f on the bottom of the pervious stratum as here the flow is horizontal according to the first assumption. The geometry of Fig. 10 exerts a major influence on the flow pattern; and, if the blanket of Fig. 10 had been longer than the relatively short distance of $\frac{5}{4}b$, the agreement between formula and flow net might have been much closer.

The flow net of Fig. 11 covers a three-layer case with a relatively thin pervious layer placed within a deposit which is one twelfth as pervious. Although the formulas are not intended to apply to this case, it appears that they could be used since the check with the flow net is very close. Actually, the influence of the third or lowest stratum is small as it carries only two thirteenths of the total underseepage and the great bulk, or ten thirteenths, of the flow passes through the pervious deposit, leaving only one thirteenth of the flow in the top stratum from points d to e.

In Fig. 12, the upstream half of the flow net is the same as that in Fig. 11, but on the right or downstream half an impervious barrier has been considered at $+3b$ to give a partly blocked outlet. This raises the uplift over the entire emergence zone as shown by the comparison of the two uplift curves from the flow nets drawn in the upper diagram of Fig. 12. The author's solutions do not cover this case and, therefore, the computations were made from Eqs. 22 and 23, which are considered solutions for a more general case. At the point of most interest on line ef, the agreement is good; but, in the zones from + 2 *b* to + 3 *b*, the influence of the third stratum becomes important and the use of the formula is not warranted for obtaining the complete uplift curve of this particular three-stratum case.

FIG. 13

In using Eqs. 22 and 23 for the solution of Fig. 12, it was necessary to select finite and large values of L_1, making the computation rather cumbersome. A further simplification, for the boundary conditions illustrated in Fig. 13, has been derived by R. A. Barron, Jun. Am. Soc. C. E., and is as follows: For $x < 0$,

$$h_x = C\,e^{ax} + h \quad \text{(34a)}$$

for $0 < x < L_4$,

$$h_x = C + h + C\,a\,x \quad \text{(34b)}$$

and, for $L_4 < x < L_5$,

$$h_x = D\left[e^{ax} + e^{a(2L_5 - x)}\right] \quad \text{(34c)}$$

in which the constants,

$$C = \frac{h}{\dfrac{1 + e^{2a(L_5 - L_4)}}{1 - e^{2a(L_5 - L_4)}} - (1 + a\,L_4)} \quad \text{(35a)}$$

and

$$D = \frac{C}{e^{aL_4}\left[1 - e^{2a(L_5-L_4)}\right]} \qquad \text{(35}b\text{)}$$

Two advantages of upstream blankets are reduction in uplift pressures in the seepage emergence zone and reduction in quantity of seepage. These apply particularly to dams holding a permanent pool where the blanket is protected by the water above and where the head lost through the blanket exerts a force compressing the blanket and thus increasing its impermeability. The author's use of the expression for x_r as a measure of blanket efficiency offers a quick method of comparing the value of different blanket dimensions.

A triangular blanket is theoretically sound and could be applied where the impervious material is very scarce; but the usual case is likely to be that of a more uniform blanket thickness. In this connection, it is difficult to visualize the author's findings (see paragraph containing Eq. 14) from comparative computations that, for the same area or volume of impervious material, a triangular blanket should be twice as long as one of uniform thickness to provide the same resistance to flow. Any further elaboration the author could inject on this point would be helpful.

In contrast to dams holding a permanent pool, an upstream blanket is not quite as advantageous for flood control dams where water is stored only intermittently with frequent rapid drawdowns of the pool and where the volume of loss from seepage is seldom important. For this use, thicker blankets are apt to be required as the frequent exposures of the blanket during nonstorage periods offer opportunities for erosion and, in the colder climates, for loosening the upper part of the blanket by frost, substantially reducing its impermeability. The latter would apply if the impervious soil of the blanket is subject to frost action as is likely to be the case.

TABLE 2.—PERMEABILITY OF NATURAL BLANKET OVERLYING A GLACIAL DEPOSIT OF PERVIOUS SAND

[a] Medium sand. [b] Sod removed. [c] Estimated.

The test results in Table 2 were obtained from sampling the surface soils found over a large glacial deposit in northern Connecticut of highly pervious sand (the parent soil), with a permeability of from 100 × 10^{-4} cm per sec to 400 × 10^{-4} cm per sec. The peat represented low-lying swamp deposits, the topsoil represented the top horizon on higher ground, and the subsoil was the horizon of weathering immediately beneath the topsoil. The high values of permeability may seem surprising at first but they are considered as being caused by the very loose state found in nature and attributed to the annual loosening by frost action. In an impervious blanket for flood control works, it is judged that the upper part of an exposed blanket should be expected to be loosened similarly where frost action is a factor.

A further precaution in using blankets on flood control structures is to avoid placing the blanket in such a position that the pressure of water trapped behind it on drawdown might be sufficient to cause flotation from seepage up through the blanket—often termed a blowout in the blanket. This situation is likely to be encountered more frequently in the case of levees than in the case of dams; and one solution, effective but expensive, is, of course, to weight the blanket down by a cover of pervious material. Another solution, occasionally possible, might be to provide a measure for relieving this back pressure as by avoiding a complete cutoff or by shortening the blanket. Blanket failures from high back pressure of trapped water have been fairly frequent when blankets were extended down over existing slopes, when inclined blankets without sufficient covering weight were placed on dams of large width and poor internal drainage, and when blankets formed canal linings. An outstanding example of piping following a blowout in a blanket is the Memphis (Tenn.) subsidence described by Karl Terzaghi,[15] M. Am. Soc. C. E., although in that case the placing of the blanket down over a river slope was due to nature.

Acknowledgment is made of assistance given by Mr. Barron in checking the computations for the uplift diagrams and by Mrs. R. D. Lacey in preparing the illustrations and making some improvements to the flow nets during tracing.

Corrections for *Transactions:* In January, 1945, *Proceedings*, change "k_z" to "k_b" in Eq. 4c (page 21), Eq. 8 (page 23), and in lines 1 and 2, page 22. Also change "m" to "n" in Eq. 15 (page 25) and in line 26, page 30.

PRESTON T. BENNETT,[16] ESQ.—The importance of anisotropic permeability, resulting from stratification of natural deposits is emphasized clearly in Mr. Cedergren's discussion. If the symbols k_b and k_f are interpreted properly, as vertical and horizontal permeabilities, no further correction for anisotropy needs to be made to bring the formulas to a degree of accuracy greater than that obtainable by graphic methods.

As Mr. Cedergren has stated, considerable skill and experience in the construction of flow nets are necessary before such graphic solutions can be relied on. The writer's dissatisfaction with his own efforts at graphic solution caused him to use electric conduction models, and his observation of the nearly straight-line equipotential lines obtained from models of blanket systems led, in turn, to the opinion that an analytical solution for simple blanket problems was entirely feasible and less time consuming than either of the other methods.

A blanket over a more pervious stratum constitutes what might be termed a foundation with "coarse-grained" anisotropy. The horizontal coefficient of transmissibility for such a foundation is the ratio, $k_f\,z_f$; and, by analogy, the term "vertical coefficient of transmissibility" may be coined for k_b/z_b. Likening these coefficients to horizontal and vertical permeabilities k_I and k_{II}, whose transformation factor is $\sqrt{\frac{k_{II}}{k_I}}$ the comparable ratio $\sqrt{\frac{k_b}{z_b\, k_f\, z_f}}$ is obtained, which is the factor common to the solutions of blanket problems by W. H. Jervis, Assoc. M. Am. Soc. C. E., by Messrs. Barron and Lane, and by the writer.

---

[15] "Earthslips and Subsidences from Underground Erosion," by Karl Terzaghi, *Engineering News-Record*, July 16, 1931, p. 91.

[16] Engr. (Soil Mechanics), U. S. Engr. Office, Omaha District, Omaha, Nebr.

The similarity of the factor a to an anisotropic transformation factor is mentioned to emphasize again the writer's opinion that no second transformation of dimensions is necessary if k_b and k_f in his notation are interpreted properly. This similarity also suggests the definition "coefficient of blanketed transmissibility" for the hitherto undesignated quantity a.

Messrs. Barron and Lane have both presented solutions for the uniform blanket which contain the term $(L_2 - L_1)$. This is equivalent to x_d of the paper. Inclusion of the term x_d eliminates the necessity for a separate equation and computation to determine values such as h_n in Eq. 9a.

Mr. Lane was not entirely correct in assuming that the writer's h_n was as defined in Fig. 8, but the modification of Eq. 9a as indicated in Eq. 29 is necessary if it is desired to generalize the blanket formula by adding factors to include flow under the impervious dam

From Fig. 2 it is evident that

$$\frac{h}{\Delta h} = \frac{x_r}{x_r + x_d} \qquad (36)$$

Rewriting Eq. 9d in hyperbolic functions, the resistance for a blanket of length L_1 is

$$x_r = \frac{\sinh (a\, L_1)}{a \cosh (a\, L_1)} \qquad (37)$$

Referring to Fig. 8, the h and Δh in the paper correspond, respectively, to h_n and h in Mr. Lane's discussion. In Mr. Lane's notation, using $(L_2 - L_1)$ for x_d, Eq. 36 becomes

$$\frac{h_n}{h} = \frac{\dfrac{\sinh (a\, L_1)}{a \cosh (a\, L_1)}}{\dfrac{\sinh (a\, L_1)}{a \cosh (a\, L_1)} + (L_1 - L_2)} \qquad (38)$$

which reduces to identity with Eq. 31, and leads to the conclusion that the writer's use of two formulas, Eq. 9a and Eq. 36, is exactly equivalent to Mr. Jervis' solution.

Although the writer's use of the concept of blanket resistance introduces extra equations into the solutions, it actually simplifies the numerical work to be done. Consider, for example, the system shown in Fig. 14, which is similar to Fig. 8 except that a line of relief wells is used instead of the slot of infinite permeability. The uplift pressure at the toe will vary from a minimum at the wells to a maximum between wells, but it may be assigned an average value, h_{x2}, dependent on characteristics of the well system and the land-side flow pattern. If the average value h_{x2} is above the land-side surface area, the line of wells is equivalent in effect, at a distance beyond the radius of influence of the wells, to a slot of infinite permeability, as in Fig. 8, except that it acts as a source of flow from potential h_{x2} to the land-side surface at potential zero.[17]

The solution of such a well and blanket system, involving a discontinuity of discharge at the line of wells, is considerably simplified by the use of blanket resistances as follows: Assume that a maximum permissible value for h_{x2} has been established. The curvilinear gradients A′B′ of Fig. 14 can be replaced, for the computation of discharge, by the tangent gradients AW and WB if the resistances x_{r1} and x_{r3} are known. The slopes of these tangents, evident from Fig. 14, determine the foundation flows Q_1 ($= s_1\, k_f\, z_f$) and Q_2 ($= s_2\, k_f\, z_f$) on either side of the wells. The discharge of the well system required to reduce the land-side toe uplift pressure is $Q_1 - Q_2$. The size, spacing, and outlet elevation for the well system can readily be computed when the required well discharge is known.[17]

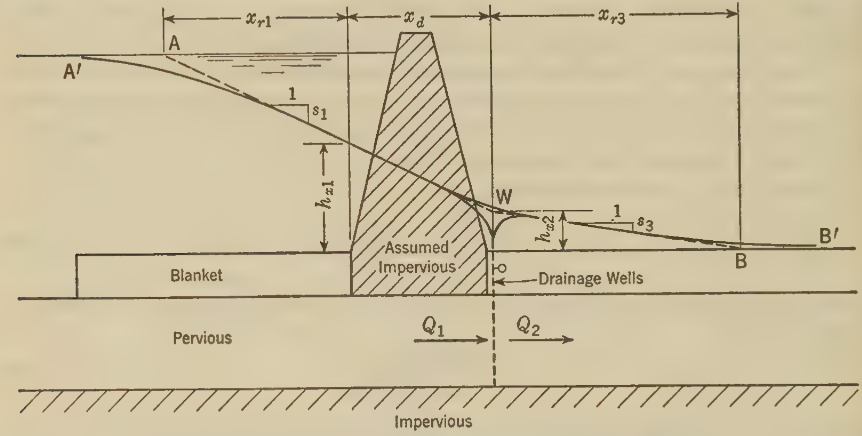

FIG. 14.—COMBINATION OF BLANKET AND DRAINAGE WELLS

If it were desired to design a well system to reduce the land-side uplift pressures in the system shown by Mr. Barron in Fig. 6, Eqs. 22 and 23 would probably be less easily applied than a solution involving the resistance values of blankets. In fact, Mr. Lane has noted that these equations are rather cumbersome for numerical work, even without the introduction of a drainage system.

Rewriting Eq. 22c with the origin at $x = L_3$, $x' = 0$:

$$h_{x'} = B' \left(e^{ax'} + e^{-ax'}\right) \qquad (39)$$

in which B' is a factor similar to B in Eq. 22c. Thus, the resistance of the interval between L_2 and L_3 in Fig. 6 is

---

[17] "Conference on Control of Underseepage," published by U. S. Waterways Experiment Station, Vicksburg, Miss. (see "Design of Relief Well Systems," by W. H. Jervis, p. 81; and "Comments on Design of Relief Wells," by P. T. Bennett, p. 87), April 1, 1945.

$$x_{r3} = \frac{h_{x'}}{\dfrac{d(h_{x'})}{dx'}} = \frac{e^{ax'} + e^{-ax'}}{a\,(e^{ax'} - e^{-ax'})} \qquad \text{.................(40)}$$

Fig. 15 is Mr. Barron's Fig. 6 redrawn with self-explanatory changes in notation which are made for easier use in resistance formulas. In the notation of Fig. 15, from Eqs. 9*d* and 40,

$$x_{r1} = \frac{\sinh\,(a\,x_1)}{a\,\cosh\,(a\,x_1)} \qquad \text{.....................(41}a\text{)}$$

and

$$x_{r3} = \frac{\cosh\,(a\,x_3)}{a\,\cosh\,(a\,x_3)} \qquad \text{.....................(41}b\text{)}$$

From Fig. 15,

$$h_{x1} = \frac{h\,(x_{d1} + x_{r3})}{x_R} \qquad \text{.....................(42}a\text{)}$$

and,

$$h_{x2} = \frac{h\,x_3}{x_R} \qquad \text{.........................(42}b\text{)}$$

and, from Eq. 39,

FIG. 15.—APPLICATION OF "RESISTANCES" TO PERVIOUS FOUNDATION TO FINITE LENGTH

$$\frac{h\,x_3}{h\,x_2} = \frac{h\,(x' = 0)}{h\,(x' = -\,x^3)} = \frac{e^0 + e^{-0}}{e^{-ax_3} + e^{ax_3}} = \frac{1}{\cosh\,(a\,x_3)} \qquad \text{........(43}a\text{)}$$

or

$$h\,x_3 = \frac{h\,x_2}{\cosh\,(a\,x_3)} \qquad \text{......................(43}b\text{)}$$

The transformation of Eqs. 22 and 23 into the forms given in Eqs. 41, 42, and 43 seems to render them more useful in numerical applications.

Quite properly, Mr. Lane has questioned the writer's comparison of uniform and triangular blankets. The conclusion (paragraph containing Eqs. 12, 13, and 14, last sentence) that a triangular blanket of maximum thickness z_b and length x is equivalent to a uniform blanket of the same thickness and length $x/2$ is obviously untrue if k_b were zero. In the latter case, the resistances would be x and $x/2$, respectively. The writer's comparison was made on blankets of optimum dimensions, such that $a\,x = \sqrt{2}$. These conclusions may be illustrated by Table 3, in which five blanket sections are superimposed for comparison of end areas and resistances. Blankets No. 1 and No. 5 are parabolic sections (see diagram in Table 3) described by

$$z = \frac{a\,x^2}{2} \qquad \text{(44)}$$

Eq. 44 can be shown analytically to represent the curve section that provides maximum resistance for a fixed-end area. The uniform blanket of length L (Section 3, Table 3) is also of optimum proportions, as can be noted from Fig. 3.

Ratio, resistance to area	1.5	1.0 to 1.26	0.63	0.88	0.72

Table 3 indicates some advantages of the vertically curved and triangular sections over the uniform section, and is the basis for the writer's assumption that sections of equal area, shaped similarly to Sections 2 and 4, are about equally effective. Even with careful determination of permeabilities as advocated by Mr. Turnbull, the best possible estimate of the factor a will not represent field conditions closely enough to justify hairsplitting in the selection of blanket shapes and dimensions.

This opinion is not to be interpreted as nonconcurrence with Mr. Turnbull's statements that field conditions should be determined with the greatest care, for only when this is done can the formulas developed in this paper and in the discussions be used to best advantage.

A PLAN FOR A MOVABLE DAM

By Isaac DeYoung,[1] M. Am. Soc. C. E.

With Discussion by Messrs. C. L. Hall, C. E. Meyerdick, Ralph R. Leffler, Jay L. Southworth, L. C. Sabin, A. W. Sargent, and Isaac DeYoung.

Synopsis

There are two general conditions under which movable dams are operated: One in which it is required to close a channel in an orderly predetermined plan and without immediate urgency; and the other, in which a sudden release of the water in a canal caused by an accident due to the wrecking of a lock gate by collision or otherwise, requires a structure that can be operated in the rushing waters, checking the flow.

The plan for a movable dam presented herewith is of the latter type. It is an emergency dam, and is designed so that it can be put in place during the rush of waters thus stopping the uncontrolled stream. It consists of plate girders (which form the dam), connected by hinges fastened together at their flanges and folded together in small compass in the bottom of the lock. The dam is held in place by rigid anchors, hinged to the girders, and embedded anchorages under the floor of the lock. The dam is raised through multiple reaved cables by two hoisting engines. The raising operation required only a short time. A single operator in a central station manipulates the controls in an orderly way as soon as the upper canal is free from all floating craft.

Introduction

The movable dam proposed in this paper is a development from the studies made in the early 1900's in connection with the design and construction of two movable dams for St. Marys Falls Canal, Michigan, in which the writer had a part. The writer's ideas leading to the proposed dam have been developed through the years intervening since that first experience.

Forms of Movable Dams

There are four general types of movable dams: (1) Overhead bridges built in conjunction with wickets, needles, and other devices; (2) submerged structures;

Note.—Published in February, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

(3) floats; and (4) lock gates (sheathed or skeleton), horizontal sliding gates, rolling segmental gates, and lift gates.

(1) Overhead bridges of the swing type, from which either horizontal or vertical stop planks, wickets, or needles are manipulated, are fairly sure to be operated so that the flow of water is checked gradually, thus minimizing the shock on all parts of the structure. The operating parts are readily accessible and easily repaired. Some of the disadvantages are that they are limited as to length of span, possibility that a sunken vessel in the locality may prevent the bridge from closing, and the lodgment of stone or other material on the sill.

(2) Among dams of the submerged type may be mentioned trestle dams, bear traps, Taintor gates, etc. The flexible shutter type of dam described in this paper belongs in this class (see Figs. 1 and 2). Some inherent objections to the typical submerged dam are that a dragging anchor may injure the structure and that, when damaged, the structure is relatively inaccessible for repairs. These objections, as applied to the flexible shutter dam, are discussed subsequently.

(3) Under the subject of floats, there is the barrier created by sinking a vessel of any shape. A circular caisson built of timber or steel can be used and floated into place at the jaws of the narrowest part of the canal or lock.

(4) Having two sets of operating gates at each end of the lock offers some safety because of the double barrier in front of a moving vessel. A gate located in the canal above the lock would accomplish a similar result, the gate being operated in such a manner as to be always closed during a danger period when the lock gates are open; but the operations under such conditions would be subject to excessive delays to navigation.

Description of the Flexible Shutter

The structure described in this paper is composed mostly of plate girders, fastened together on the downstream side by plate hinges extending the entire length of the girders (Figs. 2(*a*), 3, 4, 5, and 6). On the upstream side the dam is held by anchors connected to embedded anchorages. It is raised by two hoisting engines, through six-part cable, one on each side of the lock. In the lowered position, the dam is folded in small compass below the lock floor level (see Figs. 3 and 7). It is designed for a lock 80 ft wide, having 30 ft of water on the sills.

The selection of a type of movable dam should be based on the following requirements: (*a*) Certainty of operation when required; (*b*) reasonable facility of operation; (*c*) no obstruction to navigation; (*d*) ability to withstand shock; (*e*) simplicity of construction; (*f*) accessibility for inspection and repairs; (*g*) appearance; (*h*) freedom from enemy attack during stress of war; and (*i*) cost of construction and maintenance.

(*a*) A movable dam should be free from the possibility of being clogged or broken by the ordinary use of the canal or by the exigencies arising at the time of the accident.

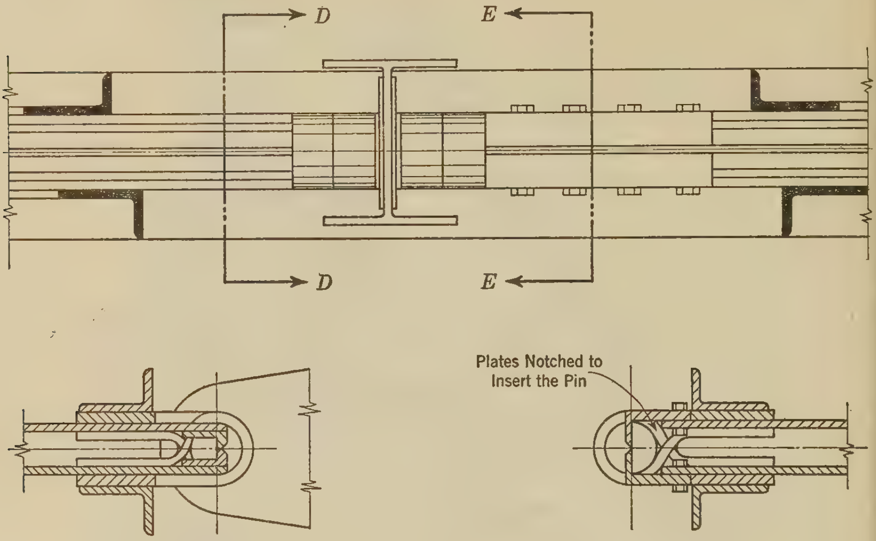
FIG. 3.—DETAILED VIEWS OF DAM IN A LOWERED POSITION

In the proposed plan the dam is folded in small compass in the bottom of the lock and protected by transverse breast walls, preventing damage from dragging equipment, such as anchors.



SECTION *D-D* SECTION *E-E*

Fig. 4.—Sections Through Upstream Hinges

As debris may be moved by the current created in the canal when a lock gate is wrecked, some provision should be made to prevent the collection of such debris on parts of the dam, so as to interfere with its successful operation. In the plan, the anchor slots, eight in number, are covered by the top anchor having angle iron attached, whose outstanding legs cover the slots completely from end to end of anchors, preventing the debris from entering these slots (see Fig. 7). Also, funnel-shaped pits between the anchor slot walls catch this debris.

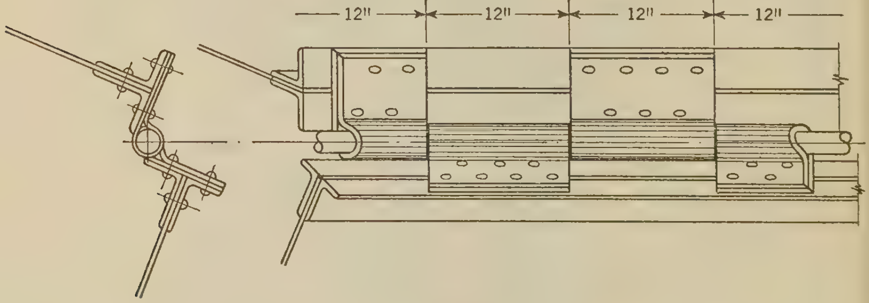


Fig. 5.—Downstream Hinges, Continuous End to End of Dam

It is not considered likely that a vessel would become stuck, because then it would itself become a barrier, building up pressure sufficient to move it through the lock.

It would be desirable if the dam could be closed before the current in the canal has reached a dangerous velocity, but this ideal is impossible in any form of dam. The flexible shutter dam can be raised in a few minutes, and as soon as all floating craft in the upper canal has passed through.

(*b*) The operating mechanism should be simple, not likely to get out of order, and it should be easily accessible for quick operation. The flexible shutter dam is operated by means of two hoisting engines, one on each side of the lock. The operation may be performed from one station through appropriate electrical connections similar to the Selsyn method of operation. (The Selsyn system of signaling and control consists of two small specially wound induction motors electrically interconnected in such a way that the movement of one armature causes the other armature to move by a corresponding amount and in the same direction. One motor is operated at the sending point as a generator and is called the transmitter and the other is operated as a motor and is known as the receiver.) The dam is operated as a single unit. The plan provides for a dam in a lock 30 ft deep and 80 ft wide. In a lock of less depth and width, the operation may be performed by hand through a train of gears.

(*c*) The structure should be of such a form as to offer no obstruction to navigation. These requirements have been met in the flexible shutter dam in that all parts are outside of the limits of the navigable cross section of the lock.

(*d*) Since the proposed structure is held rigidly in place by substantial anchor beams, which revolve slowly about their centers, there will be no sudden change of position of any part of the dam to receive any shock. The flow will be stopped gradually and there will be a smoothness of operation. It is expected that the dam will not be raised until the upper part of the canal has been entirely clear of any floating craft that may have been moored in the canal.

(*e*) This structure can be built largely of standard structural sections. The dam proper is composed of plate girders. The anchors for holding the dam are of H-sections, channels, angles, and eyebars. The hinges are of steel plates, continuous on the downstream side the full width of the lock. These hinges are riveted to the flanges of the plate girders with the hinge pins in place; the pins may be made in sections of any length. The anchor hinges on the upstream side, holding the dam, are riveted to the webs of the plate girders. All the hinge connections have rivets in transverse or direct shear. It is not considered necessary that these hinges be bushed because movement of the parts is slow and infrequent. The upstream flanges of the plate girders consist of angles having their meeting legs machined, forming a close and watertight joint. The lower girder is provided with a box section, one side of which, when the dam is raised, abuts against a rubber sill, making a watertight joint.

(*f*) The flexible shutter dam is placed within the lock enclosure, between the upper guard gate and the upper operating gate at the elevation of the canal bottom of the upper approach. When the lock is unwatered it can be completely inspected, painted, and repaired, if required.

(*g*) As all parts will be placed out of view, the proposed dam has no objectionable features from an appearance point of view.

(*h*) Because the structure is submerged, it is not a likely subject for enemy attack. The power plant can also be placed out of view, if desired.

(*i*) As the flexible shutter dam is light in weight, compared with other types of movable dams, the cost will be considerably less. Cost of maintenance is small because of the smaller number of parts and the ease of access and inspection when the lock is unwatered. The weights (in pounds) of parts of the proposed dam (lock 80 ft wide and 30 ft deep) are estimated approximately as follows:

Dam proper, including girders, connections, and half of anchors	310,000
Other half of anchors (supported on lock floor)	53,000
Wire rope and sockets	7,000
Embedded anchorages	40,000
Contingencies	15,000
Total	425,000

The weight of two hoisting engines has not been included in the foregoing estimate. Because of abnormal wartime conditions, no estimate of cost is presented. Under normal conditions the average cost of steel and iron in the structure should not exceed 15¢ per lb.

SUMMARY

Probably no engineering structure has been given more study in connection with the operation of locks than a movable dam. Should a lock gate be wrecked by collision or otherwise while restraining the waters in a canal, sudden release of the water would cause a wave that would probably result in carrying away all vessels moored at the canal walls, and such vessels would be subject to collision below the locks and be wrecked. The magnitude of the catastrophe would depend on the head depth and size of the lock and canal. Having a movable dam will not avert the wrecking of a lock gate, but such dam will serve to stop the flow of water, permitting repairs to be made and restoring the lock for service.

The importance and necessity of having a movable dam is evident. The task of stopping a flow of water in a ship canal without such a structure would be tremendous.

DISCUSSION

C. L. HALL,[2] M. AM. SOC. C. E.—In his classification of movable dams, Mr. DeYoung includes submerged structures as type (2). Among the submerged structures mentioned are trestle dams, bear traps, Tainter gates, etc., but not wicket dams of the Ohio River type. Wicket dams are found on a great many canalized rivers. In particular there are forty-three such structures on the Ohio River and through them pass the heaviest river-borne commerce in the western hemisphere. Any general discussion of movable dams which does not mention dams of the Ohio River type is likely to give a false impression. Moreover, the classification of a lock gate as a form of movable dam is still more likely to confuse the reader.

The structure described by Mr. DeYoung is a substitute for the Poiree dam[3] which has been installed in several places to stop downstream flow through a damaged lock, thus permitting repairs to be made. The main difference between the two structures is that the Poiree dam merely provides the horses and props against which wickets may be placed to establish a closure, whereas the flexible shutter type of dam includes substitutes for wickets as integral parts of the dam, thus establishing closure automatically as soon as the dam is raised. Clearly this feature is desirable; but also it is much more expensive. There are comparatively few places where such complex dams are justified. Also, there are only a few locks where a gate failure would be so disastrous that both a submerged movable dam and a set of guard gates would be economically justifiable. For most waterways the extra insurance is not worth the cost.

A study of the drawings indicates that natural sedimentation into the recesses is not feared. In a clear stream like St. Marys River there may be no sedimentation during the long periods when the dam lies on the bottom. In streams that are closed every winter, it may be possible to raise and lower the dam every spring before navigation begins; but on the Ohio River this form of dam would probably not operate. In the upper river, acid would probably corrode the steel, unless it were made of a very expensive alloy. Throughout the entire river, sediment would be deposited in any recess, in such a way that it would probably be extremely difficult to overcome initial inertia when dam raising is undertaken. With the river open to navigation all year, it would never be easy to find a convenient time to raise and inspect a flexible shutter type of dam.

The writer expresses no opinion on the proposed dam, considered from the standpoint of the mechanical engineer. He has great doubt as to the practicability of using such a dam except in a canal or canalized river with far from normal characteristics.

[3] "The Design and Construction of Dams," by Edward Wegmann, John Wiley & Sons, Inc., New York, N. Y., 8th Ed., p. 309.

C. E. MEYERDICK,[4] ESQ.—There are various methods of operating locks with guard gates and supplemental gates. The contribution by Mr. DeYoung should be greatly appreciated because it is reasonable that few locks should be built without provision for stopping the flow through the lock chamber in case of an accident. There are, of course, many ideas on how to put a set of lock gates "into the dry"—by constructing bulkheads or by making use of the various forms of movable dams enumerated by Mr. DeYoung. A lock is not necessarily guarded by the use of a set of guard gates as illustrated in Fig. 1.

A simple plan for operating a lock is the plan used on most of the Mississippi River locks from St. Louis, Mo., to St. Paul, Minn. A broken set of gates would tie up traffic through the lock, in which case an auxiliary lock is usually available. Should the lock be left entirely open, the quantity of flow through the lock would not affect other traffic activities on the river since this flow would unquestionably be less than normal flow in the river. If a navigation canal is small in size, its capability to absorb a high flow such as might surge through an open lock chamber is limited. Lock chambers on the Mississippi River are equipped with only a single set of gates at each end of the lock. Normally, one set of gates is always closed. For any other arrangement of gates, if more are considered essential, it does not necessarily follow that expenses should be increased by operating all the gates, as some of them may be left recessed to be used as stand-by units in cases of emergency. The fact that a lock has two sets of gates at each end does not necessitate utilizing both sets to lock a vessel through the river. The cost of these extra gates, including that of the extra set of gates to be used as guard gates, and the cost of movable dams (bulkheads) recessed in the bottom of the lock or otherwise installed add up to a tidy sum for construction—not to mention operation and maintenance.

There are two types of lock gates commonly considered for navigation projects. They are the miter gate and the sector gate. Both types are usually installed in pairs with a sealing arrangement on the gates to effect a seal at the center of the lock where the gates meet, and with other seals at each wall from which each gate swings. The operating procedure for the miter gate is similar to that for the garden gate since the force usually is applied at the top of the gate. In the case of the miter lock gate, considerably more force is required to swing the gate through the water than is required to swing it free in air.

In sector gate operation, the face plate, being an arc, slices through the water as the gate is swung. The resistance against the sector gate is much less than that against a miter gate unless the gate has a plate on one side in addition to the radial face plate. The operating force on the miter gate commonly is applied through the medium of an operating arm attached to the top of the gate, whereas on the sector gate the force might be applied through a pinion mounted on the lock walk and meshed with a curved rack attached to the top of the face plate of the gate.

The sector gate recess requires more room than does the miter gate recess and both gate types have other advantages and disadvantages. One of the chief advantages of the sector gate is that, because of its slicing action, it can operate against a head differential and in high velocities of flow, whereas operation of the miter gate must never be risked in high velocities. Sector gates in any combination of sets in a lock, by using any one set of the gates, provide a movable dam. The lock chambers can be "valved" by the operation of the sector gates, and there is an indication of the economy of their uses—namely, for "valving," "locking," and emergency operation against high velocities.

---

[4] Mech. Engr., U. S. Engr. Office, Sacramento, Calif.

The writer favors sector gates because of their sturdiness and minimum deflection in the gate structure during operation. The fact that the resultant of all hydrostatic load lies through the center of the hinge (trunnion) indicates the reason for mechanical economies and utility of operation. A lock can be built with only two sets of sector gates that will meet the necessary requirements of many of the most important navigation structures.

Obviously, as proposed by Mr. DeYoung, the safety of lock operation should extend to closing off the lock in case of accidental damage to any of the locking or valving mechanisms. Mr. DeYoung is to be commended for emphasizing the necessity for safety requirements for navigation structures. The writer believes, however, that by using sector lock gates the margin of safety that can be attained will be comparable to what might be expected by installing a movable dam mechanism as proposed by Mr. DeYoung.

RALPH R. LEFFLER,[5] ESQ.—The plan outlined in this paper deserves full consideration wherever the problem of designing a movable dam arises. On certain waterways that are important in wartime, such a movable dam should be installed in preparation for World War III. The cost is relatively so small that many major peacetime locks should be equipped with it.

The prospects that Mr. DeYoung's plan will receive merited consideration are not good. The proposal is new; it is novel; it is unprecedented; it is irritating to the "rut-worn" mind; and it has not been done before. It must run the gauntlet of the heavy hands of the finical designers, the high-powered executives, the "solid-minded" citizens, the "buttocky" bureaucrats, the "practical" men, and a whole host of others, adept and zealous at dodging responsibility to safeguard themselves. The design has so many merits, nevertheless, that it will overcome these obstacles.

JAY L. SOUTHWORTH,[6] ASSOC. M. AM. SOC. C. E.—The dam described in this paper is worthy of consideration both as a movable and an emergency dam. As an emergency dam, it would afford a fast remedy in case of accident to the miter gates. As a movable dam, it would greatly reduce the cost of maintenance of the gates and lock chamber. It is particularly adapted to a lock which has a shallow breast wall as illustrated. This construction should prevent silt from depositing to a harmful depth on the structure in its supine position. For a lock with a breast wall of sufficient height, it would be more economical to use the Lockport (Ill.) type of emergency dam[7] which is similarly placed between the two upper breast walls.

[7] "Engineering Features of the Illinois Waterway," by Walter M. Smith, *Transactions*, Am. Soc. C. E., Vol. 98 (1933), Fig. 11, p. 328.

The dam should be designed to withstand the warping stresses resulting from the dynamic effect of the swirl of water under high velocity. In actual experience, this swirl of water has been caused by one upper operating gate leaf hanging by its anchorage in a diagonal obstructive position after the other gate leaves have been swept clear away.

The writer is not convinced of the necessity for an emergency dam in any lock. Since 1925, the hydraulic system for emptying and filling lock chambers has been so improved that the surge—the principal cause of lock gate damage in the past—has been sufficiently reduced so that the danger is practically removed. In thirty years of operation, the emergency gates of the Panama Canal have not been used as such. There has been no occasion to test them. Since the lock gates in the old Welland Canal between Lake Erie and Lake Ontario in Canada were damaged at the rate of two or three accidents per year for a long period, metal horns were provided at great expense at the miter ends of the new Welland Canal lock gates to prevent damage by absorbing the shock of a blow from a moving vessel. Today operators have been trained to use extreme care in moving vessels through a lock.

Inasmuch as the structure described can be used at great saving in ordinary gate and lock chamber maintenance, necessity seems to have been the "prime mover" in this unique conception. This type of dam would supplant the elaborate and unwieldy emergency structures that have been in vogue at Sault Sainte Marie, Mich., and other places in the past.

L. C. Sabin,[8] Hon. M. Am. Soc. C. E.—A plan for a movable dam based on experience in the construction and operation of canals and locks at Sault Ste. Marie, Mich., is presented in this paper. Although the dimensions assumed and the observations made as to the general problem relate particularly to the conditions there found, the application of the principle is not confined to those conditions. Any criticism that may apply to these specific requirements may not be applicable to less severe situations.

Need of safety appliances to prevent or stop the free flow of water through the canal serving the navigation locks has been in the minds of all engineers who have had the responsibility for the successful and continuous operation of the waterway through the many years of development at Sault Ste. Marie. Conditions have changed as each new unit of facility has been added and the problem thus modified. The variety of devices adopted was not only the result of such changes and of the experience gained in operation of the earlier types, but perhaps these changes have been as much the result of the ideas of the responsible executives in charge at the time.

The situations involved may be considered as presenting two problems, and the first decision to be made is whether both or only one of the requirements is to be met. First, shall dependence be placed on prevention, or second, shall provision be made for stopping the flow once established? If the arrangement is such that the separation of water levels is always made to depend on at least two gates the chances of free communication by reason of a collision with a gate become very small. Such a device has been depended upon in certain situations but it has not for long been the sole dependence at the Sault Canals. Either the inconvenience of operation, or the realization of the possibility and serious result of a failure to properly operate, has resulted in the second requirement; that is, to stop the free flow once established as early as practicable. This is illustrated by a history of the developments at the Sault.

---

[8] Vice-Pres., Lake Carriers Assn., Cleveland, Ohio.

The difference in level overcome by the locks at Sault Ste. Marie is normally about 21 ft but varies from 18 ft to 22 ft according to the stages of water in Lake Superior and the lower St. Marys River. It has been estimated that, under conditions existing in some of the canals, velocity may reach from 16 ft per sec to 21 ft per sec in case of communication of levels. The upper level is a canal a mile or more in length, whereas the lower approach is quite short.

The first attempt to provide for the passage of the St. Marys rapids by other than canoes was a lock built (1853–1855) by the State of Michigan having two lifts of about 9 ft each. In connection with this construction a caisson gate was built near the head of the canal. The difficulty of operating this gate was such that about 1859 a set of guard gates, similar to the lock gates then in use, was built just below the caisson gate. For a time, beginning about 1865, these gates were closed whenever a lockage was in progress—that is, when only one pair of lock gates was restraining the upper level. These gates thus became a preventive measure. They probably could not have been closed had a free flow through the canal been established by an accident.

South or landward of the State Locks the single-lift Weitzel Lock was built (1873–1881) with a length of 515 ft, and a width of 80 ft in the chamber and 60 ft at the gates. The Weitzel Lock and the State Locks were served by the same canal, deepened to 16 ft. The State Locks were operated until 1888 when they were destroyed to make way for the next improvement.

The work done in connection with building the Weitzel Lock included a movable dam designed by the late Alfred Noble, Past-President, Am. Soc. C. E. This structure introduced the use of a swing bridge carrying girders and wickets with hand-power machinery for operation. The method of operation was first to close the bridge, the bottom chord resting against the abutments on either side. The iron girders carrying the wooden wickets were then lowered successively against the horizontal sill, the girders turning on the horizontal axis along the lower chord of the bridge. When the girders were in place the wickets, hinged within the girders, were revolved into an upright position closing the canal. This dam was in place until 1896 when the canal was deepened to 25 ft, making the dam no longer operative.

The next change was brought about by the construction (1887–1896) of the Poe Lock which replaced the old State Locks. The Poe Lock is 800 ft long between operating gates. Its original chamber width of 100 ft was reduced to 95 ft in 1942 by placing a 5-ft concrete curtain on the south wall to repair damage caused by blasting for the MacArthur Lock adjacent to it. At first the Poe Lock was served by the old canal deepened to 25 ft and having a width of 108 ft at its narrowest place where it is crossed by the International Railroad Bridge with swing span. To fit this situation a canal gate was first built of the mitering type similar to the lock gates, but constructed of timber and iron.

It was proposed at first to use this as a safety gate, having it closed during any danger period—that is, when the levels were separated by a single lock gate. To serve this purpose only the lower 18 ft was sheathed, the upper part being left open for the passage of water to fill the locks. It soon was realized that delays resulting from such operation would be intolerable in view of the heavy traffic. Accordingly, it was utilized only as a head gate and fortunately no emergency occurred to call for its closure in a current.

After the completion of the Poe Lock in 1896 the upper canal was widened (1908–1911) giving two channels at the railroad bridge location. These channels, each 108 ft wide, were separated by an island about 80 ft wide carrying the center pier of the bridge which was used also for the center pier of a new movable dam. The closing of the widened and deepened canal, in which the flow in two channels would have to be stopped in case of an emergency, presented a more serious problem and was given much study, including rough plans of many types of structure. The conclusion reached was to build a dam of the swing-bridge type provided with wickets on both leaves.

During the final planning of this dam there occurred, in the canal on the Canadian side, the only accident resulting in the actual communication of water levels. A dam of similar form had been built for this emergency and its use in stopping the flow developed some weaknesses. Advantage was taken of this fact and the plans for the new dam were modified to strengthen certain members.

Each leaf of the bridge carried sixteen steel wicket girders of box cross section about 6 ft 9 in. wide, hung on a horizontal axis at the downstream chord of the bridge and stored under the floor system of the bridge when not in use. When the girders were swung to position, the lower ends resting against the sill, the wickets were released to slide into place. In general form it thus resembled the Alfred Noble dam of 1880. This dam[9] remained in place for about thirty-four years until, in 1944, the deepening of the South Canal in connection with the construction of the MacArthur Lock made it inoperative. Although its use never had been required to stop free flow, it provided insurance and was of some service as a cofferdam in unwatering the canal. Between 1908 and 1919 two new locks were built with a separate canal north of the one to which the preceding description has referred. This north canal has a least width of 280 ft with a depth of 24 ft; the locks and lower approach were built to 24.5 ft below low water datum.

The types of dam considered advantageous were not thought suited to a span of 280 ft and, moreover, it was evidently not desirable to close the entire canal should only one lock be disabled. In the construction of these locks an important innovation was made in providing double service gates at each end. The proposed method of lock operation was such that at no time would the separation of levels depend on one set of gates. Although this is not a certain preventive of level communication it is extremely unlikely that two pairs of gates would be carried away by the collision of a ship. This being still a possibility, however, a movable dam was provided to operate at the upper end of either lock.

---

[9] *Engineering Record*, August 5, 1911, p. 161.

This dam consists of an 85-ton bridge capable of serving either the Davis Lock or Sabin Lock and when not in use is stored on the canal wall just above the upper guard gates of the lock. Two large derricks, one on either side, swing this wicket bridge into position in recesses provided in the canal walls. An operating bridge of lighter design is also provided to be placed over the canal about 40 ft upstream from the main bridge to carry a winch truck. Thirty wickets to close the opening, also stored on the canal wall, are placed consecutively by the derrick. A wicket picked up by the derrick is first hung on hinge pins on the wicket bridge; the winch truck moving on a track on the operating bridge then serves to lower the wicket into place against a timber sill at the bottom of the canal. The width of the canal section at the dam is about 90 ft, each wicket closing about 3 ft.

The principal objection to this type is the time consumed in operation. As many as two days have been required for complete closing, although it is thought that this time could be greatly reduced if the operating crew were kept in training. This objection is not as important as might appear, since the principal damage that could occur probably would take place within a few minutes, or at least within an hour after the accident; and no type has been tried which could be operated within that time. However, no traffic in the canal could be resumed until the flow in the damaged lock could be stopped.

The construction of the MacArthur Lock in 1942–1943 presented again the problem of providing means to stop the flow if the wrecking of a lock gate should permit communication of the water levels. This lock replaced the old Weitzel Lock and thus utilizes the south canal serving the Poe Lock.

The plans included the removal of "Bridge Island," thus destroying the movable dam at that location. The resulting width of the canal, with Bridge Island removed, being too great to permit the adoption of any of the types in use, it was decided to place a dam immediately above the new lock and a similar dam at the head of the Poe Lock.

The structure adopted is simple in general plan as it consists of six girders spanning the canal and sliding in vertical grooves in the canal wall. For the MacArthur Lock these girders are about 87 ft long and 6 ft high. The depth of the girders at the center is 6 ft. At the ends they are 3 ft deep and are provided with both reaction and end guide rollers to facilitate sliding to place and removal. The girders are stored on the canal wall and placed by a stationary derrick.

The dam was used as a cofferdam during one winter and considerable difficulty was experienced in removing the girders in the spring because of the formation of ice. Similar trouble might attach to other types if used in winter, but prior steaming should relieve this difficulty. As in the case of other dams its placing in a current has not been tested at the Sault but when not under pressure the time of operation is estimated at two or three hours. A similar structure was later provided at the head of the Poe Lock where the span is about 106 ft, thus requiring much heavier construction.

It may be noted that this stop-log type of dam, properly designed, has very little leakage and thus may serve as a guard gate permitting full access to the regular guard gate of the mitering type.

It is realized that some question may arise as to the justification for the expense incurred in providing the rather elaborate structures described when the probability of an accident that might call for their use has proved so remote; but the volume of the traffic and the effect of any prolonged delay must be considered.

On the completion of the Weitzel Lock in 1881, the first lock built by the United States, the traffic passing the canal the following year was 2 million tons. After the completion of the Poe Lock in 1896 the commerce passing this lock alone in its first full year of operation reached 13 million. In the first full year of operation the Davis Lock in 1915 passed 57 million; the corresponding figure for the Sabin Lock was 51 million in 1920.

A rough value for the cost of the transport concerned may be taken as 10¢ per ton per day. For an annual traffic of 100 million tons, which has been exceeded, this represents a loss of some $40,000 per day and for a delay to one lock a loss proportional to its traffic, except for the amount which may be passed through other locks. Being thus concerned with a commerce volume in excess of the total import and export of all United States ocean and gulf ports, assurance of uninterrupted passage is of such importance as to warrant considerable expenditure.

The author has indicated the relative importance of the desirable features of a movable dam, certainty and reasonable facility of operation being prime requisites, and with this there must be general acquiescence. The dam described has many excellent and novel features and appears to fulfil these prime requirements. The criticism which might be suggested by this discussion relates to the large number of movable parts and the possibility of collecting mud on any submerged structure in a silt-bearing stream. The latter may not be serious in waters of the Great Lakes.

The conservative engineer may wish to see this novel form tested under conditions somewhat less rigorous than those prevailing at Sault Ste. Marie before adopting it for that particular location, where frequent operation is not needed and where a failure to operate when required might prove disastrous. However, for these less rigid conditions it would seem to be well adapted and the author deserves much credit for his contribution in design and description to the general subject of movable dams.

A. W. SARGENT,[10] M. AM. SOC. C. E.—Some means should be provided at ship canal locks to stop the rush of water through the chamber, in case a lock gate is rammed by a ship or otherwise damaged. The method usually adopted is a dam—an emergency dam—that can be installed in swift water. The type would depend somewhat on the time that should be allowed for placing the dam, and this would vary in different localities. In some canals, the excessive loss of water from the upper pool would seriously affect shipping and the dam should be designed to be placed with the least practical delay. In other localities excessive discharge from the pool would not be of great importance and a less expensive dam, which would require several hours to install, could be used.

---

[10] Stanwood, Wash.

An emergency dam must be reliable; it must be ready for use at all times and therefore should be stored where it can be inspected and kept in perfect repair.

The author proposes an emergency dam located in a sump in the bottom of the lock where inspections and repairs can be made only when the lock is unwatered. Proper maintenance would be very difficult and wire cables could be weakened by corrosion in a short time, especially in locks bordering on sea water. Sunken timbers or other débris could lodge on the dam, preventing its successful operation and, after practice operations of the dam when the lock is not unwatered, there is no visible means of determining whether the dam has settled completely back into place or whether it is partly raised where a vessel could wreck it.

Some of the objections to this type of emergency dam are mentioned in the preceding paragraph. However, at the St. Marys Falls Canal, where the locks are not operated during winter months and there is ample time for repairs, this type of dam may prove satisfactory. It would not be a logical type to use in a lock bordering on sea water, such as Lake Washington Ship Canal, Seattle, Wash., where there is a single large lock for freight traffic which is operated throughout the year except for a very short period for general repairs.

The stop-log type of emergency dam, composed of steel girders placed horizontally across the lock, one on top of another, by a derrick and stored adjacent to the lock when not in use, is a very reliable type and perhaps one of the most costly types for large locks. The type used at St. Marys Falls Canal locks, with all parts stored on the lock walls, and where three to four hours are required to install it, is a satisfactory type at a reasonable cost.

The cost of the structure, or time required for installing, should not be the deciding factor in determining the type of emergency dams for locks. Reliability should be the first consideration.

A skeleton miter lock gate, powered to be safely closed in swift water, after which the complete closure would be made by needles or wickets, might prove a satisfactory type of emergency dam in some locks.

Isaac DeYoung,[11] M. Am. Soc. C. E.—In Mr. Sabin's discussion, a historical review is given of the developments of the various forms of safety appliances adopted at the Sault canals to stop the free flow of water, in the event a lock gate is rammed by a vessel or otherwise damaged. Seven different devices are enumerated beginning with the caisson gate for the lock of 1855 to the present form of dam of the box girder type for the MacArthur Lock, completed in 1943.

The plan of the proposed dam is based on the latest conditions existing, in that the lock has a depth of 30 ft. The application of the form of dam will be more favorable to less severe conditions.

Since the first canal and lock were opened to navigation, at St. Marys Falls Canal, Michigan, in 1855, no accident has occurred that resulted in the urgent need for a movable dam. At various times, however, the gates of the locks at St. Marys Falls Canal have been struck by vessels, with potentially serious consequences, while maneuvering through the locks (see Table 1). An accident occurred at the Sault Ste. Marie Canal, Ontario, on June 9, 1909, in which all the gates, except the intermediate and guard gates, were wrecked, making the canal and lock an open raceway. A movable dam, of the swing-bridge type, was available to stop the free flow.

---

[11] Consultant to City Mgr., Sault Ste. Marie, Mich.; formerly Supt. of St. Marys Falls Canal, Michigan (retired).

There have been no collisions with the gates of the Davis and Sabin locks since they were placed in commission in 1914 and 1919, respectively. The wooden gates of the Weitzel Lock, built in 1881, have been struck at various times by sailing vessels, but not to the extent that would require an emergency dam. More detailed information of the accidents may be obtained by reference to the Reports of the Chief of Engineers, U. S. Army.

All the gates of the locks at St. Marys Falls Canal are mitering gates. The Poe Lock, in addition to the upper and lower guard gates (which are used only for unwatering the lock), has one pair of operating gates at the upper end of the lock, and two pairs at the lower end. All the other locks have two pairs of operating gates at both ends of the lock. In the lock of the Sault Ste. Marie Canal, Ontario (item 8, Table 1), there is one pair of operating gates at the upper end of the lock and two pairs of operating gates at the lower end.

[a] Each collision occurred in the Poe Lock (St. Marys Falls Canal) except No. 8 which occurred at the Sault Ste. Marie Canal in Ontario, Canada.

In the accidents listed in Table 1, items 2, 4, 5, and 8 were the most serious. In accident 1, the upbound vessel struck the south leaf of the upper operating gate. Upon examination, after pumping out the lock, it was found that the gate was deformed only enough to prevent the use of the gate during the remainder of the season. Repairs were made during the following winter.

In accident 2, the vessel was approaching the lock upbound; it struck the downstream side of the lower south leaf, while the water in the lock was at the upper level and while upper gates were being opened for a downbound lockage. The leaf was driven upstream some distance against the high level of water; but, fortunately, the gate fell back, mitered partly with the opposite leaf, and, withstood the shock. Considerable damage was done, causing the lock to be out of commission for twenty-two days. Permanent repairs were made during the closed season.

In accident 3, the vessel struck the north leaf of the lower operating gate 3 ft from the miter post, the stem making a vertical dent 10 in. deep for 20 ft in the height of the gate. The north leaf passed the south one at the top of miter posts 3 ft to 4 ft, the water pouring in a large stream between the gates. These gates were out of commission the remainder of the season. Only the intermediate gates were used during this time, with the effect of shortening the lock by 93 ft. The repairs were made by the owners of the vessels during the closed season.

In accident 4, the steamer struck the south leaf of the upper operating gate, twisting the gate so badly that it could not be used the remainder of the season. The gate was temporarily replaced by a leaf of the upper guard gate. The lock was out of commission for seven days. The gate was completely wrecked; the work of repairs involved the dismemberment of practically all parts and the rerolling of the plates at the mill. Repairs were made by the vessel owners. The cost of repairs was extensive.

In accident 5, the vessel struck the south leaf of the upper operating gate, doing considerable damage. The gate was forced open against a high head, breaking the miter so that the distance between the toe cushions was estimated by the lockmen to be about 2 ft. Fortunately, the gates mitered perfectly when they were closed. The gate was damaged considerably.

In accident 6, the vessel struck the north wall with her anchor about 200 ft east of the upper operating gates, and scraped along the wall until the bowsprit rode up on the footbridge. The wooden bow of the steamer was wrecked for about 10 ft. The lower part of the wooden vessel was sufficiently decayed to make it a fairly effective fender or cushion.

In accident 7, the vessel backed into the intermediate gate which had a head of 3 ft on it. The pressure of the vessel's rudder broke the miter, moving the gate on its pintle support. After breaking the miter, the wheel of the steamer struck the toe of the gates, breaking off the four propeller blades The damage to the gate was not extensive.

In accident 8, in the Canadian Sault Canal, the steamer *Perry G. Walker* in approaching the lock upbound, rammed against the lower lock gate under a head of about 20 ft. The impact broke the miter, all the gates were carried away except the intermediate and guard gates, making the canal and lock an open raceway. The Canadian passenger steamer, *Assimmboria,* with one hundred passengers aboard was tied up in the lock waiting for the steamer *Crescent City*, an ore laden steamer, to enter the lock behind her. The *Assimmboria* was swept out of the lock, followed by the *Crescent City*. All three boats were damaged more or less by glancing blows when passing each other The movable dam was swung across the canal and the flow through the cana was sufficiently checked to place a spare set of gates, which had been built a short time before the accident. These gates were stepped in place on June 1 and the lock was again put in commission on June 21, 1909.

All the wickets of the dam were lowered into place successfully, except one which rested against an obstruction at the sills. That wicket became badl twisted and could not be operated. This gap was closed by stop planks This movable dam is similar to that of the South Canal of St. Marys Fall

Canal, Michigan, which was put out of commission when the canal was deepened in 1943. The Canadian dam (item 8, Table 1) is still ready for use.

Each of the accidents cited in Table 1 was the result of a misunderstanding of signals between the vessel masters and the engineers.

Colonel Hall criticizes the proposed movable dam on the premise that it will be expensive. The cost of such a structure should not be a deciding factor in determining the type of an emergency dam. In the paper it is stated that, because of the small quantity of steel and other metal required in its construction as compared to other forms of dams, the cost would be relatively less. The required weight of steel, and other metals, in the proposed dam is indicated as being about 215 tons, consisting largely of standard structural sections. In the construction of the swing-bridge, movable dam in the South Canal of the St. Marys Falls Canal, more than 2,100 tons of metal were used.

Colonel Hall questions the need for a movable dam, stating that "for most waterways the extra insurance is not worth the cost." If provisions are made by installing two sets of operating gates at each end of the lock, the chances of wrecking both sets of gates are very slight. Such an arrangement has been depended upon in certain localities, but it has not been the sole dependence at the Sault canals. As stated, all the accidents enumerated in Table 1 were the result of a misunderstanding of signals of the vessel masters and the engineers at the throttle, over which the lock personnel had no control.

The recess that houses the folded dam is protected by cross walls which will prevent the passage of boulders and other large objects from entering this recess. Large debris pits are provided upstream from these cross-walls. The anchor troughs are fully covered by angle flanges attached to the top anchors, thus preventing any debris from entering these troughs when the dam is in the lowered position. If sediment should be deposited on any or all parts of the dam, the structure can still be raised through a considerable load of sediment because, in the raising, the upper parts which constitute only a small part of the total weight of the dam are moved first.

Sedimentation will affect any form of movable dam, whether it has only a sill or any other underwater connection.

Mr. Southworth refers to the dynamic affect of a swirl of water against the dam caused by a wrecked gate leaf hanging by its anchorage in a diagonal obstructive position. The proposed dam will be placed upstream of all operating lock gates, and a swirl produced would be downstream from the dam.

Regarding Mr. Sabin's criticism that the proposed dam has a large number of parts—there are nine plate girders and forty anchors, which form practically the entire structure, and the entire assembly is operated as one unit. In comparison with the swing-bridge movable dam of the South Canal of the Sault canals it has, besides the bridge, thirty-two wickets and thirty-two wicket leaves. Each wicket and leaf is operated singly by cables through individual hoist mechanisms which are connected to a line shaft operated through motors located at the center of the bridge.

In the dam for the Davis and Sabin locks, there are two bridges to be lifted in place—the wicket bridge and the operating bridge. The dam is provided with thirty-two wickets, and into each wicket are to be inserted two 15-in.

steel channels. Each of these units is lifted singly into place by the 85-ton derrick.

A model of the proposed dam has been made to determine its workability. It was made from plans in the early stages of its development and is not exactly in accordance with the latest plan, but the general characteristics and method of operation are the same. The operation of the model is very satisfactory.

UTILIZATION OF GROUND-WATER STORAGE IN STREAM SYSTEM DEVELOPMENT

By Harold Conkling,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Raymond A. Hill, Clarence S. Jarvis, John R. Charles, C. W. Sopp, J. A. Bradley, Irving B. Crosby, G. B. Drummond, Raphael G. Kazmann, Donald M. Baker, Hyde Forbes, and Harold Conkling.

Synopsis

The scope of this paper is limited to consideration of those formations which may be called underground reservoirs, into which water is charged naturally or can be charged artificially when there is a surplus, and from which water is available when needed either as gravity escape from the ground-water reservoir into a surface stream (rising water or return flow) or as controlled extractions by wells and pumps.

Introduction

The first developers of irrigation on the stream systems in western United States utilized such surface discharges as were available. In streams fed by melting snow these discharges might be fairly large until late in the growing season, but in streams where snowfall at the headwaters was small, or where the runoff season began early, the dependable surface flow was small in the latter part of the growing season. In this circumstance and where climate and geology were favorable, recourse was had at about the turn of the century to wells and pumps to utilize ground water for supplementary irrigation; but in locations where runoff was larger and in more favorable regimen, utilization of ground water was long delayed unless artesian flows could be developed. However (especially in the 1930's which in western United States was a decade of drought generally), pressure of need forced the use of ground water by individuals even in those areas favored by fairly stable surface flow in the irrigation season and by large surface reservoir capacity. Use of pumped water for irrigation is expanding rapidly in some of these areas and in others that formerly had available only such natural discharge as occurred in the flood season of early summer.

Note.—Published in January, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Deputy State Engr., Water Rights, Sacramento, Calif.

Complete development of water supplies for irrigation in the United States will require the greatest possible use of the underground portion of the streams and of the storage capacity resident in the unconsolidated alluviums of the stream valleys. The plans for large development by federal government agencies in cooperation with state and local agencies contemplate this use of underground sources. One of the principal features of the Central Valley Project in California is the use of underground reservoirs (17)(21).[2]

Such utilization is discussed in this paper from an engineering viewpoint and a brief review is presented of the somewhat inchoate body of knowledge of the subject. This paper is a preliminary attempt to correlate the subject matter, with emphasis upon those phases most useful to an engineering approach. Omission of other phases of the hydrology and geology of underground water does not deny their importance for other than the matters discussed herein nor their possible importance even in these matters.

The object of the paper places limitations on its scope:

1. Only that part of the United States west of the 97th to 100th meridian is included. This is the arid or semiarid portion, in practically all of which irrigation is needed for successful intensive agriculture.
2. Only those situations in which the following conditions exist are considered:
   - (*a*) Ground water in the alluvium is readily accessible to extraction by pumps;
   - (*b*) The alluvium is sufficiently permeable to yield water in commercial quantities;
   - (*c*) The alluvium is naturally charged with water or is susceptible of being charged artificially to such an extent that heavy commercial drafts can be sustained; and
   - (*d*) If artificial charging is necessary it can be done at feasible cost.

The foregoing conditions are necessary for the successful use of ground water in irrigation.

The scope of the paper excludes the lava beds of Idaho, Oregon, and Washington and the limestone formations of New Mexico. Immense quantities of water might be secured from the lavas judging from the large springs that discharge from the formation, and considerable quantities are being secured from limited areas of the limestone; yet experience is small concerning the exploitation of the ground water of the lavas by wells, and such exploitation would be generally hazardous and costly. The limestone formations are limited in extent, and utilization of their waters is still more limited.

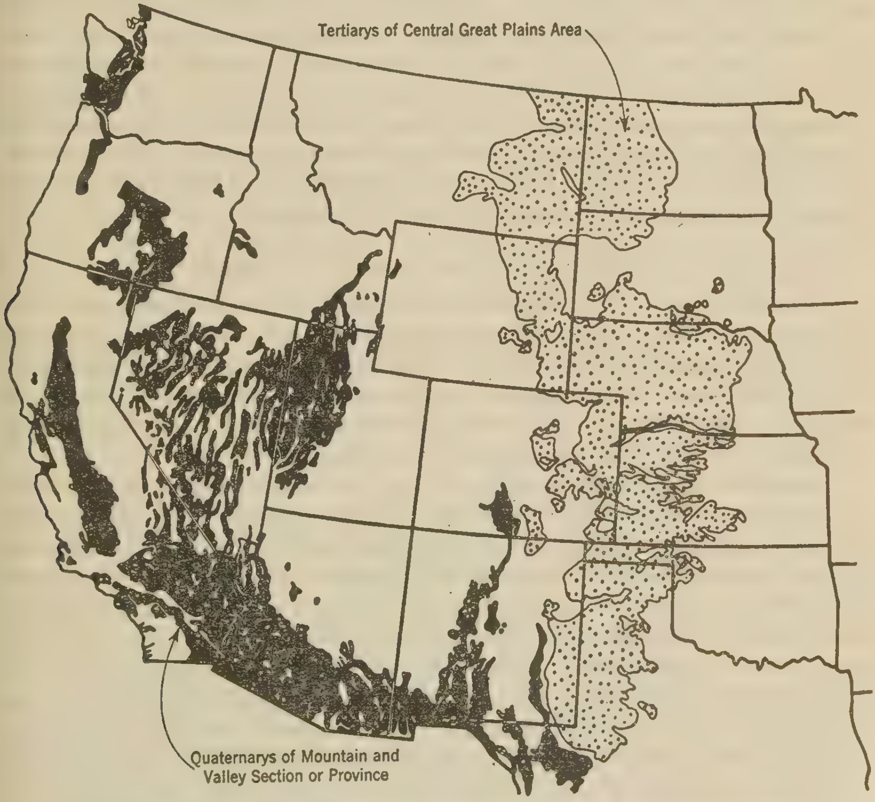
The criteria eliminate from consideration almost all of the water-bearing strata of Tertiary and early Quaternary age which underlie so great a part of the Great Plains east of the Rocky Mountains. In parts of this area these strata are close enough to the surface for water to be pumped from them and often they yield water freely in commercial quantities. However, except in the bottoms where the streams have trenched themselves through the finer surface materials down to the water-bearing strata, or in locations adjacent to the streams where water from the streams is being used or can be used for irrigation of the uplands, there is no opportunity for artificial recharge. Except for the negligible percolation from streams into these strata, the natural supply is the very small portion of the insufficient precipitation which is not used by vegetation, or which does not run off and thus must percolate to the ground-water body. The area irrigated in these regions outside of the stream bottoms is not large.

---

[2] Numerals in parentheses, thus: (17), refer to corresponding items in the Bibliography (see Appendix).

ALLUVIUM PROVINCES IMPORTANT FOR GROUND-WATER SUPPLIES

After the foregoing exclusions, only certain unconsolidated alluviums remain for consideration in this paper. These are (*a*) the Quaternary (with some Tertiary) alluviums of the "mountain and valley" ground-water province (8)(11); (*b*) the Tertiary and Quaternary alluviums in the stream bottoms of the Great Plains, and the same alluviums beneath irrigated areas near the major streams of the region. Of these the alluviums of the mountain and valley province are by far the most important for the purpose of this paper. Irrigation is practiced throughout this region and, as ground-water developments are extensive, it is believed that a greater volume of water is extracted from this



Tertiarys of Central Great Plains Area
Quaternarys of Mountain and Valley Section or Province

FIG. 1.—LOCATION OF ALLUVIUMS THAT YIELD IMPORTANT GROUND-WATER SUPPLIES

formation than from any other formation in the world. However, it is not implied that ground water can be produced in commercial quantities from all of the valleys of the province, nor even from most of them.

The mountain and valley province includes the Great Basin which embraces almost all of Nevada, western Utah, a part of southern Idaho, southeastern Oregon, and most of the southeastern desert region of California. The province also includes the coastal and central valleys of California, southern Arizona, and the Rio Grande Valley above El Paso, Tex. The portion of the Great Plains province considered herein borders the Rocky Mountains to the east and forms a wide band through North Dakota and southward almost through Texas. Fig. 1 which indicates the general locations of these sources is an adaptation of two illustrations in U. S. Geological Survey *Water-Supply Paper No. 489* (11).

The characteristic smaller valleys of the Great Basin are bolsons or semi-bolsons; that is, they either have no channel draining them and the water reaching them is disposed of by evaporation from central playas or they do have a longitudinal channel which partly drains them leaving the remainder of the water to be disposed of from playas. However, the larger streams of the basin discharge into perennial lakes and for purposes of this paper have characteristics similar to streams discharging into the ocean which drain the remainder of the mountain and valley region. In the Great Plains region all the streams under consideration are part of the Mississippi River system or of the smaller systems west of the Mississippi draining into the Gulf of Mexico.

Characteristics of Alluvial Valleys

A characteristic of the alluvial valleys of the mountain and valley province is the immense depth frequently attained by the unconsolidated alluvium, the large storage capacity of the alluvium below the water table, and its permeability. The water-yielding strata along the streams, and near-by uplands, of the Great Plains region are by contrast often of very limited thickness and thus of small water capacity although often highly permeable.

Beneath every surface stream in alluvium is an accompanying flow of water through the interstices of the alluvium. In exceptional circumstances this ground-water stream may be diverted to a direction different from that followed by the surface stream, but these circumstances do not invalidate the general rule. With the greater water supplies of a humid region this subsurface flow is almost always in contact with and supporting the surface stream. The low-water discharge of the stream is fed by the effluent seepage from the high water table. In the Great Plains area, at least in the western and drier parts, the discharge of the major streams except at times of local rain floods, in most cases, is supplied by runoff from the mountains. The natural water table of the major streams in this area is about at stream level. Generally (but not always) percolation is influent to the ground water; but only to the extent necessary to supply "evapo-transpiration" losses in the stream bottoms although there are reaches with a water table not in contact with the stream. (Effluence from the ground water to the stream when it does occur is also very small generally but a special case is the underflow—totaling annually several hundred thousand acre-feet—from the sand hills north of the Platte River in Nebraska. This flow augments the Platte from Bridgeport to Gothenburg, Nebr., a distance of 160 miles.)

In the mountain and valley province the streams discharge in general from steep mountains either in sudden rain floods or in more gentle snow-melt runoff. The flows are often sufficiently violent to cause the tributary streams to form steep cones of coarse debris along the sides of the valley and in almost all cases cones are evident. The slope along the trough of the valley is generally less steep. The water table is often far below the surface along the sides of the valley but may be near or at the surface along the trough. Obstructions beneath the surface caused by a narrowing of the valley or by a fault zone which has been active during the period of alluviation, or merely by a decrease in the permeability of the alluvium or by other reasons, will generally bring the underflow to the surface, thus joining the surface and underground streams. The seepage at this point becomes effluent; that is, it flows into the stream from the ground water, whereas in reaches where the water table is far below the ground surface it is influent.

The storage capacity in a reach of a surface stream is small or large with reference to the discharge in that reach depending on rate of flow—the slower the movement the greater will be the relative storage capacity. Water flowing through the interstices of alluvium moves very slowly; so the storage capacity in relation to discharge past any point is astronomically large. Thus any portion of the underground stream is a storage reservoir although not strictly so in the accepted sense of the term when a surface reservoir is under consideration. From this underground reservoir water can be drawn, and into it water may be charged if the water table is lower than the stream bed.

Rising water in these streams is the ground water moving downstream which has been brought to the surface by an obstruction. Even if the obstruction is not sufficient to so reduce the cross section that the underflow is brought to the surface, it will be raised to an elevation at which pumping extraction is easier. The term "basin" is often applied to the area above a subsurface or surface obstruction. Other criteria may also lead to the use of the word "basin" but there is no general definition. The term is used very loosely, but in spite of vagueness it is a convenient one. If the alluvium is deep enough, a basin in the water table could be created at almost any point by pumping and thus lowering the water table below the elevation that will be maintained some distance above or below or to the sides of the location of the pumping.

It is probable that the water supply of none of the stream systems of the west can be fully developed without utilizing some part of the storage possibilities of the unconsolidated alluvium; nor can it be fully developed without construction and utilization of surface reservoirs. The best development will balance the advantages and disadvantages of surface and underground storage, using both in the ratio found applicable to the particular stream system and the regimen of its flow.

A study of evaporation losses from hypothetical surface reservoirs on all streams in California (16) indicates that, no matter how large the reservoir capacity, streams of erratic annual and cyclic flow will yield for useful purposes no more than 50% or 60% of the annual average discharge because the remainder will be lost, over the years, by evaporation from the excessive water surface of the reservoir necessary to impound the water of the infrequent years of large discharge. Reservoirs of much smaller capacity would make almost as much water available. In streams of more regular regimen of flow the percentage of water that could be made available is larger; but it is evident from the aforementioned study, and it is common knowledge to those who have planned large developments, that the proper ratio of reservoir capacity to average annual stream discharge is definitely limited no matter what the extreme variations in annual discharge may be and that evaporation is one of the limiting factors.

On the other hand, if the elevation of the water table in a ground-water unit is below the root zone of overlying vegetation and below the limits of capillary action, loss by evaporation will be practically nil. Loss will occur, nevertheless, but it will be due to escape from the ground-water unit at the lower end of the unit whether as underflow or surface flow or transpiration from water-loving vegetation. Under the conditions presented in this paper, water underground is not static as it is in a surface reservoir when the water level is below the spillway lip and outlets are closed. On the contrary, it is moving as a stream or group of streams through the unit and toward the locus of escape.

Large and not directly controllable losses thus occur from both surface and underground reservoirs. For that reason water cannot be held in any reservoir for an indefinite period. Its supply must be replenished periodically and used before it is lost.

Factors that tend to make the use of ground water attractive are the gradually increasing cost of the gravity developments and the decreasing cost of pumping due to decreasing power cost and increasing efficiency of pumps. Furthermore, its use has two important advantages to the farmer—ground water does not carry weed seeds as does surface water, and it is available on demand for irrigation without waiting on rotation schedules. This immediate availability promotes over-all efficiency of farm operations although the cost of the pumped water may be greater than that of gravity water. Thus the relation between the desirability of construction and use of surface reservoirs as opposed to the use of underground reservoirs is altering progressively in favor of greater utilization of ground-water reservoirs in complete stream developments. The high prices paid for farm products is accelerating the construction of wells and the use of pumps. Once installed, the equipment will be used when desirable whether present prices for farm products continue or not.

In what follows frequent reference is made to the North Platte and Platte river basin of Colorado, Wyoming, and Nebraska, and to San Gabriel River Valley of Southern California. These two stream systems have been chosen because they involve extreme but quite typical conditions of the Great Plains province on the one hand and of the mountain and valley province on the other hand. In addition, an enormous amount of information is available about each.

In locations where utilization of the natural ground-water supply by pumping has been the paramount development (as has been particularly notable in California), it is being found that surface reservoirs must be built if much further conservation is to be accomplished even if the only function of such reservoirs is to equate the floods so that more of the stream flow will percolate to the water table in crossing the valley or so that it can be diverted feasibly in canals to off-stream spreading grounds.

A comparison of the situation on the coastal streams of California south from San Francisco with the situation in the Platte River basin is illustrative.

PLATTE RIVER BASIN

In the Platte River basin, surface reservoir development on both the North and South Platte rivers (which unite in Nebraska to form the Platte River) has been so large in comparison to annual stream discharge that it does not seem feasible to extend it farther although quantities of water are lost out of the irrigated area in both streams, particularly the North Platte, and severe shortages occur in parts of the irrigated areas. The irrigation projects that are diverted from the streams by gravity have created large return flows to these same streams which have been used by downstream irrigation developments. This return flow comes from the large amount of storage artificially induced beneath the surface of the lands irrigated by gravity along and near-by the streams and is fairly uniform as compared to the regimen of the natural stream flow. Individuals or groups can pump this water while it is still in storage, for use of immediately overlying lands, and thus in times of drought make it available to themselves instead of allowing it to proceed as return flow to others downstream from them. Such pumping was begun in earnest in 1934 (the worst of the drought years) and, since then, on the South Platte and on the main Platte rivers, its progress has been accelerating rapidly. It reduces the return flow and those dependent on such flow for gravity diversions are being forced to seek other methods of securing a supply. This need has been met in part by local surface reservoir construction and in part by pumping from the ground water beneath the local irrigated area which was deprived of gravity water by the new upstream draft on the ground water. Thus pressure of need is bringing about a development whereby the utilization of water is approaching the ultimate. This may be a logical development, but it is being made without long-range advance planning. The drainage area of the North Platte River

FIG. 2.—NORTH PLATTE RIVER BASIN

basin is shown in Fig. 2. Since the water of the South Platte River is virtually all consumed in Colorado, the Platte River is treated as an extension of the North Platte River.

Development of ground-water use similar to that in the Platte River basin is under way in the lower Boise Valley, Idaho, and in the Rio Grande basin in Colorado. It is well advanced in Salt River Valley and Gila River basin, both in Arizona, to mention only a few. This extensive use of ground water was not planned although the early conception of Salt River Valley project did envision some use of pumped water. Such conception was lacking in other places. The developments apparently have just happened for the most part and this fact is no great compliment to engineers and hydrologists. However, the lessons learned will be of aid in the future.

In the coastal valleys of California south from San Francisco, development has been almost exclusively from ground water, resulting in some places either in cumulative overdraft or expensive pumping lifts. Reservoir development in the headwaters of Santa Clara County streams draining into southern San Francisco Bay and of Los Angeles County streams has been made or is in process, but these developments are not designed to provide gravity water to the irrigator, but rather to give greater recharge to the ground water from which the irrigator can pump it.

Thus, whether the first and the major development of any particular water supply is from surface or from underground supplies, utilization of all opportunities for water salvage within some practical limitation finally occurs, although it almost goes without saying that the percentage of salvage by surface reservoirs, in such situations as are found in the Platte River basin where large and feasible surface reservoir sites are plentiful, will always be far greater than the percentage of salvage by ground-water reservoirs. In such situations as exist in the coastal valleys of California where surface reservoir sites in the mountain drainage areas are few, of limited capacity, and costly to construct, and where ground-water reservoirs of such large capacity exist, the ground-water reservoir will always be paramount.

Characteristics of a Ground-Water Reservoir

The capacity of a surface reservoir is determined by the safe yield from the stream that supplies it, and by the cost of the reservoir per unit of such yield. The capacity and the desired useful outflow are designed to be in harmony with one another, the relation between the two depending on the inflow and its regimen.

The ground-water reservoir, on the contrary, exists in nature and its capacity is set by nature. When man appears on the scene and proceeds to upset the balance of nature the reservoir is empty or full depending on the relation of the surface stream level to the surrounding terrain. In such a situation as the North Platte Valley astride the Nebraska-Wyoming line (and of course many other valleys of the Great Plains area) the reservoir was almost empty when developments began because it was drained by the trough of the stream which is cut far below the bordering terrain and because precipitation is not sufficient to maintain a water table appreciably above stream level. In the case of San

Gabriel Valley in California (and many other valleys of the mountain and valley province), the reservoir was full because practically the only outlet is the Paso de Bartolo (Whittier Narrows) which forms a spillway lip at the southern side (see Fig. 3). The streams entering the valley do not drain the ground water but feed it, and precipitation on the valley floor is also a considerable source of supply. Development of irrigation in the North Platte Valley, which is practically all by gravity, has resulted in filling that ground-water reservoir. Development of irrigation in San Gabriel Valley, which is practically all by pumping, has resulted in partly emptying that ground-water reservoir.

The ground-water reservoir exists in nature but its capacity is unknown and cannot be determined easily. Unlike a proposed surface reservoir its existence as such has rarely if ever been consciously envisaged until large use of water from it had developed. When pumping from it began the most important matter was whether good yields could be secured from wells at low cost. If artesian flows were discovered it was naturally so much the better.

As pumping increased and the underground reservoir was envisaged its safe yield became a most important consideration. One of the components that determines this is the capacity of the reservoir but, as before stated, its capacity cannot be measured directly as can that of a proposed surface reservoir. However, in the stage of development at which the ground-water reservoir is being consciously utilized, a mass of data will have accumulated concerning return flow, canal losses, precipitation, evaporation, consumptive use, stream-bed losses, change in water-table elevation, surface culture, stream discharge, annual pumping draft, etc. All of these items may not be applicable to any one ground-water basin but from those that are applicable, when properly assembled and interpreted, it may be possible to find the safe yield without determining capacity, as is necessary when a surface reservoir is contemplated. If such data are not available it may be necessary to estimate capacity through determination of specific yield of the alluvial material from which storage capacity may be calculated, approaching the problem much as an estimate of safe yield of a stream on which a surface reservoir is to be built is approached—that is, by determination of supply to, and demand on, the stream. This may be advisable sometimes with a ground-water unit even if all the applicable aforementioned data are available. Any such determination involves analysis of large amounts of data, but a direct determination based on recorded experience may involve less work than a determination based on capacity as an antecedent. Regardless of the work necessary the former method has merit because the result is found almost directly instead of as a residual quantity.

Safe Yield

Definitions.—"Safe yield" is the annual extraction from a ground-water unit which will not, or does not—

1. Exceed the average annual recharge;
2. So lower the water table that permissible cost of pumping is exceeded; or
3. So lower the water table as to permit intrusion of water of undesirable quality.

(*b*) GROUND WATER FLOW

Fig. 3.—Observations, San Gabriel Valley, California, in the Fall of 1941

"Specific yield" is the ratio (expressed as a percentage) of the volume of water which may be drained out by gravity from a given volume of soil. Possibly simpler terms would be "drainable voids" or "effective porosity."

"Specific retention" is the ratio (expressed as a percentage) of the volume of water which is held against the force of gravity in a given volume of soil. Possibly a simpler and sufficiently accurate term would be "field capacity."

Determination of Safe Yield.—Disposal must equal supply. This is fundamental to all physical processes. The supply of water to a unit or reach of a stream system is the surface flow and underflow into the unit and the precipitation falling on the unit. Final disposal is by surface flow or underflow or both, by evaporation, or by artificial withdrawal. If final disposal is in temporary imbalance with supply, the storage in the reach of the stream changes. The statement applies both to the part of the stream underground and to the portion on the surface.

Over a term of years the natural escape of ground water from a unit balances the natural supply to the unit. The amount escaping at any particular time is governed by the elevation of water table. In many cases the supply is also modified by this because the natural water table may be so high as to preclude percolation from parts of the streams. When pumping is begun the new and additional draft causes the water table to lower and natural outflow decreases. At the same time the lowered water table may induce a greater supply because of greater percolation opportunity. In other words, any reservoir, when half full, can and will impound more of the water that reaches it than it could if it were three fourths full or entirely full. Also, discharge through the uncontrolled outlets of a reservoir or over the spillway decreases as the water level in the reservoir decreases.

As a physical matter only, the pumping draft might become so large that outflow would be stopped. This possibility would depend on the slope of water table toward the outlet and on the depth of alluvium, but as a practical matter such lowering of the water table would probably bring about higher cost for the pumped water than would be feasible. Therefore, there is a financial as well as a physical limit to the safe yield of a ground-water unit. The essential problem of safe yield from a ground-water unit is to determine that part of the natural disposal that can be or has been diverted to beneficial use by pumping from the basin and to what extent the recharge will be or has been increased by development.

If the water is to be used on overlying land the salts in the return flow finally concentrated in the ground water would make it inexpedient to use it all. Some escape would be necessary to maintain the salt balance, for a ground-water unit needs "sewage" disposal as imperatively as does a municipality.

Thus there are two limitations on the safe yield as it might be calculated from consideration of only the supply to the unit and the void space in the alluvium. One of these is cost and the other is quality of water. However, a start must be made and the limitations due to cost and water quality may be considered after the physical possibilities have been explored.

It was stated previously that by the time the stage of development has been reached at which the ground-water basin is consciously treated as a ground-water reservoir, numerous data are available as to various phenomena that will aid in determination of safe yield. The question arises as to whether it would be possible to determine safe yield of a virgin ground-water basin. The quantities of water percolating to the ground-water basin or leaving it as transpiration, evaporation, and rising water would be the only criteria; but precipitation varies cyclically (to use a not wholly accurate but quite descriptive term) as well as annually and in the arid regions of the United States the cycle may be long and the percentage of variation in the cycle large. In Southern California the cycles during the period of record have been from 20 to 30 years long. If there had been no development in San Gabriel Valley and if an observer had measured the rising water at Paso de Bartolo for the period from 1905 to 1933 he would have been able to calculate the average surface outflow from the ground-water basin above. If he had been informed as to depth of the alluvium in the valley he would have known that sufficient capacity exists to give a safe yield equal to the average yield. However, he would not have known that the safe yield would be larger than the surface outflow because of greater recharge due to change from native to cultivated vegetation and to lowered water table which gives greater percolation opportunity. At any rate, only long-continued observation would have yielded satisfactory information. (The discharge of rising water from the valley varies with the elevation of the water table in the central part. Consistent measurements of rising water which began in 1923 and measurements of elevation of water table in the central part of the valley which go back to 1903 indicate that a fairly definite relation exists. The highest elevation was recorded in 1916 and the lowest in 1934. The highest average discharge of rising water taken from the relationship curve was 165 cu ft per sec in the water year 1915–1916 and the lowest (measured) was 38 cu ft per sec in 1933–1934.)

From some valleys, particularly those of the Great Basin, there is no surface drainage and the water supply is disposed of by evaporation from playas and transpiration from vegetation whose roots feed on the ground water near the low point of the valley. The area of high water table must vary with the climatic cycle and, although the draft on ground water per unit of area of such vegetation can be closely approximated by appropriate methods, it would seem that changes in the area of vegetation drawing on ground water would occur, thus making it necessary to wait years before this would be a definite measure of the safe yield.

It may be concluded that seldom, if ever, can safe yield be determined with any great accuracy until the data available from more or less haphazard development are at hand; but until such time comes probably approximations can be made by applying factors to a limited amount of data. However, only infrequently, if at all, would there be occasion to determine the yield of a virgin basin.

The Hydraulic Equation.—The various elements of disposal and supply for a stream in which a ground-water reservoir, basin, or unit is involved are the same as for a unit of a surface stream. The equation is as follows:

$$\left.\begin{array}{c}\text{Surface outflow}\\ \text{plus}\\ \text{Underflow out}\\ \text{plus}\\ \text{Consumptive use}\\ \text{plus}\\ \text{Change in storage}\\ \text{plus}\\ \text{Exportation}\end{array}\right\}\text{equals}\left\{\begin{array}{c}\text{Surface inflow}\\ \\ \text{plus}\\ \\ \text{Underflow in}\\ \\ \text{plus}\\ \\ \text{Precipitation on surface}\end{array}\right.$$

The equation is general but there are refinements which must be used under certain conditions.

Surface Outflow.—The lower end of a ground-water unit is generally at a geological formation either of relatively impervious alluvium or at a narrows which is a strategic location for a stream gaging station.

Surface Inflow.—The upper end of a ground-water unit is likewise generally at a strategic location for a stream gaging station. Strategic locations are generally available on tributaries also above the ground-water basin, but, if unimportant, their discharge can be estimated with sufficient accuracy.

Underflow.—Measurement of the outflow underground has been tried in various places with little success except in those cases in which its amount is negligible. As the underflow is generally small when compared to other quantities, because the area of permeable alluvium is constricted at points of outflow, a considerable error in the estimate of this item may not be important in the over-all result. Often the only inflow underground is the probably negligible amount from the rocks of the basement complex of the region.

Consumptive Use.—Much work has been done on consumptive use of individual crops and types of native vegetation by H. F. Blaney, M. Am. Soc. C. E., and associates (23)(26)(28)(29)(30)(31)(35)(39) and on total consumptive use of valleys as a whole. Therefore, it is possible to assign values to this item based on experience elsewhere, properly modified for variations in temperature and surface culture, or based on data from the unit under consideration itself (1)(4).

Change in Storage.—In all localities where ground water is important, interest has turned to measurement of depth to water from the surface at wells. As the years have passed it has come about that such measurements are generally made systematically and thoroughly. It is not always possible to determine whether a measurement discloses the distance from the surface to a column of water under pressure or whether it discloses the distance to a free water table. Consistency of measurements, study of results, and in some cases installation of recorders have helped in separating the two but difficulties will always be encountered. Changes in piezometric level, of course, do not indicate change in storage. For a pressure area the change in elevation of water table at the forebay (if such exists) is the indicator. These measurements give the change in volume of saturated alluvium which has taken place in a stated period of time and are thus indexes of change in amount of water stored.

Change in storage in an underground reservoir is the integration of the values of all the divergent forces acting on the ground-water basin. It includes the effect of the unknown underflows and, in fact, none of the other quantities noted in the equation except extractions need to be known for the determination of safe yield for any stated period. ("Safe yield" may be used as meaning the volume of water pumped or the net volume after consideration of return flow and other new recharge, which is lost to the ground-water unit due to pumpage. In this paragraph the former meaning is in mind. In the hydraulic equation the latter meaning is embraced in the terms "consumptive use" and "exportation." Consumptive use of pumped water is meant.) As compared to most of the other quantities and especially to the sum total, change in storage can be expected to be small. Even at the most it is unlikely that it would be more than 10% of the difference between total water entering (including precipitation) and leaving the unit and it will usually be far less. Error in this one quantity, even if in the same percentage order as the errors in other quantities involved, would therefore ordinarily be only a small part of the absolute errors involved in the other quantities.

Disregarding determination of underflow, determination of change of storage capacity via an antecedent determination of specific yield is the most difficult of all the items of the equation but is evidently the most important in those cases where such determination is desirable. It may be possible in many cases to estimate it from general physical conditions with sufficient accuracy for preliminary purposes and thus avoid elaborate determinations. Short cuts along this line have been evolved. The growing knowledge of values for consumptive use of vegetation is giving valuable aid.

Exportation.—Water used on overlying land gives return flow to the basin unless continuous impervious strata intervene between the surface and the aquifer. Exportations of pumped water do not give a return flow, and therefore the two must be kept separate in the hydraulic equation.

Precipitation.—In some regions fairly distant precipitation records are satisfactory. In others, notably the mountain and valley province, and particularly in the coastal valleys of California, variation is great in a few miles even on the valley floor and numerous records are necessary.

Observed General Values of Certain Phenomena.—It will be observed that the general hydraulic equation will give an accounting of the disposal of the supply for any stated period and involves both the surface flow and underflow of the reach of the stream in question. It does not necessarily provide a complete basis for extending experience into the future—that is, for the design of a project (if the term may be used), or for safeguarding prior rights dependent on the natural percolation. To do this it may be necessary to secure data on the variation in amount of percolation with variation in discharge of the streams, with variation in annual precipitation, with anticipated changes in surface culture, and with anticipated changes in elevation of water table.

In such case the hydraulic equation refers to supply to, and disposal from, the ground-water unit itself instead of from the entire portion of the stream system which contains the ground-water unit. The members of the left-hand side of the equation would be unaltered but "consumptive use," instead of being that of the entire basin, including that from precipitation direct, is only that which draws on the ground water; that is, the use by the area irrigated by pumping and by water-loving vegetation where the water table is high. "Surface inflow" on the right-hand side of the hydraulic equation becomes "percolation from stream flow," and "precipitation on surface" becomes "percolation of precipitation."

The determination of these quantities is much more difficult than the recording of precipitation and runoff since only the portion of these quantities which percolates is involved. These various items of recharge can be discussed only generally in this paper.

Percolation from Precipitation.—The portion of the rainfall on the alluvium of the valley floors which percolates past the root zone of vegetation is a supply to the underlying ground-water basin unless continuous impervious strata intervene. Average annual precipitation in the valleys of western United States varies from about 2 in. to about 30 in. East of the Rockies about 65% of the total falls in the late spring and summer, whereas on the Pacific Coast about 75% falls in the winter. In other areas the distribution through the year is more nearly uniform. Probably the runoff from any of these annual average rainfalls is not more than 5% in agricultural areas. The amount that gets through the root zone and thence to the ground water depends on the regimen of precipitation, the type of vegetation, the type of soil, and the temperature. The native vegetation tends to be of the highest type that the precipitation will support and hence consumes almost all the average rainfall even in a subhumid climate. Thus, percolation to the ground water in areas where the surface is covered with native vegetation probably occurs only in the years of considerably above-normal precipitation. A rough estimate would be that in such areas practically no precipitation escapes unless the annual average is above 15 in. and that with an annual average precipitation of 30 in. the average annual contribution to ground water is generally about 2 in., but that it varies from less than 1 in. to as much as 5 in. in exceptional circumstances.

In order to capture the rainfall the native vegetation often must develop tremendous root systems. These are lateral systems in extremely arid regions where depth of penetration of precipitation is necessarily very small and for this reason the individual plants are widely separated. On the other hand, where the soil is coarse and where precipitation is great enough to penetrate deeply, especially if it occurs in the non-growing season and thus must be stored in the soil because it is not consumed immediately, the root systems do not have disproportionately large lateral spread. Rather, they extend to great depths in order to use the greater part of that which has penetrated beneath the surface and been stored. As most cultivated vegetation except alfalfa, deciduous trees, and vines, has a comparatively shallow root system a larger amount of precipitation goes through to the water table after land in the less arid regions with the Pacific type regimen of precipitation has been placed in commercial crops.

Annual average precipitation on the well-developed Raymond basin area northeast of Los Angeles, Calif., is 22 in., of which 75% falls in the four winter months. In this area are the City of Pasadena, Calif., and several other cities, as well as irrigated groves (41). The average annual supply to ground water of this area from precipitation direct is about 5.3 in. in depth. When the area was in a virgin state, the deep percolation was about 2.0 in. Precipitation on the valley floor accounts for about 44% of total supply to the ground water. About 27% of the surface is impervious because of paving, sidewalks, and buildings. The culture on another 48% has been changed from the native state but change in root zone depth on this part has been immaterial. The major increase in penetration of rainfall to the water table has been from the remaining 25% of the area and the total amount of such increase is striking in the extreme when it is realized that it comes from so small a part of the area. In this part average annual penetration of precipitation is perhaps about 13 in., or six times as much as when it was in deep-rooted native vegetation. This increase, however, is partly due to runoff from impervious roofs of residential buildings to the pervious shallow-rooted areas of lawn and garden.

Such calculation of percolation from precipitation separate from irrigation water might not be possible where a large part of the precipitation occurs in the summer coincident with irrigation; nor in most cases would it be necessary. In such cases the precipitation is added to the irrigation water diverted to the area and the combined total is used in general calculations. Due account must be taken of increased over-all consumptive use due to almost total evaporation of small rainfalls.

After irrigation development takes place it would seem probable that in regions where precipitation occurs in the growing season contributions would occasionally occur to the ground water even with annual average precipitation of from 7 in. to 8 in. However, in a large part of the Great Plains region the soil is close textured and its field capacity is large. Although irrigation is practiced for general crops where average annual rainfall is as much as 24 in., precipitation in that region occurs mainly in the growing season when transpiration is heavy and it does not penetrate deeply; nor are deep-root systems necessary to take advantage of it inasmuch as it is used up very soon after falling and there is little accumulation. Hence contribution to ground water from precipitation on such soils is small even after the surface culture changes from native to cultivated types. Actually in this region (except in coarse soils such as the sand hills of western Nebraska, where the average annual rainfall is about 20 in.) the contribution to ground water from precipitation is almost negligible and exploitation may quickly cause overdraft.

Percolation from Stream Flow.—Under natural conditions and in regions of less than about 15 in. average annual precipitation, percolation from streams supplies practically all of the natural ground water of the valleys in the mountain and valley province. The water table is generally far below the surface and the material of the stream beds is generally very receptive of water. Percolation is greater in that portion of the stream beds consisting of coarse sands than it is in the portions wherein larger particles, termed gravel and boulders, are found because these particles occupy a considerable portion of the mass, whereas the percolate can travel only through the interstices of the sand which fills the space between the larger particles. In the San Gabriel River bed the material changes rapidly from coarse gravel, boulders, and sand near the mountains to rather coarse sand about six miles below. Farther downstream the sand is finer.

Percolation rates from this stream measured by the State Division of Water Resources varied from 0.90 cu ft per sec per acre near the mountains to 4.84 cu ft per sec per acre at about 6 miles below for the first few days of flood discharge (18)(20). From that point downstream, measured percolation rates decrease gradually to about 1 cu ft per sec per acre in the next two miles and presumably the rate is smaller farther downstream. A feature of percolation in this vicinity is its rapid decrease in the portion of the river bed near the mountains as the flow recedes and becomes more uniform after a flood. This is because of the deposit of calcareous material which forms on the stream bed near the mountains. In these reaches the gravel and boulders are of sufficient size to be undisturbed by the smaller flows. Downstream from this coarser material the lighter sands are moved continually by flows which do not disturb the heavier material and the calcareous coating is not formed until the flow gets smaller.

By a series of intensive measurements on San Gabriel River during flood times and subsequently until water ceased to flow into the ocean, a formula was established which has been expressed on a diagram (20) giving the volume of water which will percolate for different discharges at the mouth of the canyon from which the waters of the river debouch on to the valley. This diagram is somewhat similar to a rating curve for a stream measuring station but is more complicated.

A similar series of measurements and determination of percolation on Alameda Creek tributary to San Francisco Bay has also been made. The formulas derived apply only when the condition of the stream bottoms is as it was at the time of the investigations. The conditions in many of the coastal streams of California are similar to those of the San Gabriel River, and the formula applicable to the San Gabriel River has been used in calculations of loss from these other streams in the belief that substantial error would not result even if the ratio of percolation to discharge on these other streams was considerably different, which seems unlikely. This seems permissible and especially so because the number of days of flood flow in which the streams persist to the ocean is comparatively few. At other times the entire stream percolates and the cumulative total of percolation at such times is much more than the cumulative total during flood times.

Ordinarily, stream-flow measurements to determine percolation are too expensive to be practical except at low flows but, in these cases, were believed to be necessary for protection of prior rights, inasmuch as proposed reservoirs would disturb the flows and the percolation.

Percolation from Water Spread on Surface (*5*).—In Southern California at about the turn of the century, the practice was introduced of diverting the water of a stream over waste land below the canyon mouths where the water table was distant below the surface thus causing it to cover a greater area and giving it a greater opportunity to percolate. This is much the same as irrigating the land by wild flooding although for a different purpose than ordinary irrigation. Water is also caused to occupy a large area of the stream bed itself for the same purpose. In some cases the water diverted from the stream is ponded behind low dams or rock walls. The practice has since been adopted in other states.

Unless the stream is regulated by a reservoir which will also desilt the water, spreading cannot be done in times of violent rain floods because of the hazard or because the silty water will seal the surface of the gravel and decrease the percolation rate. Therefore, spreading on unregulated streams is usually done at other than flood times, and most of the discharge in many such times would percolate even if not spread (because of the small volume), although at some lower point on the stream.

The more uniform snow-melt floods carry less silt and fewer precautions are necessary. Spreading other than small quantities on unregulated streams may be quite a costly matter when net benefits are considered. Published data are misleading in that they give gross amounts diverted and spread without reference to the amount which would have percolated anyway. Often too, published data are not actual records of even gross amounts diverted.

Spreading from regulated streams is more successful and possibly will be ultimately developed in many streams where conditions are favorable. The surface reservoir regulates the flow so that it can be handled more easily. Spreading under such conditions is equivalent to a transfer of water from a surface on-stream reservoir to a surface off-stream reservoir, in this case represented by the underground reservoir. Even in such cases published records may give exaggerated values.

The initial rate of percolation from spreading grounds may gradually decrease through each spreading season and the average rate for each successive spreading season may decrease until spreading is no longer possible. This phenomenon may be due to changes in the soil caused by base exchanges. Other possible causes exist. This deterioration appears to be less evident, or entirely lacking, on debris cones of coarse material where native vegetation is undisturbed.

Water is sometimes diverted to wells which are not being used and the water is forced into the gravels by the head in the well thus created. The amounts thus caused to percolate have been comparatively insignificant and in some regions, due to deposition on the sides, the possible future utility of the well may have been impaired. However, in regions where deposition would not occur, it would appear possible to recharge ground water through wells in situations where a distribution system is installed having surplus capacity and surplus gravity water at a coincident period. Such recharge would seem to be of special importance in connection with demands on ground water for air conditioning now expanding so rapidly and also for general municipal drafts because such distribution systems lend themselves more readily to the practice and the draft is more localized than in the situations under discussion here. The matter is somewhat outside the scope of this paper and is here mentioned only in passing.

An important consideration often overlooked in evaluation of the benefit of spreading to induce additional underground supply is as follows: Unless the draft on the ground water of the basin into which the water is caused to percolate is greater than the recharge the water caused to percolate will be lost by increased transpiration from water-loving vegetation near the lower side of the basin or by escape as increased surface outflow or underflow. The sum of these increases would equal the additional water caused to percolate. The benefit from spreading in such basins is limited to the smaller pumping cost due to higher water table which exists primarily in the drought phase of the precipitation cycle inasmuch as, during the surplus phase, the water table would raise from the natural supply to about the same elevation as it would with the additional induced percolation. This benefit must be balanced against cost of spreading and loss of water to the stream due to increased transpiration in areas of high water table which reduces the supply to other users below.

Percolation from Gravity Irrigation.—Whenever water is used for irrigation the surplus beyond the amount consumed or returned directly to a water course percolates to the ground water. This deep percolation may be small or large depending on soil, crops, cost of water, etc., but it is inevitable. If the water is from a stream, thus constituting a new supply, the percolate finally fills the alluvium beneath to the level at which it will be disposed of in obedience with physical law. The disposal will be accomplished by evaporation if the topography is such that the water table approaches close to, or intercepts, the ground surface or by seepage into or by discharge of springs into drainage channels. Such discharge is called "return flow." It is the escape from the ground-water reservoir beneath the irrigated area which has been filled by percolation of water diverted from a stream and by any additional percolation of precipitation due to irrigation.

These irrigation enterprises accomplish much the same thing as "spreading" to induce percolation, but actually the amount of percolation is generally much larger although in most cases only an incident to direct beneficial use. Possibly the first conscious use of the alluvium as a water reservoir came about because of such deep percolation. This was so in San Joaquin Valley (California) where, in many parts, the excess water does not readily escape as return flow but swamps the land instead. Ground water was pumped through necessity near the beginning of the century, and, during subsequent dry periods which brought about recession of water table, water was diverted and placed upon the land during the non-growing season, or excess quantities were diverted during the growing season, in order to augment the ground water.

Specific Yield.—If the specific yield can be determined the water capacity of the underground reservoir can be calculated. Changes in elevation of water table registered in feet can be interpreted into changes in quantity of water—that is, into additions to and subtractions from the amount of water in storage. If extractions by pumping, specific yield, and change in water-table elevation are known, the safe yield for any stated period in which data are available can be determined. This information for a shorter period must be modified to find the long-time average safe yield.

In 1923 Mr. Meinzer listed seven methods for determining specific yield (11) and in 1932 he again listed the identical methods (13). In 1937 C. F. Tolman relisted them (8). It is safe to say that all direct determinations that have been made had one or more of the seven methods as a basis.

As given by Mr. Meinzer (headings are by the writer) the seven methods are:

A. Direct Determinations of Specific Yield:
  1. Laboratory saturation and drainage of columns of alluvium;
  2. Field saturation and drainage of alluvium as it lies in place;
  3. Determining from samples the specific retention and porosity after water has been drained in field;
  4. Pumping from ground water, exporting or using the water and observing the volume of alluvium unwatered; and
  5. Observing the volume of water entering alluvium and the corresponding volume of the alluvium in which a rise in water table occurs.

B. Indirect Laboratory Determinations of Specific Yield:
  6. By the centrifuge; and
  7. Mechanical analysis and determinations of porosity, estimating therefrom the specific retention and specific yield.

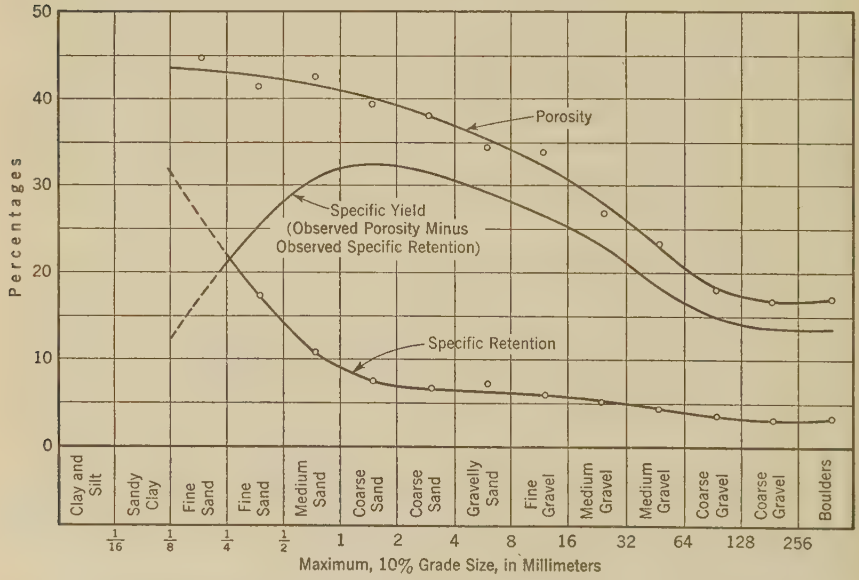

FIG. 4.—POROSITY, SPECIFIC RETENTION, AND SPECIFIC YIELD FOR SEDIMENTS OF THE SOUTH COASTAL BASIN

Adaptation in California.—Items 1 and 7, combined with much field work, are the basis of methods used for estimating safe yield in a large part of the coastal valleys of California south from San Francisco, by the State Division of Water Resources. In these valleys the water table is generally far below the surface. Supply to, and draft on, the ground water vary widely from year to year and data necessary to direct methods of determining safe yield are sometimes difficult to secure; or the methods may not be applicable in a large part of the area. In such cases specific yield must be known as an antecedent. In parts of the valleys, however, none of the aforementioned methods are applicable and other more roundabout procedures have been adopted although they are less satisfactory.

Laboratory methods naturally involve the application of the determination of specific yield at several points to the specific yield of a large mass and the procedure is open to objection from that standpoint; but this same sampling procedure is followed in determinations of many other physical properties. It happens that, in determining specific yield, it is possible to take advantage of other well-known physical phenomena for applying data secured at one point to the larger area. The result is to decrease materially the amount of work necessary, and to increase the accuracy. After several years of intensive work in the South Coastal Basin of California, notably in San Gabriel and Santa Ana river basins, procedures were evolved which may be applicable to the alluvium in other portions of the mountain and valley province where conditions are similar to those in coastal California (26).

A feature of this work was the objective of determining whether the slope of the debris cones formed by the streams could be used as a criterion for determining the variation in specific yield of unaltered surface material along radial lines from apex to distal portion, and whether the specific yield of unaltered surface material could be used as a criterion for the yield of altered similar material beneath the surface. It was thought that, if such relations did exist, a short cut would be available which could be used elsewhere in similar valleys under investigation with a minimum of field and laboratory work.

The study therefore involved laboratory determinations of porosity and specific retention of unaltered materials encountered in cut banks or well pits near the surface and at depth. It involved similar determinations of size of material at various distances from the mountains for streams of various sizes and various slopes of the surface. Fig. 4 shows the porosity and specific retention of a range of sands and gravels as determined by tests in the laboratory of more than 200 samples of unaltered material taken from near the surface (27). The curve labeled "specific yield" is the result of subtracting values in the "specific retention" curve from values in the "porosity" curve. It will be noted that even the finest of these materials is sufficiently permeable to yield water freely. As an easy method of determining the coarseness of the sample in the field the "maximum 10% grade size" is used. This is the grade size in which the cumulative total, beginning with the coarsest material, reaches 10% of the total sample and in these alluviums it is generally the next to largest grade size or sometimes the grade size next smaller. The maximum 10% grade size is the exact opposite of the "effective size" used by the late Allen Hazen, M. Am. Soc. C. E., in his investigations on sand filters which is the grade size in which the cumulative total beginning with the finest material reaches 10% of the total sample. For the entire South Coastal Basin a map showing lines of equal specific yield of surface materials was drawn and the part of it for San Gabriel Valley is shown in Fig. 5(*a*). Drillers' logs were studied and materials from wells in process of being drilled were tested so that it was found that certain expressions used by drillers such as "gravelly clay," for instance, referred to a material altered by decay from its original characteristics to a specific yield

about one third that of the original material at or near the surface. Well logs were studied by groups and the specific yield for the group was placed at a point on the map at approximately the center of gravity of the well locations. Other criteria, such as decrease in porosity due to depth, and the steepness of cone, etc., were given weight. All this was used in drawing contours of equal specific yield for the material within the probable range of fluctuation of water table (see Fig. 5(*b*)).

It was found that distance from the mountains and the steepness of slope of the debris cone were useful as indicators of specific yield. The method resulting from this intensive study has been applied to some extent with a very small amount of laboratory work to other similar valleys in California. The results have not been tested by other means in those valleys. In the central San Gabriel Valley and in the Raymond basin area of San Gabriel Valley from which many of the samples analyzed were secured and in which much of the work was done, studies have indicated that the values for specific yield thus determined in those locations are sufficiently reliable. This method is well suited to a large part of the coastal valleys of the state and should be also suited to much of the entire mountain and valley province.

Direct Methods of Safe Yield Determination

The foregoing involves measurement of capacity for water storage between different elevations of the water table of the unit involved and this is analogous to a survey made to determine capacity of a surface reservoir. In some cases operation of a surface reservoir has shown that the surveys made to determine its capacity were in error and that actual capacity was considerably different. This has been indicated by the fact that, after allowing for losses and inflow, release of a certain quantity of water did not produce the change in elevation of the water table which, according to the surveys, it should have. In such a case safe yield can be determined from operational data and capacity can be ignored. In other words, safe yield may be determined directly without knowing capacity.

Similarly with underground reservoirs: Given a set of conditions which comply with the requirements, safe yield and other desired information can be determined. There are three variables concerned—supply, draft, and change in water-table elevation. The requirement is that one variable must be sufficiently uniform to be considered constant, thus leaving only two. The most convenient method is graphic by platting on rectangular coordinates.

Two cases will be examined by way of illustration:

Case I. Supply to the Ground-Water Unit Is Uniform Year by Year, or Period by Period.—The variables are (*a*) the annual change in water-table elevation, and (*b*) the annual draft.

Case II. Draft on the Supply of a Unit, Whether Surface or Underground, Is Uniform Year by Year, or Period by Period.—The variables in this case are (*a*) the annual changes in water-table elevation, and (*b*) the annual differences in the quantity of surface water retained in the unit, as found by measuring inflow and outflow.

In either case, even if the period of record includes only years in which the water table fell, or only years in which it rose, the points when platted will define the slope of a straight line which, prolonged, will intercept the line of zero change in water-table elevation. This value on the axis on which volume of water is platted is the safe yield in Case I. In Case II it is the quantity required to supply the demand, whereas the quantity retained as determined by the measurements of inflow and outflow is the safe yield.

For Case I the net supply to the ground water might be sufficiently uniform to be so assumed (*a*) under an irrigation project in a fairly arid country, (*b*) in an area where the supply is by lateral percolation from ground water at higher elevation, and (*c*) in an area where, even if the water reaching the overlying surface is variable from year to year, distance to the water table is so great and perviousness so small that annual variations in percolation of the surface supply are eliminated to a large extent. In general it could not be used in a region of fairly large precipitation during the non-growing season although special circumstances might make it applicable in limited areas in such regions.

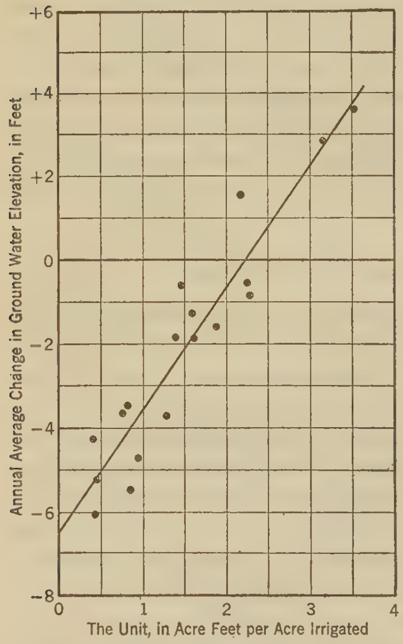

FIG. 6.—RELATION OF ANNUAL SURFACE INFLOW RETAINED TO CHANGE IN AVERAGE WATER-TABLE ELEVATION, TULE RIVER-DEER CREEK AREA

For Case II the net draft on the general water supply can be considered uniform in a unit where the irrigated area is fairly constant from year to year, and where deficiency in surface flow can be made up by pumping from the ground water. If precipitation on the surface of the unit were large and occurred in the non-growing season it might not be possible to use this procedure because of the great variability in apparent and actual consumptive use from year to year.

So far as is known to the writer, the Case I method was first used by Raymond A. Hill, M. Am. Soc. C. E., in work in Arizona. Similarly, the Case II method in this form was first used by S. T. Harding, M. Am. Soc. C. E. (17), in San Joaquin Valley and was used by the State Division of Water Resources in its studies for Central Valley Project. In both of these regions precipitation is small on the valley floors.

Fig. 6 illustrates Case II. It shows the surface inflow minus outflow per acre irrigated each year, platted against the average change in water-table elevation for that year, for the Tule River-Deer Creek area, which is one of the ground-water units of southern San Joaquin Valley (3)(8). The surface supply is from the two streams mentioned which head in the Sierra Nevada mountain range in eastern California. The flow is diverted by gravity and when deficient is augmented by pumping from ground water which is supplied by percolation from the streams from irrigated lands.

Underflow, either in or out, is unknown and is believed to be negligible; at least the difference is believed negligible. However, this is immaterial because the change in water table is the integration of all the forces acting on the ground-water supply. The net surface supply was sufficient in those years in which no change in water table occurred to supply the consumptive use plus or minus the net underflow.

The average area irrigated in the Tule River-Deer Creek area during the 18-yr period from 1921 to 1939, inclusive, was 67,800 acres and the maximum variation from this was about 10% plus or minus. The net average annual stream flow retained was 103,500 acre-ft or 1.53 acre-ft per acre irrigated. This is the safe yield for the 18-yr period. If 2.22 acre-ft per acre had been retained, the water-table elevation would have remained constant indicating that 2.22 acre-ft per acre (plus or minus any difference between underflow, in or out) is the net requirement or a total of 150,500 acre-ft for the 67,800 acres. Therefore, the average annual overdraft on the ground water of the unit for the 18-yr period is 47,000 acre-ft. The gross area of the unit is 239,000 acres and the water table lowered an annual average of 2.06 ft during the 18-yr period. Thus the soil volume drained was 492,000 acre-ft per yr and as the overdraft was 47,000 acre-ft the specific yield of the alluvium is 9.5%.

Whether the long-time average safe yield is 103,500 acre-ft is not disclosed by analysis of these data. To determine it would require a comparison of long-time average net surface inflow with that which occurred during the 18-yr period. A similar adjustment would be necessary with any other method. To make such adjustment would require a detailed analysis of the amount of percolation reaching the ground water from stream flow and precipitation during a long-time average period of precipitation to estimate the difference between that amount and the amount which did reach the ground water during the 18-yr period. Consideration would also be given to the changed amounts of underflow in and out which might occur with a changed elevation of water table.

In southern San Joaquin Valley the precipitation occurs in the winter and the annual average varies from 5 in. to 10 in. according to location. The direct contribution from precipitation to ground water may be regarded as negligible since the area with precipitation approaching 10 in. is small. Annual changes in water-table elevation at many wells in the various cones of the major streams or ground-water units have been recorded since the early 1920's and the average for the period of record can be calculated. Surface stream discharge into and out of each unit has been recorded. Underflow either in or out is probably negligible. The acreage irrigated each year is known approximately. In the particular unit under discussion, and in some other units, it has been fairly static for many years past.

In many situations large annual variations in supply or demand may be ironed out by using moving averages embracing sequences of several years. If this occurs it may be found that the methods of Case I and Case II will be applicable to the solution in particular areas, although not in regions of long swings in the precipitation cycle except perhaps in limited areas.

Dissolved Solids—Quality of Water

It is now known that not all the water of a stream system can be consumed in irrigation because the gradually increasing concentration of dissolved solids in it causes it finally to become so toxic to plant life that it cannot be used. A certain percentage of the water of a stream must be used to carry off the toxic material and to maintain a salt balance.

About 2500 years ago the great empires built upon the large irrigation developments of the Tigris and Euphrates river valleys deteriorated. It is surmised by some that these ancient empires retrograded because of lack of knowledge about the damage by dissolved salts to plant life; but, be that as it may, even as late as 1900 engineers in the United States knew so little about the matter that some irrigation developments (even in the part of the country where the geological formations are such that the moving water gathers large quantities of various salts) were designed without this difficulty in mind.

The problem is much less serious in some parts of the West than in others. Probably it is worst in west Texas, New Mexico, southwest Colorado, southwest Utah, Arizona, and the southeastern part of California. In some streams in other western regions there is little evidence of such toxicity, but the matter is one of degree. Water will dissolve some salts from all formations and, if the final residue of water is small enough, the solids will be sufficiently concentrated in it to be detrimental.

The same difficulty occurs with ground-water developments as with surface water but the likelihood exists, in the case of some ground-water developments, that the final disposal must be by pumping and exportation of sufficient water to carry off the dissolved solids.

Ground water suffers also in this respect from causes of concentration of solids which are not likely to exist in surface waters. Three examples may be cited:

1. Near the ocean beaches or other salt-water bodies, salinity may encroach into the pumping field if the water table is lowered sufficiently to reverse the normal gradient. This is not greatly different from the situation found in fresh-water streams for it is true also that salt water may encroach into such streams at their mouths and deteriorate the quality of the water in the lower reaches of the stream.

2. Well casings may be perforated incorrectly or they may be imperfectly set, allowing water with high concentrations of solids from a perched water table or other source to flow into the strata from which the wells of a field are drawing.

3. The ground-water basin was at one time a part of the ocean. Salt water was trapped in it and there remains below the fresh water because of its greater weight. As the weight of fresh water on it is lightened by pumping from it, and especially at the cones of depression and drawdown due to such

pumping, the salt and fresh waters tend to be mingled and difficulty occurs (2)(25).

Once the aquifers of a ground-water unit are impregnated with salt water it may be years, even with cessation of pumping, before the quality of water will be restored.

Movement of Ground Water

The rate of forward movement or flow of ground water would seldom be important to the purpose of this paper, because in most cases pumping is widely distributed over the surface of the ground-water unit and except in pressure areas the recharge is from the immediate surface. If the recharge is not predominantly vertical it may be possible to use the direct determination of safe yield by Case I without knowledge as to transmissibility. However if the recharge is largely lateral and if a part of the supply comes from a source in which concentration of dissolved solids is high (such as might be the case with a ground-water unit along an ocean beach) it would be found desirable to determine only the amount of the fresh-water supply. This could be done either by calculating the rate of movement of such supply into the ground-water unit (the cross section of the flow being known) or by calculating by other means the volume which must be entering the unit. Either method leaves much to be desired.

One important aid in determining direction of movement and influence of any one source of supply in any particular part of a ground-water unit is often the dissolved solids in the ground water and this matter should be given consideration in all ground-water studies (2)(25). However, the importance of this decreases as the slope of the water table steepens. If there are no discontinuities in the water table its slope should be a more definite indicator of direction of movement than the solid constituents of the water and their proportions. It would not, however, tell the amounts of water from each of two or more sources which reach the area of extraction. This would be best answered by determination of the dissolved solids.

Summary

This paper has sought to accentuate the fact that ground water is merely water beneath the earth's surface and that surface water is merely water on the earth's surface. The same drop of water moves from above the surface to below the surface and vice versa. Whether above or below, it follows the same physical laws at all times. Consideration of this fact should remove a part of the mystery which sometimes seems to surround the subject of ground water. The facts concerning movement of water underground are more difficult to obtain than those for water on the surface and this has caused less definite application of well-known principles than has been the case with water on the surface, but accumulating knowledge is giving methods for, and sureness in, dealing with ground water. This paper has presented, briefly, some of the values found and methods so far achieved, keeping in mind always that a solution of any water problem of the nature discussed in this paper is accomplished by merely substituting correct values in a simple equation. It is the values which are often difficult to determine correctly; but as data accumulate this difficulty decreases.

Ground water in alluvium is moving as a stream but at the same time the analytical approach to determination of yield is often, probably generally, best made if the ground-water body is treated as a reservoir. Regardless of this a clearer view will be had if the conception of it as a stream is not lost.

Each ground-water problem is unique in some of its elements. Even though the field has been very narrowly delimited, it is still so broad that it cannot be handled with anything approaching adequacy in a paper such as this; but, if the paper has served in any way to outline the possibilities in ground-water utilization and will promote discussion of the general engineering approach to such utilization, it has served its purpose.

DISCUSSION

Raymond A. Hill,[3] M. Am. Soc. C. E.—It might be inferred from the author's presentation of the subject that the safe yield of any ground-water unit is a definite quantity, as it is in the case of any normal surface reservoir formed by construction of a dam across a flowing stream. The safe yield of such a reservoir can be defined as the maximum rate at which water can be withdrawn continuously between times of filling, because all of the inflow is captured, until the reservoir fills and overflows, and losses are restricted to evaporation from the water surface and nominal leakage.

In the case of a subsurface reservoir, however, the proportion of the contributing supply which is captured and the magnitude of losses through evaporation and leakage are dependent in large degree upon the depth at which the ground water is held below the surface; this depth in turn is dependent upon the draft which is made on this reservoir. The safe yield—that is, the rate at which water may be withdrawn from any ground-water basin for use within or without the boundaries of the basin—is thus not a fixed quantity but a variable. Under any given set of conditions it is only necessary that the following general equation be satisfied:

Primary Equation of Hydrologic Equilibrium.—

$$\left.\begin{array}{c}\text{Surface inflow across the}\\ \text{boundaries of the basin}\\ \\ \text{plus}\\ \\ \text{Subsurface inflow across the}\\ \text{boundaries of the basin}\\ \\ \text{plus}\\ \\ \text{Precipitation within the}\\ \text{boundaries of the basin}\end{array}\right\}\text{ equals }\left\{\begin{array}{c}\text{Surface outflow across the}\\ \text{boundaries of the basin}\\ \\ \text{plus}\\ \\ \text{Subsurface outflow across the}\\ \text{boundaries of the basin}\\ \\ \text{plus}\\ \\ \text{Evapo-transpiration losses within}\\ \text{the boundaries of the basin}\end{array}\right.$$

The magnitudes of the terms on the left side of this equation are substantially independent of any condition or change in conditions within the boundaries of a ground-water basin; consequently, development of a supply of ground water generally requires a change in either the magnitude or the composition of one or more of the terms on the right side of the equation. If the unused surface outflow is decreased, then there can be a corresponding increase in the consumption of water within the basin, or an equal amount can be exported for use elsewhere. In like manner, exportations or greater use of water within the basin can be offset by restriction of nonbeneficial evapo-transpiration losses or by reduction of the subsurface outflow. The latter necessarily requires that the ground-water level be lowered within the basin except in the rare instance where subsurface outflow is cut off or reduced by construction of some barrier.

---

[3] (Leeds, Hill, Barnard & Jewett), Los Angeles, Calif.

The term "safe yield," as applied to a ground-water basin, has frequently been defined as that quantity of water which can be extracted each year without progressive and permanent lowering of the ground-water level. Although this definition is applicable to alluvial valleys along a stream where the safe yield is limited only by the rate of channel absorption and by the time during which the flow of the surface stream is much greater than the rate of withdrawal from the ground-water supply, it is too restrictive when applied to closed basins and to those where the ground water is not normally near the surface.

In neither of these latter cases could any quantity of water be withdrawn continuously without causing permanent but not necessarily progressive lowering of the ground-water level. The following general definition of safe yield is therefore suggested:

> "The safe yield of a ground-water basin is that quantity of usable water which can be extracted therefrom each year without progressive lowering below the level at which the same quantity can be obtained at reasonable cost."

Determination of Safe Yield.—In general, the determination of the safe yield of a ground-water basin under any set of physical and economic limitations can be made by evaluation of all terms in two primary equations of hydrologic equilibrium: One for the conditions which prevailed in the past and another for the conditions assumed for the future. This method, which evidently is preferred by the author, is necessarily subject to considerable error, because second differences as well as first differences between quantities of relatively great magnitude must be computed.

The problem may frequently be simplified by eliminating all factors which do not affect directly the ground-water supply. The following general equation is then applicable:

Secondary Equation of Hydrologic Equilibrium.—

Absorption of surface inflow within the boundaries of the basin		Subsurface outflow across the boundaries of the basin
plus		plus
Subsurface inflow across the boundaries of the basin	equals	Exportations of water across the boundaries of the basin
plus		plus
Absorption of precipitation within the boundaries of the basin		Evapo-transpiration losses within the boundaries of the basin

Most of the terms on the left side of the secondary equation are subject to less variation than the corresponding terms in the primary equation. For example, although absorption of surface inflow within the boundaries of the basin must equal the difference between surface inflow and surface outflow across these boundaries, it can be computed from measurements of the wetted channel area of the streams and observed rates of percolation. Likewise, it is generally true that the rate of absorption of precipitation is limited and that, when the intensity of rainfall exceeds such observed rates, all the excess passes out of the area in the form of surface runoff.

TABLE 1.—Hypothetical Basin (Area 10,000 Acres)

Successive years	Acre-Feet		Feet
	Annual contribution less outflow[a]	Annual quantity pumped[b]	Change in water level during year
1	17,000	8,000	+ 9.0
2	15,000	20,000	− 5.0
3	13,000	6,000	+ 7.0
4	17,000	16,000	+ 1.0
5	15,000	22,000	− 7.0
6	13,000	10,000	+ 3.0
7	15,000	18,000	− 3.0
8	13,000	4,000	+ 9.0
9	17,000	12,000	+ 5.0
10	15,000	14,000	+ 1.0

[a] Total contributions to ground-water supply minus total natural outflow vary from 13,000 to 17,000 acre-ft per yr. [b] Pumping draft on ground-water supply varies from 4,000 to 20,000 acre-ft per yr.

Direct Methods.—In many cases there are more direct solutions of the problem, which take advantage of the fact that contributions to and losses from a ground-water basin are not characterized by the wide variations typical of other hydrologic phenomena. Such direct methods, described briefly by the author, involve correlation between changes in the ground-water level and observed variations in either the contribution to or the extraction of water from the basin. It is believed that they have much wider application than is assumed by him. The direct method developed by the writer (Case I of the author) may best be demonstrated by assuming, first, a hypothetical case and then showing the result of certain actual determinations of safe yield of ground-water basins. Such a hypothetical case is given in Table 1.

In Fig. 7(*a*) the observed change in the average depth to water throughout this hypothetical basin is plotted against the corresponding annual amount of water pumped. The curve which best fits the plotted data is evidently a straight line. The points that fall on the straight line correspond to years in which the annual net inflow equals the average net inflow. The points that fall to the right of the straight line correspond to years in which the net inflow exceeded the average, and the remaining points which fall to the left of the straight line are for those years in which the net inflow is smaller than the average.

The departure of such points from the straight line is equal in each case to the difference between the actual net inflow and the average net inflow. The intercept with the x-axis therefore indicates the safe yield, which in this case is 15,000 acre-ft per yr.

In Table 2 the relationships are given between actual fluctuations of the ground-water level in the Pasadena basin in Los Angeles County, California (Fig. 3), and the quantity of water pumped from that basin from 1922 to 1938. Each point in Fig. 7(*b*) represents the average annual amount of water pumped for five consecutive years in relation to the average annual change in water level during the same five years. Progressive 5-yr periods were taken covering the entire number of years of record to smooth out annual variations in supply.

The area of this basin is 11,900 acres, bounded on the north by a line extending generally east from Arroyo Seco below Devils Gate and Monk Hill.

The area immediately tributary to Santa Anita Wash is excluded, as is the southwest corner lying between Eagle Rock Fault and Raymond Fault.

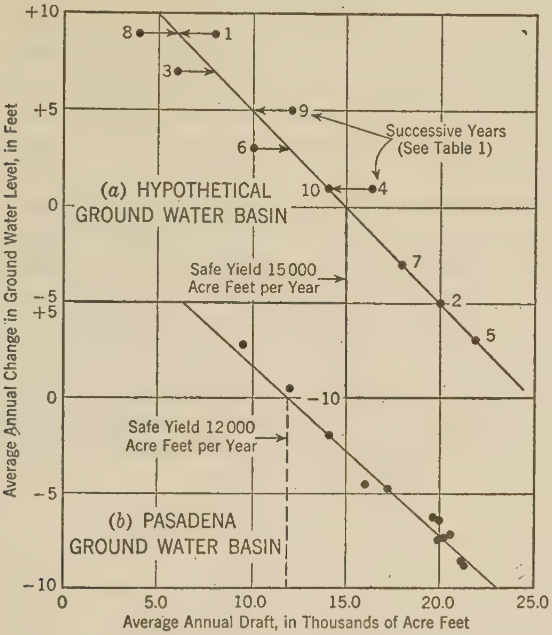

FIG. 7.—DIRECT METHOD FOR THE DETERMINATION OF SAFE YIELD

It is significant in this actual case that the plotted points lie substantially on a straight line and the greatest departure from that line does not exceed 1,000 acre-ft. It must be concluded, therefore, that the net inflow to the Pasadena basin is substantially constant. The straight line intersects the x-axis at 12,000 acre-ft per yr, as compared with the average pumping of about 18,500 acre-ft. Consequently, the safe yield—that is, the difference between the contribution to the ground-water supply and natural outflow and losses from that supply under the conditions which prevailed from 1922 to 1938—was a little less than two thirds of the draft.

TABLE 2.—HISTORICAL RECORD OF PASADENA (CALIFORNIA) BASIN (AVERAGE ANNUAL VALUES)

Successive periods[a]	Quantity pumped (acre-ft)	Change in water level (ft)
1922 to 1927	19,705	− 6.2
1923 to 1928	20,088	− 7.3
1924 to 1929	19,939	− 6.4
1925 to 1930	20,529	− 7.1
1926 to 1931	21,086	− 8.5
1927 to 1932	21,210	− 8.7
1928 to 1933	20,919	− 8.3
1929 to 1934	19,779	− 7.4
1930 to 1935	17,233	− 4.7
1931 to 1936	16,147	− 4.5
1932 to 1937	14,205	− 1.9
1933 to 1938	11,979	+ 0.4

[a] Five-year moving average.

The data pertaining to the Pasadena basin illustrate a single condition of equilibrium. In Fig. 8 the data are plotted corresponding to two different conditions for a ground-water basin located along a major fault in Southern

California. Prior to 1927 the safe yield of this small basin was approximately 3,100 acre-ft per yr, but since 1930 an average of only 1,700 acre-ft annually could be withdrawn without progressive lowering of the water level over a typical series of wet and dry years. The shift from one condition of equilibrium to another in the foregoing case was probably caused by some change in natural conditions, presumably by movement along a major fault in 1927.

Similar reductions in the safe yield of the Cortaro basin along the Santa Cruz River in Arizona were disclosed by correlating the amount of pumping from wells with changes in ground-water levels. The land overlying the ground-water basin was irrigated for a number of years, and the return flow from the application of water on the fields reduced the effective draft upon the ground-water supply. Subsequently, farming operations were shifted to another part of the project, and the water pumped from the wells was collected in canals and exported from the basin. The return flow was then limited to leakage from the canals, and lowering of the water level quickly took place. Later, to conserve the supply, the canals were lined with concrete, thereby increasing the net draft upon the ground-water basin. This again resulted in a reduction in the amount of water which could be pumped without progressive lowering of the ground-water level.

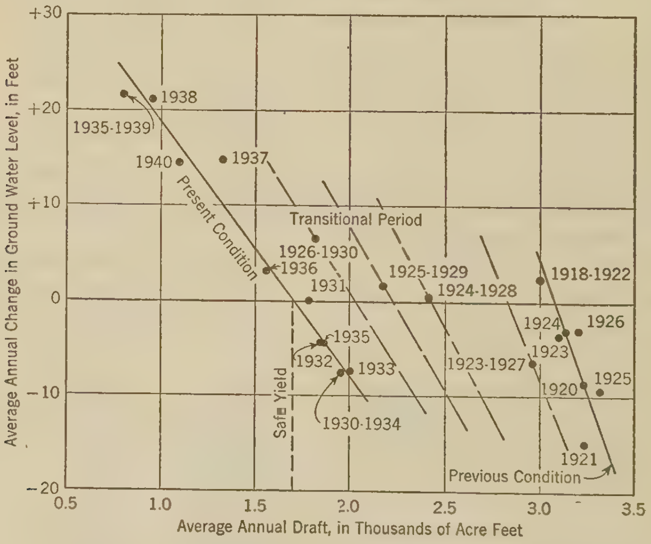

FIG. 8.—CHANGE IN THE SAFE YIELD OF A SMALL GROUND-WATER BASIN

Determination of Specific Yield or Area.—The specific yield or the area of a ground-water basin, when either is known, can be determined by the direct method from the slope of the straight line which best fits the plotted points. In the case of the hypothetical basin described in Table 1, a change of 1,000 acre-ft per yr in the rate of withdrawal produced a corresponding change of 1 ft in the average ground-water level. The area of this hypothetical basin is 10,000 acres, so that the gross displacement for a 1-ft change in level was 10,000 acre-ft; consequently, the specific yield (that is, the proportion of drainable voids) was 10%.

In the case of the Pasadena basin the area is 11,900 acres, and the average specific yield of the alluvium in this basin is 9.4%, as measured by the rate of change in level compared with the rate of change in draft.

In some cases the actual extent of the ground-water basin, or at least the zone of influence of pumping from the basin, is not known. The effective area can be approximated, however, by assuming a reasonable value for the average specific yield. An extreme case in point was a ground-water basin in Arizona, which was generally thought to extend over only about 1,000 acres. When the quantity of water pumped from this basin was plotted against the corresponding changes in ground-water level, the slope of the curve fitting the points was so flat that the specific yield would have had to be more than 50% if the area of the basin were only 1,000 acres. No natural alluvium has gross voids as large as 50%, and there are few instances in which the drainable voids exceed 15% of the total volume displaced. Obviously, in this case, the ground-water basin extended beyond what had been assumed to be its boundaries, and the effective area of the subsurface reservoir must have been almost 4,000 acres.

Summary.—The direct method of determining the safe yield of a ground-water basin necessarily depends upon the availability of records of performance for that basin under known conditions. However, most of the available supplies of ground water have already been tapped and used sufficiently to establish the relation between rates of withdrawal and changes in level. Even if it is found on trial that the variations in supply from year to year are such as to make indefinite the draft at which there would be no change in level under average conditions, these variations can be smoothed out by taking periods of time longer than one year. Essentially the method involves only recognition of the fact that continuous pumping in excess of the average net supply to a ground-water basin will produce progressive lowering, and that conversely any reduction in draft will cause the ground-water level to rise to some higher stage of equilibrium.

In the application of the indirect or difference method favored by the author, there is the same need for historical data. Furthermore, these data must be more accurate than those required for direct determination, because of the multiplication of errors resulting from the computation of small differences between large quantities, each subject to observational error.

Where historical records are not available, any determination of the safe yield of a ground-water basin can be only speculative between the reasonable upper and lower limits indicated by experience and sound judgment.

Clarence S. Jarvis,[4] M. Am. Soc. C. E.—A welcome and practical addition to the voluminous literature on the subject of ground-water storage is presented in this paper. The author's contribution in clarifying the basic concepts and translating them into familiar, readily understandable terms should benefit a wide circle of readers who must have awaited such a simple and logical approach.

---

[4] Senior Civ. Engr., Intelligence Div., Office, Chf. of Engrs., Washington, D. C.

The comprehensive title would seem to invite consideration of the entire field of ground-water storage and utilization, without regard for any specified limitations, either geographical or functional. Viewed broadly, projects involving domestic stock watering, industrial water supply, municipal water supply, and irrigation are all dependent on ground-water storage. In addition, ground-water storage is important in a still broader field, governing integrated stream flow in the intervals between storms—namely, the maintenance of dependable navigation depths and power output. Essentially the same basic principles and physical laws govern the storage and withdrawal of ground water from any and all basins, whether the immediate purpose is to maintain irrigation in the semiarid regions of the Southwest, or to provide municipal supplies along the Atlantic seaboard. The wide range of behavior reflects the variety and integrated effect of modifying conditions.

The familiar example of depressed ground-water surface, due to overdraft by pumping for irrigation in the Santa Clara Valley of California, has much in common with the water supply situation of the Amboys in New Jersey. Rapid industrial expansion in Perth Amboy and South Amboy in 1917 and during succeeding years sorely overtaxed the supplies pumped from wells near Runyon, N. J., adjacent to the Raritan Bay and estuary. These wells were therefore subject to salinity intrusions. The installation of a pumping plant far enough up the estuary to avoid salt water insured the delivery of a bountiful water supply via wood-stave pipe to the Runyon area for the purpose of replenishing the depleted ground-water reservoir. Thus, the threatened contamination by sea water following excessive drawdown was thwarted.

Somewhat similar experiences attending overdraft of water supply wells have been noted from New England and Long Island to Florida and to the west. The remedy most often applied is a reduced pumping demand to permit natural replenishment. What part of the total volume supplied in this manner along the Atlantic and Gulf Coast regions has been diverted for such irrigation purposes as lawns, a large variety of domestic gardens, choice orchards (occasionally), market gardens, and seed farms?

Supplementary Irrigation in Humid Regions.—A legislative directive (42) required examination of the principal river systems of the United States with a view to formulating a coordinated plan for each system that would best serve the public interest with due consideration of the fourfold uses—navigation, power development, flood control, and irrigation. Some of the early reports disposed of the last-named with some such statement as the following: "Inasmuch as the normal precipitation is well distributed throughout the year and ample in amount for the maturing of standard crops, irrigation is not required." As a consequence, municipal and industrial water supplies were ordinarily substituted for irrigation in humid regions. Then came the years of drought in the early 1930's, causing widespread damage to crops, or their total loss. Wells and springs that had never failed became dry.

It was the writer's privilege to tour the outstanding agricultural regions from New York to the tidewater areas of Maryland and Virginia during the final days of the two successive years of pronounced rainfall deficiency, 1930 and 1931. The devastation in some of the most fertile and usually productive farming areas was quite reminiscent of scenes the writer had viewed in the semiarid and desert regions of the West when the water supplies, control structures, or distributing systems failed. One outstanding difference was noted: Here and there a field had grown and matured standard crops of at least medium quality and tonnage, in the midst of the widespread blight and ruin. These exceptional crops had been planted early enough to establish strong root systems before the period of drought and accompanying intensified summer heat had seared the more tender sprouts of later plantings. The declining water table and associated capillary fringe had evidently been followed to the increased depth by the strongly established root systems of the early plantings, whereas crops on adjoining fields gradually wilted beyond recovery.

During the week or more between preliminary wilting and utter ruin of the standard crops, many farmers missed golden opportunities to save their crops by hastily installed irrigation systems. With fresh-water supplies a fraction of a mile from the choicest fields, and with portable pumps to elevate the water from natural stream channels or from existing wells, lines of pipe or flume, or even backfurrowed ditches, would readily have conveyed a generous irrigation supply to the most accessible and the choicest areas to insure bounteous crops instead of total failures. The drenching rains that followed the months of drought, representing nearly the year's accumulated deficiency at some stations, were weeks too late to restore the wilting crops, some of which had been totally lost by neglect of irrigation resources within reach.

Opinions contributed by the writer and others familiar with the hydrology of the eastern states—which recognized the inviting field for supplemental irrigation not only during severe drought periods, but also during minor shortages such as may be expected within one month or more of the growing season, during years of normal annual precipitation—have gradually gained recognition and standing. The same inertia against the practical need for irrigation in humid regions as that quoted previously has operated against the incorporation of progressive views (42). Likewise, opinions in rural communities were so disinterested that the farmers were not alert, or prepared with the necessary equipment, when severe drought conditions demanded prompt and effective measures to save and insure growing crops. Many similar situations have been met, through ingenious adaptation and utilization of equipment already at hand, when the normal gravity supply in arid regions suffered interruption. For example, power from tractor, truck, or even automobile engines has operated centrifugal or other pumping machinery, thus supplying some of the most valuable growths (often including the orchards, vineyards, and selected field or garden crops) from ground-water reservoirs or sometimes from surface storage.

The several tens of thousands of acres along the Atlantic Coast devoted to market gardening, seed culture, and floriculture, together with the smaller, more numerous tracts that have been equipped by individual farmers to supply stand-by service during the inevitable months of subnormal rainfall, have apparently proved the benefits of irrigation in humid regions beyond challenge. The provision of sprinkling systems for lawns and shrubs in public park systems in all metropolitan districts of the United States, and the customary restrictions imposed on the use of city water for gardens and lawns in midsummer, in order to conserve pressure and volume for fire protection—both testify to the widespread need for supplemental irrigation throughout the United States. In Washington, D. C., the meticulous attention to the stately trees and to the park system, by copious watering to prevent midsummer defoliation, is both impressive and praiseworthy.

Considering specialized agricultural, horiticultural, and floricultural projects, which demand irrigation facilities, even in humid regions, to meet the inequalities of rainfall distribution and to maintain optimum soil-moisture conditions throughout the growing season, it must be admitted frankly that irrigation is almost as requisite for special crops in the eastern states as it is for general purposes in the southwestern region. Undoubtedly, with supplemental facilities for utilizing ground-water resources, both the quantity and the quality of orchards, gardens, and field products may be improved.

Coincidental with reliance on ground-water supplies to increase crop tonnage and marketability, normally each year interest in soil and water conservation would be awakened and stimulated. Practices and devices for decreasing surface runoff, or for practically eliminating surface runoff on both farm and woodland, have progressed to the extent that engineers recognize such procedures as both effective and profitable. Under the complete program as prescribed for retaining and utilizing the rain where it falls, rising water tables and augmented base flow in drainage channels have resulted in hundreds of localities. Whether the increased opportunity for infiltration is caused by terracing, contour plowing, check-basin development, grass sod or other vegetal cover, diversion into open cuts, sand or gravel pits, or abandoned quarry sites, volumes of water, many times greater than the capacities of the foregoing, may be successively detained and gradually conducted to the underground storage.

Man's progress in the solution of ground-water problems and in the thorough utilization of water resources has been evident mainly in the field of recharging or replenishment. The location, tapping, and conveyance of dependable streams from infiltration galleries seem to date back to the reigns of Darius and Cyrus of Persia in the sixth century, B. C., or to an earlier period (43).

The Quest for Ground Water.—Somewhere between a horizontal plane and the surface of talus or alluvial slopes flanking a river valley, the surface of saturation or the ground-water table is ordinarily located. In many instances, it approaches the position of the bisector of the angle of talus slope; or, in rare cases, it inclines in a reverse direction as if infiltration from the river channel were diverted outside the basin. Some of the great springs from limestone formations in Texas presumably are supplied in this manner, with no regard for surface topography. The remoteness of these springs from intake areas helps to insure against pollution; successive filtration and sedimentation along the underground courses seem to remove organic material, although hardness may increase progressively through contact with readily soluble minerals along the system of solution channels at varying depths underground. When may one hope to see patterns of underground channels delineated on maps that show the surface drainage channels superimposed, using distinctive symbols or colors for the separate systems? When such maps are available, hydrologists may have a logical explanation for the disparity in runoff yields of apparently similar tributaries, with nearly equal drainage areas and observed rainfall. Subdrainage systems may subtract the underflow from one basin and add it to the base discharge of a neighboring tributary.

In the nearly desert regions of the Southwest or any other semiarid region, what would an isolated traveler seek as an indicator of dependable ground-water supply? Some species of cactus might afford enough sap moisture to quench the first edge of thirst; but a zone of saturation would not likely be found within range of cactus roots. Better indicators would be rabbit brush, grease wood, or, best of all, tufts of willow growth. Likewise, some lush and prominent patches of bunch grass, reeds, rushes, or even salt grass might be within a few feet of the water table.

Structural and geologic, as well as geomorphic, features furnish just as positive and simple indicators of ground-water occurrence to specialists in that field. What thrilling chapters are yet to be written concerning the accomplishments of these indicators on every recent invasion and battle front in locating plentiful supplies of potable water! What enrichment both the graphical and the textual treatment of such practical problems, with approved solutions, will provide!

For ages, open wells and trench cuts leading to water tables even in the fine-grained alluvium of such valleys and deltas as those of the Nile River in Egypt and the Ganges River in India have served as dependable sources of irrigation supply. Whether the water is elevated to the field surface by human labor, animal power, windmill, or other mechanical devices, the expense must have been justified by resulting crop yields or the practice would not have spread and survived. Strange as it may appear at first sight, such irrigation may bring much richer returns in fairly humid regions than in distinctly arid ones. A single application of water to a depth of from 3 in. to 6 in. may suffice for the purpose of supplemental irrigation, whereas five times such depths ordinarily would be required for the growth and maturing of standard crops in desert surroundings. In the latter case, the power charge may be increased more than the volume of water required, as the water table recedes under such heavy demand and output throughout the long season of growth, or even throughout the year. Eventually there must be a reckoning, a balancing of accounts; either the pumping demand must be regulated or the intake increased by some positive and dependable means.

What portion of the cost entailed in steep mountain terracing, with successive units spilling into the next terrace down the slope, is represented by increased base flow from springs and seeps? Likewise, what portion of this cost is repaid by stabilized earth mantles, stream beds, and adjacent alluvial plains on which the increased base flow is utilized? Surely the parallel retaining walls on steep slopes represented an investment of more than the actual value of the narrow terraced strips; only an integrated program of soil and water conservation, stream regulation, flood protection, and promotion of the public welfare could have justified such projects.

Unmistakable evidences of rock wall barriers and earth terraces to insure the detention of rainfall for the immediate benefit of growing crops and accessions to ground-water storage have been identified both in northern Africa and in Palestine. The more ambitious and comprehensive terracing, still used in favored regions of oriental countries, the East Indies, and the Mediterranean areas, seems to have been equaled by similar works on the Andean slopes of Peru, Bolivia, and neighboring South American countries centuries ago.

For miles beyond some of the oases in desert regions the water table is within practicable limits for mechanical pumping, although it may be beyond the reach of native vegetation. This fact may account for the dependable water supply in the central area constituting the actual verdant oasis; the insulating blanket of desert earth conserves the underground storage for a series of years to provide a dependable supply for the limited and favored area in and about the oasis.

The monumental wells of Asia Minor, with helical strairways or inclined ramps providing access to the water table and supply pool, have been unfailing sources of water for the replenishment of rawhide bags and water jars for centuries; the variations between wet and dry cycles, if such have occurred, were registered volumetrically in the outlet springs and seeps wherever the descending water table outcropped. The failure of such springs is merely a signal that the time has come for replenishing the underground storage by conserving the usual wastage.

Within the Colorado River basin in the Southwest, the precipitous faces of the bold vermilion cliffs and other sedimentary formations abounding there are monuments to the action of ground water. Accelerated weathering and crushing, within the saturated strata outcropping at the base, account for the successive slicing and arching along the overhanging faces, from which falling masses supply shattered stone, placed within reach of the river. It is a fairly debatable question whether the steady pressure from within the sedimentary ledge masses, due to ground water, is more or less potent than the attrition and erosion caused by the turbulent river in carving the canyon sections (of course, reserving the actual transportation along the channel to stream flow—both water and wind).

Although the ordinary problems of ground-water occurrence may be essentially simple and understandable, those associated with faults and other deep-seated crustal disturbances may long await explanation. Note, for example: (*a*) The occurrence of distinctly ferrous, sulfur, and other mineral springs of varying temperatures within an area of one square mile on the slope of Mount Rainier, in the State of Washington, not far from Paradise Valley; and (*b*) the hot sulfur springs along the trace of the Wasatch Fault in Utah, emerging only a few miles from a cold spring in a lava bed, where ice forms and remains every day in the year until harvested by visitors in need of such a commodity. The escape of air under pressure from subterranean caverns, attended by rapid expansion at the lava vent within a naturally roofed rock basin, accounts for the constant refrigeration.

Other interesting questions pertain to the development of great caverns in limestone formations, with successive chapters distinctly punctuated by changes in the rate or in the manner of channel enlargement, or by alternate solution and deposition of calcareous material—as if token payments were an essential part of the plan. Every travertine deposit around thermal springs surely represents material transported from underground caverns or solution channels in the making. Also, the successive horizons in great caverns such as the Carlsbad Caverns in New Mexico, where fossilized lily forms predominate, must represent partial repayment in kind for materials previously removed by solution processes to be precipitated later in pools which either cooled or shrank in volume to the saturation point.

The surface drainage channel terminating in the original bat-cave discovery portal of Carlsbad Caverns affords a striking illustration of the interlocking of physical sciences such as ecology (dealing with the adaptation of plants and organisms to their surroundings) and the restricted meteorologic and hydrologic resources prevailing on top of the Guadalupe Mountains in New Mexico. There, on the naked, shattered outcroppings of highly soluble, laminated limestone, practically all vestiges of soil are in the interstices and crevices of ledge rock, and the mean annual rainfall of some 13 in. is subject to extreme variations of 10 in. above or below the mean. Nevertheless, the familiar prickly pear of the desert is apparently at its best, yielding heavy fruitage in spite of the dearth of both soil and moisture and the remote depths to ground-water tables. In the same location, the native American black walnut, normally dependent on access to abundant ground water, has degenerated to the form of a bush or shrub. It bears perfectly formed walnuts, septum divisions and all, which retain the characteristic flavor but have pygmy dimensions, comparable with those of service berries and wild currants.

Perhaps the conservation habits of the most distinctive desert vegetation may indicate at once the more positive replenishment, and more nearly complete utilization, of ground-water storage. The stomata seem to be ever ready to receive the slightest trickle of moisture from the smooth, wax-like surfaces of desert foliage, and storage is maintained with minimum losses for weeks or even months between showers. As is well known, the changes made by man on the land surface, whether by deforestation, overgrazing, or exposing cultivated soil to ruinous erosion through wasteful practices, have all tended toward accelerated runoff through fouling or sealing the porous soil structure. The counterpart and inevitable result of such accelerated runoff is decreased infiltration opportunity, as well as capacity, thus robbing underground storage of its rightful quota.

Ground-Water Conservation.—Wasteful practices with regard to ground-water resources are best illustrated by reference to artesian areas. While engaged in assembling basic material for an official report (44), the writer noted a definite reluctance on the part of landowners to turn off artesian wells for periods of nonuse. The objections seemed to be well founded, from the viewpoint of the landowners, since a definite decrease in discharge had been observed upon resumption of flow from a well that had been idle. The item that was almost universally disregarded was the inertia of the water column. Some time is required for available pressure to start the entire column within a deep well and to accelerate motion until a steady normal discharge approaches the maximum attainable.

Artesian wells were left uncapped and continued to waste the underground storage and incidentally to waterlog the adjacent farm or pasture areas, in spite of the earnest pleas of advisers for agricultural college extension courses and other officials. Three decades were required before the Utah State Legislature enacted the necessary regulatory laws to correct the situation for coming years, after most of the pressures and the artesian reservoirs had become seriously depleted.

Similarly, the great artesian basin in Australia declined 40% in the 30-yr period, from 1909 to 1939, despite the fourfold increase in the number of wells—with capacities of from 563 million gal to 340 million gal daily, or from 870 cu ft per sec to 525 cu ft per sec (45). What opportunities await the diversion of the surplus waters that escape to the sea, practically unused except for occasional power developments, to rejuvenate the depleted aquifers of the interior (46)!

One of the deterrents against direct diversion of storm runoff into porous underground formations, such as gravel, sand, or checked and laminated sedimentary ledges, using open cuts, pits, and well shafts may be the fear of pollution. The replenishment of dwindling underground storage must be weighed against possible contamination. No one is likely to claim that flood runoff from ordinary land surfaces could escape the pollution which is generally associated with pathogenic bacteria. It is yet to be determined under what conditions and at what distances from a well site the diversion of surface runoff directly into an aquifer would be safe.

Recently it was required to test the safe yield of an underground storage reservoir with a view to increasing the output through new wells included in the municipality's plans for the coming season. The novel test imposed was to release the accumulated storage from one of the city's large elevated tanks directly into some of the existing wells. Since this added volume did not change the elevation of the water table perceptibly, it was concluded that the underground reservoir was extensive and capable of supplying the increased demand. This fact was later demonstrated. More of these practical, understandable, and direct approaches to hydrologic and ground-water problems are needed.

Conclusion.—The author has contributed much to the formulation and simplification of the fundamental concepts of ground-water occurrence, safe yield, depletion with overdraft, and replenishment by either the necessary reduction of output or a corresponding increase of input. Finally, he has stressed the importance of long-range planning to insure utmost beneficial use, as well as security against serious shortage of supply. Increased recognition awaits wisely planned developments and research in this field. The field was never more inviting.

JOHN R. CHARLES,[5] ASSOC. M. AM. SOC. C. E.—The author has restricted consideration to the unconsolidated and sand gravel deposits of the "mountain and valley" ground-water province and to the Tertiary and Quaternary alluviums in the Great Plains area, under or near the major streams. However, the fundamental concepts are equally applicable to unconsolidated sands and gravels wherever these occur. The writer will attempt to illustrate how the fundamental equation can be applied to most ground-water supplies obtained from unconsolidated deposits. The discussion is restricted to a consideration of unconsolidated deposits, which constitute the sources of a large proportion of all ground-water supplies in the United States.

It has not been generally appreciated (see heading, "Summary") that

> "* * * ground water is merely water beneath the earth's surface and that surface water is merely water on the earth's surface. The same drop of water moves from above the surface to below the surface and vice versa. Whether above or below, it follows the same physical laws at all times."

If the author has done nothing more than to help establish the fact that surface water may not be wholly disconnected from the ground water, his contribution has been immense. If the author has illustrated how underground reservoirs can be used for storage in the same manner as surface reservoirs, his contribution will have been still greater.

Lowering the ground-water table may be only evidence of better development and use of the ground-water unit. Such lowering of the water table would be serious only when the level approached the practical limit on the basis of pumping cost, or in areas where there might be danger of encroaching salt water from the sea or from a connate salt water body.

However, there has been a recently evidenced tendency to indulge in propaganda concerning the lowering of the water table, wherever this may occur, and whether or not it is merely evidence of better development and use. Recent articles in nonscientific publications indicate this lack of understanding. To pump water from a well, the water level must be lowered to produce a flow into the well; to use the underground storage reservoir, the water level must be lowered in dry periods, as would be done with any other kind of reservoir.

The author has shown that the loss from large surface reservoirs in some areas may be 50% to 60% of available supply, lost in evaporation, whereas the loss from evaporation for underground reservoirs may be practically nil. Writers have used Ohio as an alarming illustration of the result of lowering water tables during the present drought in that area. However, the most notable water failures were the surface water supplies for the cities of Columbus and Lima, Ohio.

---

[5] Dist. Engr., Layne-New York Co., Inc., Pittsburgh, Pa.

The author states (see heading, "Safe Yield: Determination of Safe Yield"):

> "In many cases the supply is also modified by this [the elevation of the water table] because the natural water table may be so high as to preclude percolation from parts of the streams. When pumping is begun the new and additional draft causes the water table to lower and natural outflow decreases. At the same time the lowered water table may induce a greater supply because of greater percolation opportunity. In other words, any reservoir, when half full, can and will impound more of the water that reaches it than it could if it were three fourths full or entirely full. Also, discharge through the uncontrolled outlets of a reservoir or over the spillway decreases as the water level in the reservoir decreases."

C. F. Tolman (*8a*) has stated the same fundamental principle:

> "It must not be concluded that a considerable lowering of the water table is serious or detrimental to the water supply. Just as a surface reservoir must be drawn down in order to catch and preserve flood flow, so the subsurface-reservoir level (water table) must be lowered sufficiently to prevent loss by effluent seepage. A decrease in the area of effluent seepage increases the area of influent seepage (absorptive area) and in turn increases the rate of ground-water recharge. A depleted reservoir at the end of the dry season or cycle of dry years is necessary if the water is to be salvaged in the following wet season or cycle."

The author states (see heading, "Characteristics of Alluvial Valleys"):

> "It is probable that the water supply of none of the stream systems of the west can be fully developed without utilizing some part of the storage possibilities of the unconsolidated alluvium * * *."

The writer would simply add that this statement is true of any stream system containing alluviums—east or west, north or south. Furthermore, development and use of any ground-water reservoir will require the lowering of the water table.

To induce additional percolation or surface inflow, to increase available ground water, or to use the ground-water reservoir, the water table must be lowered. The possibilities of ground-water storage utilization are immense. These reservoirs can be used to catch and preserve flood flow; and also in many stream systems they might be developed for flood control.

The tendency among some engineers, hydrologists, and members of federal government bureaus has been to consider ground water similar to other underground natural resources such as oil and gas, which are not constantly replenished. On this basis, any lowering of the water table has been considered a sign of depletion and loss, when it may be only an indication of normal useful withdrawal.

Where replenishment from rainfall is admitted, ground water has often been considered a stream from some far-off source, completely separated from the surface water. Attempts have been made to predict "safe yield" from the formula:

$$Q = P\,I\,A \qquad (1)$$

in which: Q is the "safe yield"; P is the coefficient of permeability for the formation; I is the hydraulic gradient; and A is the cross-sectional area of the formation under consideration.

The explanatory text indicates carefully how the coefficient of permeability may be determined, but stipulates that the existing hydraulic gradient of the ground water be used in making the calculations of safe yield. This concept is obviously in error since it does not consider water source. Assuming the source to be infinite, it can readily be seen that, in doubling the hydraulic gradient by pumping to lower the water table, the "safe yield" can similarly be doubled by Eq. 1.

Conversely, the "safe yield" determined under the existing hydraulic gradient will be only that quantity of water that is presently flowing through the formation. The amount of increased percolation or surface inflow that may be obtained by lowering the water table is completely disregarded.

Safe yield has been defined by O. E. Meinzer as "* * * the practical rate of withdrawing water for human use." The writer prefers this definition to the one used by the author (see heading, "Safe Yield: Definitions"). The word "practical" includes the three items of the author's definition, and eliminates the use of the words, "permissible cost" and "undesirable quality."

"Safe yield" is such an empirical term that the writer suggests the use of just plain "yield" with all the reservations that engineers may care to make, fully outlined in the text. Obviously, it is "safe" to induce additional percolation and surface inflow by lowering water tables, in most cases, but even these might be subject to various opinions. "Safe" yield indicates the engineer's opinion of what is safe and what may not be safe, based on his knowledge and the facts at his disposal.

Fairly exhaustive tests have been made on the filtering qualities of unconsolidated sands and gravels. It is generally accepted that properly constructed wells more than 200 ft from a source of pollution will produce potable water. Therefore, except for the danger of waters with a high dissolved solids content and the method of well construction, full development and use of the ground-water reservoirs should not change the quality of the water, and should not be detrimental to the quality, except possibly in terms of ground-water temperatures.

Development of water supplies drawing on ground water near Meadville, Pa., has demonstrated the fallacy of foretelling the yield of such areas, by formulas involving a permeability coefficient (Eq. 1).

The formula method of determining permeability has been applied in the Meadville district—first by the U. S. Geological Survey, with a test in 1929, on the wells northwest of the city. A pumping test requiring two observation holes at different distances from the pumped well was made. To solve for permeability, a simplified form of the equation was used as follows:

$$P = \frac{527.7\,Q \log \frac{L}{L_1}}{H\,(h - h_1)} \qquad (2)$$

in which: P is the coefficient of permeability—that is, the number of gallons per day under prevailing conditions that are conducted laterally through each mile of water-bearing bed under investigation (measured at right angles to direction of flow), for each foot of thickness of the bed and for each foot per mile of hydraulic gradient; Q is the rate of pumping in gallons per minute at distances L_1 and L between the two observation wells and the pumped well; H is the average thickness of the water-bearing bed, in feet; and h_1 and h represent the drawdown of the two observation holes in feet.

The coefficient of permeability was determined by Eq. 2. L. K. Wenzel, Assoc. M. Am. Soc. C. E. (47), has outlined this method and several other methods of making permeability determinations. All these formulas seem to arrive at about the same value for permeability with the exception of the recovery method which Mr. Wenzel indicates will require an empirical correction. The margin of error may be reduced by installing additional observation wells, but the method is superior to laboratory methods and in general is correct.

However, when the value of 14,264 for permeability in the area northwest of Meadville had been determined—and the following data were known: Width of the valley, 0.7 miles; thickness of water-bearing bed, 53 ft; and existing hydraulic gradient, 6 ft per mile—then the product of 3,175,000 gal per day was obtained by multiplication in Eq. 1. This quantity was arbitrarily called safe yield. Perennial pumping has proved that the yield for this area is 10,200,000 gal per day, without exceeding the annual recharge. Annual recharge in this area restores the ground water removed from storage during the spring flood season, with water levels returning to those noted in 1903. This recharge is a function of the stream banks and flood plains, not mathematically predictable from Eq. 1.

By a similar method, it was predicted in 1942 that the first three wells installed for the Keystone Ordnance Works, near Geneva, Pa., southwest of Meadville, would have a combined capacity of 1,000,000 gal per day, at a pumping level below the bottoms of the wells, within a period of one month. However, constant pumping has proved that the safe yield is 2,200,000 gal per day at levels above the tops of the screens. Additional percolation from rainfall was induced by lowered water levels following pumping.

Similarly, the capacity of well No. 10 of the ordnance works in the French Creek Valley near Shaws, Pa., was predicted to be 1,860,000 gal per day, and the possibility of surface inflow for a time was overlooked. The safe yield of this well, on a yearly pumping basis, is actually 4,300,000 gal per day, obviously induced when the water table was lowered below the level of French Creek.

In the Meadville district, induced additional percolation and surface inflow by developing well fields has increased the available ground water by several times the amount indicated to be flowing through the virgin areas.

Negative predictions based on formulas, without careful investigation of the influence of near-by tributary seepage, and other important factors affecting yield, might lead to the abandonment of an adequate ground-water project in ng of less desirable and more expensive construction of dams, diversion ms, and cooling plants with added expense in construction costs. In the achella district, in three instances, the safe yield of the formations has oved to be several times the quantity predicted by the ordinary approach in Fig. 3. In each case, had these predictions been followed, a great natural source *would have remained undeveloped.*

The writer agrees with the author that it would be almost impossible to tain safe yield for a single area. In the Coachella district, all the water bles were above, or equal to, stream level. In one case, northwest of [illegible] la, annual recharge in large volume during the spring flood season would not have occurred if the water table had not been drawn down, and the ound-water reservoir had not been utilized. In the other two areas, it was cessary to lower the levels to permit surface inflow, and to induce additional rcolation of rainfall. For undeveloped areas, or ground-water units, estiates of yield must be matters of judgment based on long experience with milar problems. Careful consideration must be given to all the complex ctors that make up the ground-water inventory.

The author's equation (see heading, "Safe Yield: The Hydrologic Equation") n be rewritten to include safe yields from unconsolidated deposits, expressed terms of the yield that may be used for consumptive use, or for exportation ther than in runoff below the unit, or in discharge after industrial or municipal es, thus:

Yield equals:
- Percolation of precipitation on the surface or intake
- plus
- Surface inflow minus surface outflow
- plus
- Underflow in minus underflow out
- plus
- Percolation of irrigation or other water spread on surface or into wells
- plus
- Effective reservoir capacity

It can readily be seen that lowered water levels following pumping may crease yield in any of the following ways:

1. Drawing down a water table which is at or near the surface makes possible percolation of precipitation which otherwise would flow away as noff, and may enlarge the [illegible] area.

2. Lowering the water level in the ground will obviously decrease or stop urface outflow; surface inflow may be increased by lowering the water level hich would otherwise preclude that possibility, and may enlarge the area of rface infiltration.

3. Reducing the water level will obviously decrease or stop underflow from eas not drained at the former level and may produce additional underflow to these areas.

4. Lowered water level may make possible percolation of water spread on the surface or into wells, which was impossible at former levels.

5. The water levels must be lowered to make possible, or to increase, the use of the formations as an underground reservoir.

The author has outlined two direct methods for determining "safe yield" of a ground-water unit which has been highly developed, and concerning which there is a wealth of data. The writer believes that, under the conditions outlined by the author (which are very special conditions), the determinations may be fairly exact.

In the area under consideration, percolation of precipitation on the surface is believed to be negligible; the water table is far below the surface, underflow in or out is considered negligible, and the total source is the surface inflow minus the surface outflow.

The Tule River-Deer Creek area was most carefully considered, and the drawbacks to making the safe yield determinations in this area were carefully outlined by the author. Irrigation was continuous from 1921 to 1939, inclusive, at a practically constant rate. The water table dropped a total of about 36 ft in 18 years; the quantity of water pumped to cause this drop was determined; and the specific yield of the formation was called 9.5%. However, and as the author states, the amount of underflow, in or out, might change with the changed elevation of the water table. Similarly, the writer believes that at some point in the mountains, the water table will meet the surface of the ground or the igneous rocks, so that, with the changed water table, surface inflow may have been increased during the 18-yr period, by the lowered water table. In other words, lowering may not indicate an overdraft, but only a development of the supply.

Although the same number of acres have been irrigated by surface water augmented by ground-water pumping, for the 18-yr period, the author has not made clear whether the amount of ground-water pumping has been constant during the 18-yr period.

To use the direct method (Case II, under the heading, "Direct Methods of Safe Yield Determination"), it should be understood that the draft on the supply, whether surface or underground, must be measured carefully. It is often most difficult to measure outward underflow, or the changes produced by lowering the water table.

If Case I, for which supply to the ground-water unit must be uniform year by year, is used, supply to the unit may become variable because of the changed water-level elevation which induces additional percolation or surface inflow and decreases surface outflow or outward underflow.

The author has also made some observations on the determination of "specific yield," a concept that usually has been expressed in percentages. The author shows specific yield as a percentage obtained by subtracting percentage of specific retention from percentage of porosity. The writer suggests the definition of specific yield in terms of gallons per cubic foot.

Considerable confusion has originated from calling "yield" a percentage. One engineer estimated yield for a ground-water unit as follows:

Description	Percentage	Quantity (inches)
Rainfall	(100)	(40)
Percolation	25	10
Minus specific retention	10	4
Yield	15	6

Then he arrived at the conclusion that the yield of the area would be 6 in. per yr over the basin. In other words, 10% per yr of the percolation would be lost in specific retention. A formation that could retain 10% of the percolation per year would soon have the water built up in blocks above the ground higher than the derrick.

In areas subject to the encroachment of salt water, dissolved solids content of the water produced should be carefully noted, and some measure of local control instituted to prevent this serious detriment to the ground-water supplies. In all other areas, lowering the water table may produce additional water which was formerly lost in runoff. Therefore, until lowering approaches the practical limit imposed by the cost of pumping and the use of water, control (either local or federal) based on insufficient information or unreliable methods might lead to loss of great natural resources. Every ground-water unit is unique in some of its features. Possibly in time some method—other than the practical limit of pumping costs—may be developed for determining the limit to which the water table should be drawn down.

In areas that are highly developed in ground-water use, careful study of the records of pumping, use and exportation of water, comparisons with water-table decline, and annual precipitation should indicate the solution. A considerable amount of water-table lowering may develop additional available ground water. With all the facts carefully recorded, over a period of a year or two it could be demonstrated, to the satisfaction of all concerned, that further lowering the water table would not produce any additional water, and that some measure of cooperation or control was necessary to increase the supply available. Such measures will be beneficial and will lead to cooperation and wise control of the quantity of water used.

Such control could be best directed by a state water authority, for any affected ground-water area. Its action should be based upon considerable study over a sufficient period of time to have the effect of average rainfall. This will insure the maximum practical use without excessive lowering of the water table, and the employment of every feasible method to augment the total ground-water supply.

Of most serious consequence would be federal control by a department that might autocratically apply some of the theories that have been proved fallacious in the determination of probable ground-water yield. Such negative type of control, with the bureaucratic power to impose regulations, might lead to a loss of great natural resources.

Each state should make available for its citizens, immediately, a department on ground water to study those areas in which there may be danger of a local ground-water shortage. Subsequently, there should be state control, through authorized water authorities, over those areas that require control. Only in this manner will centralized bureaucratic power be avoided, and the development of the ground waters of the United States brought to full realization.

Mr. Conkling has added much knowledge to this relatively new and little understood field. The paper has indicated the unique character of each ground-water problem. The author has demonstrated the difficulty of determining values correctly, the need for exercising extreme care in the general engineering approach to the problem of full ground-water utilization, and the necessity of insuring eventual state control.

C. W. Sopp,[6] M. Am. Soc. C. E.—Ground water is of vast importance in the economic development of the midwestern and western states. That ground-water storage is an important factor for preserving water resources is recognized by artificial recharge in certain localities and by limitation of the pumping draft to the safe yield in other areas.

The author mentions the recharge of ground-water basins by diverting water to wells which are not being used. This practice generally has not been successful because of reduction in the intake capacity of the wells. The wells act as a sand filter in reverse; and, if they are not equipped with pumps, there is no opportunity for backwashing. Bacterial growth in the wells and in the surrounding alluvium may also reduce the rate of infiltration. It might be necessary to filter and chlorinate water to be infiltrated into basins by means of wells. Near Lytle Creek, in California, a shaft was dug to a depth of 250 ft, all of which was through gravel except 8 ft. Openings were left in the cribbing throughout the length of the shaft. Initially, the shaft had an infiltration capacity of from 5 cu ft per sec to 6 cu ft per sec, but after seven years this capacity had been reduced to 2 cu ft per sec.

The total storage capacity of the ground-water unit may not be available for economic use for the following three reasons: (*a*) The "specific yield" or available porosity decreases with depth due to consolidation of the alluvium; (*b*) where storage is developed by pumping, only the storage within the range of pumping lifts is usable; and (*c*) all storage should not be exhausted, thus making the annual supply in the ground-water unit fluctuate in accordance with its annual recharge.

In one basin studied by the writer the "specific yield" decreased from 15% to 7% at 150 ft greater depth. Mr. Conkling lists many factors that may enter the hydraulic equation to determine the safe yield of a ground-water unit. The safe yield equals the water entering the unit minus water losses, including leakage. Records of the requisite data may not exist, and the data are often difficult to estimate. The safe yield, being the difference between fairly large quantities, is subject to large error if this method of computation is followed.

Mr. Conkling also gives a method of determining the safe yield by using the factors of draft and change in storage but mentions the difficulty of evaluating change in storage due to the obscure factor of "specific yield." Nevertheless, this method has the advantage of making many records or estimates unnecessary as it gives the safe yield from all sources without the necessity of segregation. Satisfactory computation of the safe yield can be made by this method in many cases.

---

[6] Asst. Chf. Engr. and Gen. Mgr., Pasadena Water Dept., Pasadena, Calif.

In the use of ground-water storage, the true occurrence of ground water as a subterranean stream, or as in a basin, is of great importance under the laws of certain states.

The underflow of a river may follow the course of the surface channel; but part of the underflow may leave the surface channel at some point and may not rejoin it. The interrelation between a surface stream and its underflow is more evident when the stream is traversing a mountain valley, where it may be in contact with or support the surface flow, than after the stream has debouched upon a broad plain. In this latter case, part of the underflow may follow an ancient, buried channel of the stream, and water moving in such an ancient underground channel may conform to the classification of ground water flowing in a defined channel. Other ground water flowing in the general region and perhaps in the same direction may not, strictly, be traversing a definite underground channel and may more properly conform to the definition of percolating water. Water flowing in an ancient channel cannot be developed independently of other overlying ground water.

The San Gabriel River and basin cited by the author illustrate certain differences in occurrence of ground water in a subterranean stream with a known and definite channel and basin water. In the canyon the underflow is confined between the impervious canyon walls and is clearly a subterranean stream with a known and definite channel. Below the canyon mouth in San Gabriel basin, but upstream from the Paso de Bartolo (Whittier Narrows), the ground water is far below the stream bed. The boundaries of the ground-water body are somewhat indefinite and are several miles apart—in fact, the width is about eight tenths of the length. The direction of movement of ground water in the basin generally follows that of the surface stream, but the ground water in the basin clearly occurs as percolating water. Immediately above the Paso de Bartolo the movement is again like that of a subterranean stream (see Fig. 3). D. G. Thompson (48) states that he

> "* * * does not know whether any Court decision has classified the movement of ground-water in the San Gabriel Basin as 'percolation,' but he believes that it is a proper classification according to the customary conception of that term as it is commonly used except perhaps for minor parts of the basin where certain geological conditions produce special conditions * * *."

Beneath the water table in a basin there may be distributary arteries of principal movement and of water in a buried channel, but the whole may be properly classified as percolating water.

The flow of water through the alluvium in a ground-water stream or through a basin as percolation is caused and controlled by the same hydraulic laws that govern percolation through a porous medium. It should be well recognized that ground water in a basin is never at rest but moves from points of recharge to points of extraction or discharge. The courts have merely applied a name, "percolating water," to classify ground water moving through a basin to distinguish it from ground water moving in a channel. The author seeks to remove the mystery of movement of ground water from the minds of laymen, and some courts by stating (see heading, "Characteristics of Alluvial Valleys") that "* * * it is moving as a stream or group of streams through the unit * * *." Such a mystery does not exist in the minds of hydrologists and this comparison may cause legal confusion. The comparison and any extension to classify all ground waters as streams lead to legal difficulties in certain states depending on the various state laws.

The rate of movement of ground water is important if a large portion of the recharge to a basin is localized as percolation from a stream overlying the basin. Ground-water movement is usually a combination of displacement and the actual movement of a particle of water. A study of water-table fluctuation and of chemical constituents of water in wells in the Raymond basin indicates that a displacement wave travels at the rate of about 124 ft per day, whereas the actual movement of a particle of water was only 8 ft per day.

Storage, rather than flow, is the dominant feature in the occurrence of ground water, whereas, for a stream, flow is the principal feature. The subflow of canyons is illustrative of the small amount of water flowing in ground-water streams. In San Gabriel canyon, the Edison Company's diversion dam developed 50 miner's inches of subflow; and the subflow at the Morris Dam of the City of Pasadena was 20 miner's inches. The subflow at the dams of the Los Angeles County Flood Control District on other streams was measured during construction as follows:

Dam	Miner's inches
Pacoima	2.3
Sawpit	5.3
Dalton	1.4
Tujunga	12.0

Contrasting with the flow of ground-water streams is storage in basins such as the Raymond basin. Here the specific yield is about 2,000 acre-ft per foot of depth; and, assuming 100 ft of fluctuation of the water table, the total usable storage is 200,000 acre-ft, whereas the annual movement in and through the basin is about 31,000 acre-ft. This large storage capacity equates the supply from wet and dry periods and has supported an overdraft since about 1917–1918.

In nature a ground-water basin is in equilibrium—that is, the water entering the basin is discharged as a regulated flow at the outlet or by evaporation and transpiration in areas where the water table is reached by the root zone of vegetation. In the natural state there is no safe yield; the outflow equals the inflow. Disturbance of natural conditions by pumping from the ground water creates a safe yield by reducing the outflow and facilitating percolation from overlying rainfall and streams. The safe yield of a basin can be increased by ground-water drafts, limited by economical lifts, up to the point where the outflow ceases, thereby utilizing the complete water supply of the hydrologic system, provided that the basin storage capacity is adequate. Development of the safe yield of a basin is accompanied by increased pumping lifts; but, with the present art of pumping and return from crops, water can be produced from lifts of several hundred feet with resulting profit to growers of crops. In utilizing the storage capacity of a ground-water basin, the water table will fluctuate over wet and dry periods. A greater fluctuation is more feasible where the pumping lift is small than where it is large.

In certain states ground water must be divided into the following classes: (*a*) Water flowing in defined subterranean streams; and (*b*) percolating water.

To judge the water storage capacity in alluvium, it is necessary to distinguish between these two classes of ground water. The reasons for such distinction are largely legal, pertaining to water rights. Distinction is unnecessary in certain states, such as Utah, Idaho, and Nevada, where permits are required for well drilling. Section 42 of the Water Commission Act of California provides that:

> "* * * whenever the terms 'streams,' 'stream system,' 'lake' or 'other body of water,' or 'water' occur in sections of this act relating to applications to appropriate water or permits issued pursuant to such applications * * * such terms shall be interpreted to refer only to surface water and subterranean streams flowing through known and definite channels."

C. S. Kinney (49) states:

> "* * * that the word 'defined' means a contracted and bounded channel, though the course of the stream may be undefined by human knowledge; and the word 'known' refers to the knowledge of the course of the stream by reasonable inference."

The presumption that ground waters are percolating runs through many court decisions. The burden of proof is upon the party who asserts that a defined underground stream exists. The rules of law in certain states pertaining to surface or subterranean streams, flowing in known and definite channels and percolating ground water in a basin, differ as follows:

A. Application of the Water Commission Act of California would require permits from the State Division of Water Resources for drilling wells to ground-water streams, whereas no permits are required for wells drawing percolating water from a ground-water basin.

B. Owners of wells drawing from a ground-water stream can acquire rights adverse to downstream producers but the contrary is not true. This rule is not applicable to percolating water in a basin where all pumping is mutually adverse.

C. Under section 20*a* of the California Water Commission Act, 3 years of nonuse of water from a ground-water stream would be interpreted as constituting a forfeiture of the right, whereas under court decisions 5 years of nonuse of water from a basin is required for a forfeiture.

The maximum supply from a stream system requires use of the large storage capacity of the underflow and of any ground-water basin to which the stream is contributory. Such storage requires no dam and is not subject to evaporation losses although the leakage may be large.

J. A. BRADLEY,[7] ASSOC. M. AM. SOC. C. E.—A comprehensive and excellent discussion of ground-water reservoirs on certain stream systems in the western United States and of the determination of their utilization from an engineer's standpoint is presented by Mr. Conkling. It is common knowledge that man's need for supplemental water in most of the alluvium ground-water provinces shown in Fig. 1 is increasing. No better evidence can be found than the already constructed works and further contemplated developments for the control of flood waters and the prevention of uneconomic "evapo-transpiration" losses from areas of high ground water which frequently occur at the lower ends of ground-water basins. These flood and wasted waters must be controlled and conserved if additional supplies are to be obtained. As Mr. Conkling has stated (see heading, "Characteristics of Alluvial Valleys"), full utilization of the water supply of the stream systems of the west cannot be attained without balancing the advantages and disadvantages of surface and underground storage, which will ultimately result in the use of "some part of the storage possibilities of the unconsolidated alluvium."

The terms, "ground-water reservoir" and "ground-water basin," are generally used synonymously. As Mr. Conkling explains, the term, "basin," is used very loosely; but it is a convenient term, nevertheless. However, the term, "ground-water basin," may be considered univocal. A surface stream has a bed and banks; a lake has a bottom and shores; but a basin is a depressed land form and has a "bottom" and a marginal boundary or "rim." Geologically, basins may have resulted from the operation of subterranean forces or may have originated in the constructional or destructional processes of nature (50). If the term, "basin," is applied to a ground-water basin, the "bottom" is the foundation upon which a more porous valley fill material rests—generally considered the basement complex underlying that porous material. The "rim" may be an elevated extension of the bottom; but, in any event, it is a physiographic or geologic feature acting like an obstruction to the movement of ground water. The material composing the bottom and rim will have at least one or more characteristics to distinguish it from the porous material which it surrounds or at least partly surrounds (the rim may be nonexistent along parts of an "open" type basin). The degree of imperviousness of bottom and rim is, or may be, only a relative matter. However, the term, "reservoir," indicates an extra supply or storage detained for future usefulness and, in the writer's opinion, should be preferred in describing the performance of a ground-water body.

According to the writer's conception of essential requirements, a ground-water reservoir in alluvium should have the following characteristics:

---

[7] Asst. Flood Control Engr., Orange County Flood Control Dist., Santa Ana, Calif.

(*a*) Water in the porous material everywhere in contact and moving in compliance with the physical laws of seepage and percolation;

(*b*) Capacity sufficient to yield water of good quality, in commercial quantities, by pumping at feasible cost;

(*c*) Capability of being recharged either naturally or artificially; and

(*d*) Some escape as outflow (surface or subsurface or both), to prevent the water from becoming so saline as to be unsuitable for use.

Since the introduction of the deep-well turbine pump, the development of ground-water supplies in Southern California basins has increased rapidly. The water table in these various ground-water reservoirs has shown considerable annual, as well as cyclic, fluctuation. One inference that might be gained from Mr. Conkling's paper is that, once a ground-water reservoir reaches a stage of development in which the water table is lowered, the supply may actually be increased because of greater percolation opportunity and improved recharge conditions caused by change from native to cultivated vegetation. In consequence, more emphasis has been placed recently on studies of methods for replenishment by ground-water investigators.

As the author has indicated, a ground-water basin may consist of two parts —a pressure area (containing confined water), and a forebay or intake area (containing a free water table). However, changes in storage are possible only in the intake area. Where this combination occurs, it appears to be an inherent characteristic of an underground basin in alluvium that the intake area is around the higher boundaries of the basin. Only a small portion of the intake area is generally used by nature at normal flood times for distributary channels to carry runoff. In intermittent streams, crossing alluvium water is lost underground from the beds of the distributary channels: First, by the physical laws of seepage; and second, after field capacity has been reached, by those laws attendant upon percolation. In any event, the movement of water is predominantly downward to the water table (unless intercepted by impervious strata and thence carried laterally and downward to the water table). Naturally, an attempt to increase the wetted area of these channels was made; hence, off-stream spreading was resorted to where topographically feasible on adjacent porous lands having sufficiently pervious soil types.

Spreading water for storage in underground reservoirs has already been described by A. T. Mitchelson and Dean C. Muckel (5). However, the writer wishes to add to the experience of recharging ground-water reservoirs through the use of wells drilled solely for that purpose by illustrating the performance (see Fig. 9) of a typical well drilled in the quaternary alluvium of the Orange County, California, coastal plain. The well is one of six, driven in a peripherally-leveed spreading ground of 70 acres, constructed and operated by the Orange County Flood Control District for the purpose of sinking water underground. This spreading ground overlies a part of the intake area of one of the ground-water reservoirs of the South Coastal Basin of California (27). The supply to the spreading grounds consists wholly of the storm-water runoff collected from an entire city area (which formerly had no definite outlet channels) by a system of storm drains. It is delivered by gravity to the spreading area, where it is permitted to flood over the entire surface. The water is absorbed and cleared of silt by the porous sandy soil, and then drains into a system of 6-in. concrete tile drains laid at an average depth of 10 ft below the surface in a rock-filled trench. These drains empty into each side of 4-ft square redwood intake cribs constructed around each well. The rotatory motion of the water is induced as it passes through the intake perforations in the well tube to the underground strata.

Fig. 9.—Graphic Log and Operation of Typical Recharging Well

In discussing the performance of a ground-water reservoir, Mr. Conkling has justly stressed the necessity for determining the specific yield of the water-bearing material—an important factor in estimating storage capacity. The writer believes that, in those underground reservoirs of considerable extent where pumps are drawing from confined water (and it is feasible to salvage wasted waters from areas of high ground water), knowledge of the permeability of the underlying aquifers is equally desirable if the long-time average safe yield is to be estimated and the ground-water reservoir is to be managed efficiently. Transmissibility is generally determined as the coefficient of permeability and, as stated by Leland K. Wenzel, Assoc. M. Am. Soc. C. E. (51), and C. F. Tolman (8) but as credited to O. E. Meinzer, is defined as the rate of flow in gallons a day through a square foot of cross section of material, under a hydraulic gradient of 100%, at a temperature of 60° F. In 1940 the writer had charge of some pumping tests on drilled wells for determining permeability and specific yield (effective porosity) of water-bearing materials in a ground-water reservoir on the stream system of the Santa Ana River in California. Values computed for the coefficient of permeability from some of the tests varied from 4,880 to 6,070, and those for the specific yield varied from 16.3% to 18.7%, respectively. The Thiem method (51), as described by Mr. Wenzel, was used. Provided that free water-table conditions prevail in the material tested, both the coefficient of permeability and the specific yield may be computed from data obtained during a single pumping test. Although it is expensive, the method is advantageous because the results obtained are for undisturbed material lying in the natural state.

Well-developed underground reservoirs operated on a sound management basis will generally experience considerable fluctuation in elevation of the water table. Consequently, after consideration of the views of some geologists and pedologists (soil scientists), it appears that the specific yield of the water-bearing material may not remain constant throughout time, because the effects of compaction, weathering, and chemical action result in cementation. These effects may extend more or less throughout the zone of aeration.

Mr. Conkling has ably outlined the methods so far developed and the objectives to be attained in ground-water reservoir investigation. Continuity of proper records and wise management are essential to avoid depleted ground-water supplies if the many planned works for future construction are to accomplish their purpose.

IRVING B. CROSBY,[8] AFFILIATE AM. SOC. C. E.—The scope of this paper is deliberately restricted to the arid or semiarid regions of the United States west of the 97th meridian. The paper is largely confined to a discussion of the use of ground water for irrigation. This tends to give the impression that ground-water storage is more highly developed in the west than elsewhere and that the most important use of ground-water storage is for irrigation. Mr. Conkling also restricts his paper to ground-water storage in alluvium. It should be interesting and valuable, therefore, to cite some instances of the development of ground-water storage in other regions, for other purposes, and in other geological formations.

The use of ground-water storage for irrigation, its development, and climatic conditions are stressed by the author; but he includes little concerning the geologic conditions which make possible the accumulation and use of ground water in the valleys of the west. The two regions for which ground-water storage is discussed are the Great Plains and the "mountain and valley province." These two regions cover a vast area with widely varying conditions. Although the term, "mountain and valley province," is mentioned in connection with references to C. F. Tolman (8) and O. E. Meinzer (11), it does not appear to be used by them. Since there are already two classifications of ground-water provinces in the west, this attempt to introduce a different term is unfortunate and unnecessary. The region included in the author's term, "mountain and valley province," is subdivided into five provinces in Mr. Tolman's classification (8*b*). These are: (*A*) The Great Basin province covering parts of California, Nevada, Utah, and Idaho; (*B*) the Columbia Plateau province in Idaho, Washington, Oregon, and California; (*C*) the Great Valley of California; (*D*) the Coast Ranges of Central and Southern California; and (*E*) the northern Coast Ranges. The author's examples are largely from province (*D*), the Coast Ranges of Central and Southern California. The geologic conditions of this province are very different from those of other parts of the region and the attempt to lump these five ground-water provinces into one province oversimplifies the case.

---

[8] Cons. Eng. Geologist, Boston, Mass.

Although the author's discussion of ground-water storage is restricted to alluvium, the principles he presents apply to pervious rocks and are important in many places. Some geologic formations, in addition to alluvium, in which ground-water storage may be significant are: (*a*) Very pervious sandstones, (*b*) beds of volcanic ash, (*c*) beds of fractured lava, (*d*) cavernous limestones, and (*e*) highly fractured zones in any type of rock. In the last three cases, in which the water occupies fractures and cavities rather than pores, wells for recharging the ground water may be important.

A peculiar case of underground storage in limestone was encountered by the writer in the West Indies. The water supply of Port Au Prince, Haiti, was formerly obtained entirely from springs at the base of Morne l'Hopital, a long limestone ridge which rises 3,000 ft directly behind the city. In 1938 and 1939 an investigation of possible additional water resources was made by the writer, acting as consulting geologist for the J. G. White Engineering Corporation, and it was decided to drive a tunnel into the mountain directly back of the city. A large flow of water was encountered 1,500 ft from the entrance, with a volume, at first, of 2.75 mgd. Later this volume gradually decreased to 1 mgd and became constant. Subsequent observations indicated that a large subterranean cavity filled with water had been tapped, that the large temporary flow was caused by the draining of this stored water, and that the smaller constant flow was the average yield resulting from rain on the mountain. During wet seasons this underground storage reservoir fills; the flow increases; and, during dry seasons, the reservoir is drawn down.

The two areas discussed in detail by the author—the Platte River Valley in the Great Plains and the valleys of the Coast Ranges in Southern California—are both outside the glaciated region, but similar conditions exist in the glaciated regions. In the valleys of Southern California the ground water occurs in alluvial fans at the base of the mountains. The alluvial material filling these valleys grades from very coarse gravel at the base of the mountains to finer sand at some distance but is all pervious in varying degree and is generally very thick. The alluvial fill of the valleys of the Great Plains, on the contrary, is generally thin.

Valleys with deep alluvial fill are common in New England and in other parts of the glaciated regions (52). In contrast with the unglaciated valleys, however, there is no regular gradation from coarse alluvium in the upper parts of the valleys to finer alluvium in the lower part. Because of the irregularities of glacial deposition, there may be an impervious dam of fine alluvium across a valley with basins of pervious gravel above and below it. The pattern of surface drainage is often very different from that of the buried preglacial valleys, and ground-water basins in the buried valleys may drain in different directions from surface streams. Therefore, it is more difficult to determine the size of ground-water reservoirs in glaciated regions. Such reservoirs exist in many places, however, and are used for municipal and industrial water supplies. Generally, no attempt is made to recharge these ground-water reservoirs artificially, but one system which is so operated will be described briefly.

The first public water supply of the City of Cambridge (Mass.) was Fresh Pond in the western part of the city, and the pond is still used as part of the supply. Fresh Pond occupies a glacial kettle hole at the southern end of a glacial sand plain in a buried preglacial valley. No surface stream follows the entire length of this valley; but the upper part is occupied by the Mystic River, and the Charles River crosses the valley a mile south of Fresh Pond. The buried valley is filled with alluvium to a depth of about 170 ft. Immediately south of Fresh Pond is a glacial moraine which forms a ground-water dam and isolates the ground-water basin of Fresh Pond from the Charles River Valley. Another ground-water divide, a mile and a quarter north of the pond, separates the Fresh Pond ground-water basin from that part of the buried valley occupied by the Mystic River. Fresh Pond has an area of 85 acres and is 55 ft deep. The total surface drainage area tributary to it is 1.25 sq miles, but the area tributary to the sand plain is about 5 sq miles. Since 1887 there has been an additional water supply by conduit from Stony Brook Reservoir in Waltham, Mass.

In 1941 Cambridge needed additional water to supply war industries, and an investigation of ground-water possibilities was made by the writer who recommended that greater use should be made of ground-water storage, that Fresh Pond should be lowered much more in the summer to draw upon more ground-water storage, and that Fresh Pond should be filled in the spring to replenish the storage. Since then Fresh Pond has been drawn down in the summer, obtaining a large additional yield from the ground, and both pond and ground are filled in the spring by surplus water from Stony Brook which would otherwise be wasted over the dam.

Artificial recharge by water spreading is practiced at several plaecs in New Jersey, both in and outside the glaciated region. Artificial recharge has been practiced for more than 30 years at the Perth Amboy Water Works where rates of recharge ranging from 4,000 to 90,000 gal per acre per day have been measured. Ground-water recharge is also practiced in Long Island where it is recharged into glacial beds by means of wells and pits.

One of the most intensely developed rivers in the world is the Ruhr River in Germany. Although the climate is different, the geology somewhat different, and the water use very different, from the conditions in Southern California, there are interesting similarities in the developments. The Ruhr River flows west into the Rhine River at Duisburg-Ruhrort and has a drainage basin of 1,715 sq miles. The average natural flow before the construction of reservoirs or water works was 1,989 mgd, or 2,800 cu ft per sec. The Ruhr River is just outside the glaciated region, and it flows in an alluvial valley between low bluffs of slate and other relatively impervious rocks. The valley is floored with clay beneath which is a relatively thick layer of coarse, pervious gravel. This gravel layer forms a very long, narrow ground-water storage reservoir in which the water table is frequently lower than the river. The river is then influent to the ground water. The Ruhr River cuts through the clay layer into the gravel, but the river bed is generally coated with sludge which hinders infiltration of river water into the ground.

The Ruhr River is the only source of water supply for the Ruhr industrial district, which includes a large area north of the Ruhr Valley. The total area served is 2,500 sq miles, with a population of 3,500,000. The average consumption, all obtained from the gravel, is 250 mgd, or more than the low-water flow of the river (53). This supply was obtained from ninety different water works. In 1929, the year of greatest consumption and lowest flow, 476 mgd were used. During September, 1929, no water flowed into the Rhine River from the Ruhr River.

An elaborate series of planned developments has been completed to use the limited water resources (54) to the greatest possible extent. Water is obtained from batteries of wells and from infiltration galleries near the riverbanks. To replenish the ground-water reservoir, river water is conducted to off-stream spreading grounds, which are basins excavated through the layer of clay into the gravel. These basins are floored with sand which is cleaned occasionally. Thus, there is an extensive underground reservoir protected from evaporation losses. The only loss is seepage through the gravel down the Ruhr Valley to the Rhine River. To develop the water resources further, a series of storage reservoirs was built on tributaries of the Ruhr River. Excessive deposition of sludge was caused by the reaction of the acid water from the Lenne River, which flows through an iron mining district, with the alkaline water from the Ruhr River, which comes from a paper mill district. To precipitate this sludge, a series of lakes was formed by low dams on the Ruhr River. The sludge is flushed out of the lakes during high water. This combined development of the surface and ground-water resources of the Ruhr River provides water supply, river regulation, navigation, water power, and recreation.

Another example of intensively developed ground-water storage is the water supply of the City of Haltern at the junction of the Stever and Lippe rivers in Germany. The Lippe River, the next large stream north of the Ruhr River, flows west and enters the Rhine River at Wesel. Salt springs and drainage from mines make the water of the Lippe River saline. The Stever River comes from the north and joins the Lippe River at Haltern. The Stever River Valley is filled to a depth of 400 ft with sand, whose grain size is 1 mm or less. The permeability of the sand is 340 ft per day at unit head. The drainage area of the Stever River is 395 sq miles. The annual precipitation on this area is 547,100 acre-ft and the annual runoff is 186,400 acre-ft (55). To obtain the maximum safe yield without drawing in saline water from the Lippe Valley, a dam with a sheet-pile cutoff was built on the Stever River, raising the water level 20 ft and forming two reservoirs (56). From these reservoirs, water is conducted to spreading grounds from which it seeps into the ground. The surface storage is 7,629 acre-ft, and the underground storage is estimated at 4,621 acre-ft. By making full use of the underground storage, an annual supply of 64,850 acre-ft, or 58 mgd, is available—even in extremely dry years. The water is obtained by a battery of gravel-packed wells arranged in an east-west line across the valley.

These scattered examples of the uses of ground-water storage in the intensive development of stream systems show that the principle is not closely restricted by climatic or geologic conditions or by types of water use but that its application is feasible and valuable in a wide variety of conditions. By his detailed discussion of conditions and controlling factors in the semiarid western states, Mr. Conkling has made a valuable contribution to the subject.

G. B. DRUMMOND,[9] ASSOC. M. AM. SOC. C. E.—People of the semi-dehydrated west read with interest anything about water, particularly a paper as able as that prepared by Mr. Conkling. However, it is to be remembered that the most comprehensive understanding of the phenomena of waters is of little avail unless administrative action conforms to correct scientific knowledge.

In New Mexico the laws covering ground water have been written on the basis of a scientific knowledge of hydrology. The State Constitution defines the doctrine of "appropriation" when it states:

> "The unappropriated water of every natural stream, perennial or torrential, within the State of New Mexico, is hereby declared to belong to the public and to be subject to appropriation for beneficial use, in accordance with the laws of the state. Priority of appropriation shall give the better right."

The Constitution continues: "Beneficial use shall be the basis, the measure and the limit of the right to the use of water."

The statute of the State of New Mexico passed in 1927 authorizing the appropriation of ground water was declared unconstitutional because of a technical error. In this case (Yeo vs. Tweedy, 286 Pacific 970), the New Mexico Supreme Court discussed in detail the common law principle that an owner in fee has dominion to the center of the earth, but declared that a sensible pursuit of that theory required reasonable use of any right and that the use shall be of such a nature as to avoid injury to others. On the basis of that decision, the present statute was passed in 1931. By this statute, "Waters of underground streams, channels, artesian basins, reservoirs or lakes, having reasonably ascertainable boundaries" are public waters subject to appropriation for beneficial use.

The law is administered by the State Engineer to whom persons desiring to drill wells for irrigation or industrial purposes make application. After publication, if an interval passes during which no objections are filed and if the

---

[9] Asst. Prof., Civ. Eng., Univ. of New Mexico, Albuquerque, N. Mex.

State Engineer ascertains that there are available unused waters in the area, a drilling permit is issued subject to the rights of previous appropriators from the source. If protests are filed, a hearing may be held. Appeals from the decision of the State Engineer may be taken to the courts. The State Engineer can establish ground-water districts, can set limits on the quantity of water appropriated in a district, and can exercise police power to prevent waste. "Beneficial use" being the basis of the right to use water, an appropriation is effective only as long as it is used beneficially, and water rights not exercised for a period of four consecutive years are forfeited.

The careful administration of this law has prevented the overexpansion of certain ground-water areas; and, in other areas where serious depletion of the water supply was threatened, rehabilitation has commenced.

Raphael G. Kazmann,[10] Assoc. M. Am. Soc. C. E.—A distinct contribution to ground-water hydrology is presented in this paper because it discusses, from an engineering viewpoint, a subject that has been all too neglected in the past by the majority of civil engineers. However, the self-imposed restrictions on the scope of the paper are too severe—many of the concepts outlined are applicable east of the 97th meridian and are useful to industry as well as to agriculture. Limitation 2 (see "Introduction") deserves to be quoted again in full, as it expresses conditions which are also necessary for the successful use of ground water by industry.

> "2. Only these situations in which the following conditions exist are considered:
>
> "(*a*) Ground water in the alluvium is readily accessible to extraction by pumps;
>
> "(*b*) The alluvium is sufficiently permeable to yield water in commercial quantities;
>
> "(*c*) The alluvium is naturally charged with water or is susceptible of being charged artificially to such an extent that heavy commercial drafts can be sustained; and
>
> "(*d*) If artificial charging is necessary it can be done at feasible cost."

In the eastern part of the United States, many deposits of alluvium furnish large supplies of ground water; and, in the northern states, many river valleys are filled with glacial outwash that may be a productive source of water. Many of these valleys are largely or wholly untouched by industrial or agricultural ground-water developments, thus making the problem of the safe yield from a "virgin valley" a very real one.

With regard to the industrial development of ground water, the major limiting factors are hydrologic and not economic. The utility of ground water for industrial purposes is so great that the cost of lifting the necessary quantities an additional distance is generally insignificant as compared with the cost of replacing the ground-water supply. Furthermore, this water is either discharged in sewers or, when uncontaminated, is returned to water-bearing sand through recharge wells, as in Long Island, New York (57).

---

[10] Res. Engr. (Hydr. Engr. P-2), U. S. Geological Survey, Memphis, Tenn.

The methods used by Mr. Conkling in the determination of the safe yield from a valley are based on the sampling of material followed by laboratory work. As is recognized in the paper, this procedure is subject to large errors.

The most fundamental difficulty in applying the results of laboratory analyses to field conditions is the tacit assumption that the sum of the properties of the parts of a water-bearing formation is equal to the properties of the formation as a whole. This is seldom, if ever, true. The sum of the properties of the parts of any complex unit is usually something different from the properties of the entire unit. This can be illustrated by an analogy: An automobile is far more than the equivalent of the sum of the unassembled parts—it has properties gained from the relation of the parts acting together that the parts, unassembled, do not have. In much the same way an aquifer, as a unit, has properties different from the properties of the materials comprising it—when the individual properties are determined and added in any of a number of complicated ways. This basic difficulty remains no matter how carefully the samples are taken. There are other difficulties, such as the problem of obtaining representative samples and the disturbance of the sample as it is brought into the laboratory for analysis. This latter condition is especially true of unconsolidated materials.

A questionable procedure should not be justified merely by stating that it is followed in determining other physical properties. The procedure may be satisfactory for determining some physical properties and yet be unsatisfactory for determining hydrologic coefficients. To carry the previous analogy a step further: The weight of the car is equal to the sum of the weights of the parts. However, without testing the car in an assembled condition, how can one determine how far the car will go or what horsepower will be developed at 50 miles per hour?

There are methods for testing materials in place and determining hydrologic coefficients such as permeability and specific yield without relying on samples for quantitative determinations. Such methods can be applied profitably to alluvial deposits. For example, the problem of the safe yield of an essentially "virgin valley" was encountered in 1942 by the writer and associates in the valley of the Miami River south of Hamilton, Ohio (58). As the work was done under circumstances typifying the industrial utilization of ground water in the east, details may be of interest. The estimates of the safe yield were based on determinations of hydrologic coefficients of the aquifer in place, resulting in an increase in the reliability of the results as compared with those based on laboratory determinations.

The problem started in the Mill Creek Valley near Cincinnati, Ohio, where large industrial plants were in operation—partly because of the plentiful supply of ground water. By 1942 the industries and the municipalities in suburban Cincinnati were pumping more than 16 mgd from the water-bearing alluvium in the valley. The cumulative effect of the pumping was to lower ground-water levels in some parts of the area as much as 90 ft over a period of 50 years. By 1942 only 40 ft of saturated, water-bearing sand remained in some of the most heavily pumped areas. In others a saturated thickness of 60 ft or 70 ft remained.

In 1941 a new plant for the manufacture of airplane engines was built in the Mill Creek Valley just north of Lockland, Ohio. Even as originally designed, the plant was a giant one. Then, under the forced draft of war, its capacity was doubled. The water requirements, already high when the available ground-water supply was considered, also climbed. Before the attack on Pearl Harbor, Hawaii, in 1941, the water source for the big engine plant was a battery of large diameter wells tapping the valley fill underlying the plant property.

As water demands rose, water levels in the vicinity of the plant declined rapidly; and, partly on the basis of previous work by the U. S. Geological Survey, it was decided to install a new well field in the outwash-filled valley of the Miami River south of Hamilton, Ohio, and to abandon the well field at the plant except for emergency service. This plan necessitated the construction of about 20 miles of 42-in. and 36-in. pipe line, which, together with smaller pipe lines, wells, pumps, and motors, cost nearly three million dollars. This sum indicates the industrial value of cool, clean, ground water.

The Federal Works Agency, which was to construct the well field and pipe line, requested the Geological Survey to determine the effects of the new well field on existing ground-water supplies in the near-by Hamilton area and to make estimates of the perennial safe yield of the well-field area. In this connection, "safe yield" was defined as in Mr. Conkling's definition (see heading, "Safe Yield: Definitions"):

> "* * * the annual extraction from a ground-water unit which will not, or does not—
>
> "1. Exceed the average annual recharge * * *."

During the course of the investigation, thirty-two new wells were drilled in the area of the well field, including twelve production wells, and the geologic information obtained was analyzed carefully to delineate the area and the thickness of the ground-water reservoir. A number of farm and industrial wells that had been located and measured during an earlier investigation yielded valuable water-level information, as well as some geologic data (59)(60).

Water levels in the Miami Valley south of Hamilton had been measured periodically since 1939 and hydrographs of a number of observation wells were available, as illustrated in Fig. 10. A study of these graphs revealed an average annual water-level fluctuation of 8 ft.

The ground-water reservoir is recharged each spring by water from rain and snow, following which the water levels slowly decline as the water is evaporated and transpired while moving toward the Miami River. In 1941 and 1942, which were very dry years, the water levels did not recover normally, but in 1943 they rose to about the 1940 levels.

Maps of the piezometric surface were prepared and these showed conclusively that ground water south of Hamilton was feeding the Miami River. Fig. 11 is such a contour map. The slope of the water table is toward the Miami River. There was no heavy pumping in the area concerned, although arge quantities of water have been pumped for many years in Hamilton, and his pumping undoubtedly has had some effect on the water levels in the area o the south. In the latter area, the inhabitants used the ground-water supply nly for domestic purposes and for stock. At the time of the investigation, here was no development for irrigation.

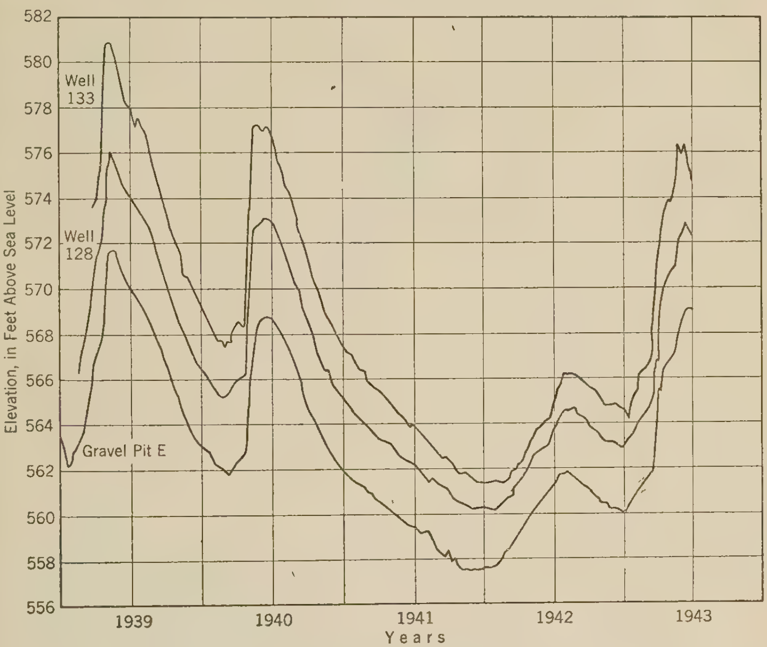

FIG. 10.—TYPICAL HYDROGRAPHS OF WELLS AND GRAVEL PITS IN THE AREA SOUTH OF HAMILTON, OHIO

To translate the available information into useful computations of safe yield, two pumping test investigations were conducted using methods developed by C. V. Theis (61) and described by L. K. Wenzel, Assoc. M. Am. Soc. C. E. (62). The method of investigation consists of sinking observation wells on a line from a well that is being pumped and observing the drawdowns that occur after pumping begins. From the discharge rate, the shape of the cone of depression at different times, and the rate of decline of the piezometric surface at the several observation wells, it is possible to compute the transmissibility of the water-bearing formation and the specific yield, or coefficient of storage, of the aquifer.

Using the quantities obtained from such pumping tests, two independent methods of computing safe yield were available:

1. By use of maps of the piezometric surface, together with the related geologic information, the average gradient and cross-sectional area were determined. The average gradient multipled by the cross-sectional area and the

coefficient of transmissibility on any line perpendicular to the direction of ground-water flow gave the daily rate of flow through the cross section.

2. The preceding computation should give results similar to those obtained by using the product of the specific yield times the average annual rise of the water level, multiplied by the up-gradient area between the given cross-section line and the ground-water divide, divided by 365 to convert the result to a daily basis. Such an assumption is based on the theory that precipitation is the source of the ground water and that, after reaching the water table, the water flows toward the Miami River, as indicated by contour maps.

Fig. 11.—Piezometric Contour Map of Area of the Proposed Well Field South of Hamilton, Ohio, in April, 1943

The results were in reasonable agreement, and it was found that an average of about 13 mgd would be available from precipitation alone. However, the results of one of the pumping tests showed that, by lowering the ground-water level near the Miami River, water would infiltrate from the river into the aquifer, thus increasing appreciably the indicated safe yield of the area. From the geometry of the new well field, computations were made which showed that a minimum of 6.5 mgd could be expected to infiltrate from the river over a ong period of well-field operation. This value was undoubtedly conservative s it did not include the effects of occasional floods which cover part of the welleld area—undoubtedly helping to replenish the ground-water reservoir.

The quantity of water recharged from the Miami River was found to deend, in large part, on the pumping distribution within the well field. Thus, n unwise pumping distribution would reduce the recharge from the river and ause unnecessary declines in ground-water levels in the Hamilton area.

Inasmuch as the water was to be used for industrial cooling, it was important hat river infiltration should be encouraged in the winter when the temperature f the river water is low, and should be discouraged in the summer when the iver temperature reaches from 85° F to 90° F. A schedule was devised for wellield operation which would cause the smallest decline in water levels in the Hamilton area and would produce the coolest water for use by industry.

The methods used in this investigation can be applied, with appropriate modifications, to other alluvial deposits.

Donald M. Baker,[11] M. Am. Soc. C. E.—A method of water conservation long known and exercised has been clarified by the author. However, this procedure has just recently been considered in the planning of comprehensive stream system developments. An important point in the paper is the reference to the fact that, in the past, ground-water storage in such developments has occurred not as a result of systematic foresight and planning, but rather as a by-product of direct utilization of waters. As these comprehensive developments become more common, greater reliance upon underground storage in certain sections of the United States for complete conservation can be expected; but, before this is possible to the fullest extent, rights to the use of water so conserved must be susceptible of reasonably exact determination.

Nearly 1,000 decisions of importance with respect to the rights to the use of surface and underground water have been handed down by the supreme courts of the seventeen western states and by the federal courts, since the admission of California into the Union in 1850. All these states, except Montana, have centralized agencies for the administration of surface waters, and in some states, of underground waters. These decisions, plus constitutional and legislative enactments, as well as practices and policies developed by state administrative officials, have fairly well crystallized the legal principles that relate to rights to the use of both surface and underground waters, when such waters occur as the result of the natural phenomena of precipitation and runoff.

The doctrines of appropriation and of riparian rights for surface waters and underground waters in known and defined channels are well established. The former is recognized in some states, whereas both doctrines exist side by side in others. In the case of percolating underground water, the "common law" doctrine, under which the landowner is presumed to own all water under his land as part and parcel of the soil thereof, the doctrine of correlative rights, more or less analogous to that of riparian rights in surface flow, and the doctrine of appropriation—all have been reasonably clearly defined.

---

[11] (Ruscardon Engrs.), Los Angeles, Calif.

When water occurs in underground storage as a result of man's activities and when it is extracted for beneficial purposes or finds its way into a natural stream, augmenting the flow thereof before diversion, the rights to use of such waters are not so clearly established. Most cases that have reached the higher courts as a result of controversies over the foregoing types of waters have dealt with return flow from irrigated lands, which has reached either an artificial or a natural drainage channel. In some states, those responsible for the occurrence of such waters are allowed to dispose of them to others. In other states, once the waters reach a natural stream—particularly when they have passed beyond the limits of the area from whose irrigation they result—they are considered part and parcel of the stream. Nearly all the decisions relating to this type of controversy have arisen in those states where the riparian doctrine does not exist.

During the next decade or two, however—particularly when a period of deficient precipitation and stream flow occurs—situations resulting from developments initiated since 1925 may be expected to cause serious controversies. In some instances, difficulties may be obviated by legislative enactments or constitutional amendments, whereas in others they must be settled by court decisions.

One factor to which the courts in many states appear to give consideration is the intent of the agency that is responsible for the occurrence of water in underground storage. If the agency has ignored the existence of such water—usually return flow, although sometimes surface waste—as an augmented supply to an underground basin or to a surface stream, the tendency has been to allow others to assert and secure rights to the supply. On the other hand, if the agency responsible for the occurrence of the water has consistently claimed the right to the use of the water, it has usually been allowed. Another principle, which has been favored with but little recognition by the courts, is that of the "foreignness in time" of return waters which augment natural stream flow.

Waters, originating outside a drainage basin and entering a stream, are considered as "foreign." In some states, riparian rights are not attached to the use of these "foreign" waters, since such waters are not a part of the natural flow of the stream. Somewhat similarly, an appropriator, when he made his appropriation and planned his development and use of water, might consider as available to him such waters of the natural flow of the stream as existed over and above existing prior rights. If the natural flow were augmented by artificial means, it would seem that such water should not inure to the appropriator, but should be subject to appropriation by the first comer. The return water, appearing and augmenting the natural flow, although water of the stream in question, nevertheless is no more a part of the natural flow occurring at the time than water from a distant drainage basin is part of the natural flow of the stream. However, most of the higher courts where the subject has been considered do not agree with this opinion.

The following problems may be considered as representative of many that may be expected during the next decade or so:

1. A flood control district gradually releases flood waters from its reservoirs, a considerable portion of these seeping from the stream channel into an under-

ground basin, thus resulting in a substantial increase in the normal replenishment of such a basin. Prior to the construction of the flood control reservoirs, replenishment of the basin had been in excess of draft; and, after adjudication, the pumping rights had been substantially reduced. In the adjudication proceeding, a substantial area of land within the basin was enjoined from ever using ground water. Does this augmented supply benefit those pumpers whose pumping rights were reduced in the adjudication? Does it inure to those others who were enjoined because of an inadequate supply? In other words, how should the supply be apportioned?

2. In a situation similar to that in problem 1, the increased replenishment caused a substantial increase in surface flow in a lower constricted section of the stream during the period of low flow. Does this augmented supply in the stream benefit existing appropriators in this section, or riparians, or may any one secure an appropriative right by filing a claim?

3. In a given underground basin, pumping draft over a period of years equals replenishment, and pumping rights have been adjudicated and restricted upon this basis. Gravity water is brought into the basin from a distant source, and return water from this source materially increases the replenishment. Can the original pumpers from the basin increase their draft because of the augmented supply, or are they limited to a draft equal to previous natural replenishment? In the latter case, could owners of overlying land, previously precluded from pumping because of deficiency in supply, utilize the return water, or would the agency importing the water have the first right to its recovery and use?

4. An irrigation district stores winter and early spring flood waters and uses them for irrigation. At the time plans were being prepared for the project, it was expected that the summer flow of the stream, which is inadequate to supply existing lower appropriative rights, would be augmented by return flow. Therefore, the district filed a claim on such augmented flow at the time of the original storage filing, for use on lands in the lower reaches of the project. Can the district secure a prior appropriative right to this augmented flow, or does such flow inure to existing and prior lower appropriators or to riparians to augment deficient summer supply?

5. Water from a surface stream is "spread," or placed in underground storage artificially, by an agency that expects to recover it later from wells. Because of physical conditions, not all the water so spread can be recovered by the agency doing the spreading. A party who has been exporting water from the basin is physically able to secure the remainder not recovered by the agency spreading it. However, certain overlying pumpers also claim this augmented supply. Who has the right to such water?

These and similar problems will be before the courts in the future. Sound legislation, passed to settle such controversies before they arise, or intelligent decisions, based upon an informed knowledge of the technical and economical features involved in the cases as well as upon legal precedent, will do much to crystallize the legal principles applying to water occurring in underground storage as a result of man's activities, and will encourage conservation. Much knowledge has become available concerning the occurrence and behavior of ground water since 1925 or 1930, and the fact of the existence of ground water should allow legislatures and courts to act with far more assurance than they were able to do shortly after the turn of the century.

HYDE FORBES,[12] M. AM. SOC. C. E.—This discussion of ground-water utilization provides an excellent over-all view of the objectives and accomplishments of such work in the west. The geologically modern alluvial fans built up by the major streams of the California Central Valley, southwestern Arizona, western Nevada, parts of Oregon, and south-central Washington and the alluvium filling of geological structural basins of mountain valleys and coastal plains of the west provide underground storage reservoirs whose utilization in connection with the development of the surface water resources should be a requirement in drainage basin development. Such reservoirs aid in the irrigation of less favorably situated lands and, in some instances, in the control of contamination of soils through alkali concentrations caused by the excessive accumulation of ground water.

In the "Summary," the author states:

> "This paper has presented, briefly, some of the values found and methods so far achieved, keeping in mind always that a solution of any water problem of the nature discussed in this paper [ground water] is accomplished by merely substituting correct values in a simple equation. It is the values which are often difficult to determine correctly; but as data accumulate this difficulty decreases."

Such a statement is the essence of all investigation involving underground conditions; and the writer finds, as the data accumulate, that preconceived simple relationships are not in reality simple and that the complexity of factors and of values increases. However, simple relationships or simple equations are a good starting point, subject to modification as more is learned about each specific problem.

In connection with the California State Wide Plan (later known as the Central Valley Project), in 1930 the writer undertook an investigation of the geology and underground water storage capacity of the Sacramento (63) and San Joaquin valleys (22*a*). Drainage factors for the ground-water reservoirs were assigned on the basis of grain size of the alluvial materials comprising broad areas as determined from penetration records of wells bored in those areas. The total capacity of underground storage was based on the extent of materials of a water-absorptive character delimited through an areal geological survey and on the practical limitations of water-table fluctuations. The recharge values were assumed as average seepage contributions, determined by test and measurement.

The writer's conception of the problem was that ground-water reservoirs (inflow and yield) could be treated like surface reservoirs—once the factors relative to capacity and yield had been assigned. However, the years since 1930 have produced data which indicate that the storage capacity, as measured by yield of most basins, is greatly reduced with depth below ground surface due to compaction under overburden load. The storage capacity is further reduced by the compaction of the material taking place after the first dewatering, and it is to be expected that further compaction will occur with each substantial lowering of water levels after recharge.

---

[12] Cons. Engr. and Geologist, San Francisco, Calif.

The increase in density of the water-bearing materials and decrease in yield as the depth below ground surface increases were determined quantitatively during the drilling of the plant 6 well for the City of Lodi in the Mokelumne River area of the California Central Valley. A continuous core was obtained and examined for compaction density and cementation in connection with pump tests and water level measurements made in 1937. When the well was 92 ft deep and had a water column of 66.6 ft, it produced an average of 65.6 gal per min of water per foot of drawdown, at discharge rates varying from 618 gal per min to 2,280 gal per min. The zone of pumping influence extended over a maximum area of 0.315 sq miles. The yield factor per foot of water column drawn upon $\left(\frac{66.6}{65.6}\right)$ was close to 1.00.

The well was driven to 270 ft and the pumping tests were repeated, extending the area of the zone of pumping influence to 0.546 sq miles and reducing the drawdown, but giving a resultant yield factor of 0.40. The final depth was 450 ft with a maximum pumping influence of 0.641 sq miles and a yield factor of 0.30—or less than one third of the yield in gallons per minute per foot of drawdown per foot of well column obtained at shallow depth. A current meter in an orifice was lowered into the well during the pumping tests at the 270-ft and 450-ft depths to measure the water yield of each section of the coarse sand developed. The results showed that the yield per foot of sand diminished rapidly with depth. More than half of the total well yield came from the top 66.6 ft of the column which contained eleven lenses of sand totaling 29 ft in thickness. The well bore hole between 92 ft and 270 ft intercepted twenty-six lenses of sand, totaling 46 ft in thickness, and the bottom 180 ft of the bore hole contained a total thickness of 58 ft of coarse sand lenses.

It is probable that yields from underground reservoirs will diminish with each foot of water-table lowering. The degree of diminishing return will depend on the character of the material comprising the reservoir. Each ground-water basin is a problem in itself and it is doubtful that values obtained from one area or combination of geological conditions are applicable to other areas. The question is: How much compaction, if any, will take place in the upper portion of the column where overburden load is not great and where seasonal fluctuation of the water table due to recharge and draft is effective?

The example of the subsidence of the Santa Clara Valley around San Francisco Bay in California due to ground-water drainage has been cited frequently—namely, 1 in. at Redwood City, 0.5 ft at Palo Alto, and 4.1 ft at San Jose in the 12 years from 1920 to 1932. Further subsidence was measured in the 6 years from 1932 to 1938 during which time conservation dams were constructed and spreading recharge was practiced (for the last 3 years) over the upper stream fans. This subsidence was measured as 0.15 ft at Palo Alto and 1.6 ft at San Jose.

The water-table levels of well-field area for the City of Palo Alto had declined to a critical elevation; and, by 1937, the water drawn upon was of poor quality. Water was purchased from the municipal supply of San Francisco and pump draft was reduced more than half. The wet years from 1940 through 1942 rapidly raised the well-field water levels. The writer has obtained the seasonal fluctuation of water levels in numerous wells in and surrounding the city well field since 1933. The plotted hydrologic pattern of these wells has been closely repetitive year after year, declining from 1933 through 1937 and rising in point of elevation from 1938 through 1942 until the fall of 1943 when the pattern broke and a decline started which has continued through the dry years of 1944 and 1945.

Pumping was further reduced in 1944 but the decline continued. It is not possible to obtain an exact quantitative measure; but, during the 5 years preceding October, 1937, the Palo Alto pump draft averaged 819.7 million gal per season and the average seasonal replenishment was 70.8% of normal—the water level of the ground-water reservoir was lowered 4 ft, or only 0.8 ft per season (about 0.1 ft per 100 million gal pumped). During the following 5 years, when the supplemental supply was brought in, the average seasonal pumpage amounted to 425 million gal per season and the average seasonal replenishment was 110% of normal. The basin water level rose 48.5 ft, or an average of 9.7 ft per season. During the season of 1943–1944 replenishment was 68.5% of normal, comparable to the first 5-yr period of record, and pump draft was reduced to 388 million gal. The basin water level lowered an average of 5.5 ft or 1.4 ft per million gal pumped as against 0.1 ft per million gal of pump draft when the basin was first dewatered. These data indicate that there is a substantial loss of storage capacity due to compaction upon drainage from ground-water storage. This capacity may not be recovered when the water levels rise.

A considerable area in California has been devoted to ground-water recharge through spreading, particularly since 1930, and a large amount of data has been accumulated relative to specific test plots, methods, and effects. The author has mentioned some of the more general results and difficulties that have been encountered. Recharge is readily effected in the ground-water areas most intimately connected with and adjacent to large surface streams. The flow of such streams, possibly needing regulation, is adequate to serve all the lands and purposes. On the other hand, ground-water basins provided by the limited alluvial cones of small intermittent streams, or interstream areas are those wherein ground-water resources are of the most value, have been most heavily drawn upon, and, in many localities, are critically exhausted. The problem of recharge of such areas is far from solution at present.

The ramifications of the general problem of ground-water utilization, draft, and recharge, cover many scientific fields and economic and legal considerations. In stream system development, an exchange of water—service from surface water over areas of ground-water depletion and to a considerable extent from wells for areas bordering major streams of the west—should be the answer. The economic adjustment and legal difficulties, when property or water rights are involved, are probably insurmountable.

Harold Conkling,[13] M. Am. Soc. C. E.—The scope of the ten discussions of this paper is broad. Mr. Jarvis has contributed an illuminating discussion on underground water developments and problems throughout the world. Mr. Crosby has drawn attention to the artificial recharge of ground-water aquifers in Europe antedating similar projects in the United States. Mr. Hill has developed the method of determining safe yield from pumpage records which was mentioned briefly as Case I under the heading, "Direct Methods of Safe Yield Determination." Mr. Kazmann has discussed the permeability method used by the U. S. Geological Survey, the same method which is criticized by Mr. Charles in his broad discussion. Mr. Bradley has made an interesting contribution drawn from his own experience in Southern California. The method of causing recharge by means of a well which he describes is ingenious and worthy of note. Mr. Bradley also sounds a note of caution as to deterioration of the storage capacity of alluvium with the passage of time. Mr. Sopp has gone into certain phases of the legal aspects, and his statements as to his findings as to certain physical conditions should be noted. Mr. Baker and Mr. Drummond have confined themselves to legal phases. Mr. Forbes gives some startling calculations on decrease in storage capacity after the first unwatering of an aquifer.

Several have noted that the scope of the paper was too narrowly delimited inasmuch as the same principles apply to humid regions as well as to arid, and to industrial use as well as to irrigation use. This is true, of course, but even with the limitation imposed the paper was long and, to the writer, seemed to "take in a large amount of territory." Had there been no such limitation the paper, conceivably, could have filled four times as many pages. Presumably the space would not have been available. In addition, by such delimitation the writer had the considerable advantage of discussing situations with which he is more or less familiar.

This closure is limited to discussion of methods of estimating safe yield, of changes in storage capacity of aquifers due to unwatering, and of the legal phases which were brought into the picture by the discussers. There are methods of determining safe yield other than those mentioned in the paper or in the discussions, and it is a disappointment that those most familiar with them did not contribute a discussion. One of the purposes of the paper was to provoke a symposium, as it were, of recent experience particularly in that aspect of the matter. Records of such experience other than by permeability methods are generally not given much publicity.

In the paper, in discussion of the Hill method of direct determination of safe yield under Case I, it was stated that the recharge of the ground water must be fairly uniform from period to period, whether the period were a year in length or longer, for the method to be usable in any particular investigation.

---

[13] Cons. Engr., Los Angeles, Calif.

It was also stated that large annual variations in supply might be "ironed out" by using moving averages embracing sequences of years. In other words, it would be necessary to use a sufficient number of years in obtaining the averages so that the recharge in each period would be approximately uniform. In Southern California, especially, and in most of arid California, in general, the periods required to obtain an approximately average supply are from twenty to thirty years inasmuch as the weather moves in "cycles" of about that length in which somewhat more than half of the years are deficient in precipitation and somewhat less than half have a surplus. In the wet phase of the cycle almost all the years have excess precipitation. In the dry phase almost all have deficient precipitation. Therefore, an inordinately large number of years must be taken to reach the average, and the period of record is not long enough to give a sufficient number of averages. In addition, development has been so rapid, and so many changes have taken place during the period of record, that recharge of a quarter century ago may not be comparable with present recharge. Probably somewhat the same conditions are found in some other parts of arid America.

Regardless of this, if the recharge to the particular portion of the acquifer for which safe yield is to be determined is by lateral percolation from a more or less distant source, so that inequalities in recharge for different periods are averaged; or, if the deep percolation of direct precipitation on the overlying surface is sufficiently impeded by impervious lenses of material so that inequalities from that source are also "ironed out," the method is usable for that particular zone.

In a large part of the coastal area of California, precipitation is large as compared to that of the southern part of Central Valley, and as compared to that of most of arid America. In much of the coastal area, also, the water table is free. In other words, recharge is largely vertical, whether from streams or from direct precipitation, so the necessary condition of equated recharge cannot exist. In some parts, however, notably for some distance from the ocean in the flat coastal plains and also in some parts of the interior valleys, the prerequisite conditions do exist.

If attempt is made to use the Case I method described by Mr. Hill in the areas with large direct vertical recharge or with lateral recharge from a not sufficiently distant source, the result will be a series of points on the graph which obviously can bear no relation to one another because they give the change in elevation of water table with the recharge of that particular period. Through each of these points, parallel curves may be drawn but there is no criterion to guide the slope of the curves unless it should happen that some two of them represent average recharge.

The point is well illustrated by Fig. 8 in Mr. Hill's discussion, in that recharge from 1918 through 1926 was approximately uniform. Then conditions began to change and a series of curves are drawn through individual points with slope gradually changing from that which obtained in the above period to that labeled "present conditions" which began in 1932 and presumably still exists. Something changed the recharge after 1926 and it did not become static again until 1932. Mr. Hill states that the change was presumably aused by movement along a major fault in 1927. The point is that if it were ot for the antecedent uniform recharge, and the present uniform recharge, here would have been nothing to indicate the direction of the intermediate urves. In Fig. 7, a successful application of the method is shown; but this is ue to the fact that, in the area to which the curve applies, the recharge is airly uniform as Mr. Hill suggests. This is because of the impedance to novement of water brought about by many clay strata formed as the original ediments changed with age.

It would seem that the restrictions on the use of this method suggested in he paper are demonstrated to be valid by Fig. 8. That does not mean, however, that the method is not a very useful one where the necessary conditions xist, as they probably do over much of arid America.

Mr. Kazmann discusses the permeability method of determining safe yield vhich is the subject of several bulletins of the U. S. Geological Survey. This onsists of determining the permeability of an aquifer by pumping tests, that is, letermining by application of Darcy's law the rate at which water will flow hrough the cross section of an aquifer. The method may be used to estimate he yield of a single proposed well, or of an entire aquifer, together with the ecessary spacing of wells to extract it.

This method seems peculiarly suited to an aquifer which has been little xploited, and, particularly, to one in which the water table is close to the ground surface so that observations on the drawdown caused by pumping the test well can be measured by small test holes. It would also be necessary for the tests to be made at the least permeable cross section of the aquifer.

It would be difficult to use it in a large part of California or in other parts of the arid states where the water table is far below the surface, because of the xpense of drilling the observation wells. This might not be necessary if sufficient wells drilled for production existed in proper locations; such a condition would be rare. Another difficulty would be the variation in specific yield as illustrated in Fig. 5. However, it would be useful in many other situations nvolving the confined aquifers of the coastal plains of California and the central parts of many valleys not on the coast, where the ground water is confined. In such cases, where pumping has already reached considerable proportions, the Hill method also is applicable and the answer secured by it might be more lependable. However, in this case, probably it would be better to use both methods plus the hydraulic equation mentioned subsequently which gives the yield as a differential.

Mr. Kazmann cites an interesting illustration of results by the permeability method in Miami Valley, Ohio, where new drafts on ground water were suddenly mposed by the war.

On the other hand, Mr. Charles gives three illustrations of predictions of safe yield by this method for water production zones in Pennsylvania as compared to results actually achieved. Actual safe yield as demonstrated by xperience was from two to three times the prediction. Had industrial levelopment been limited to that which could use the predicted yield, production of war material might have been seriously hampered. The fact that actual yield far exceeded estimated yield is perhaps corroborative of the writer's belief that it is difficult to estimate the safe yield of a little exploited territory. Probably in many cases, if not in most, exploitation increases the recharge because greater opportunity exists after the water table has been lowered by pumping.

The method of determining safe yield (that is, determination of drainable voids primarily) was described by the writer at considerable length. Mr. Kazmann seems to feel that the permeability method is preferable because it is more accurate. However (leaving aside the moot question of greater accuracy), as mentioned in a preceding paragraph it would be difficult to apply the permeability method in much of the arid West because of depth to water table, changes in permeability of the aquifer, and (not previously mentioned) fault zones across the aquifer.

The calculation of safe yield by substituting values in the hydraulic equation is laborious and, as both Mr. Hill and Mr. Sopp indicate, errors may accumulate in the residual which is the answer sought. A variation of this used by some is to calculate the deep percolation for each rainstorm and for each irrigation, and to measure the stream percolation. This is even more laborious but good results have been achieved.

It appears that for most situations some one of the methods of determining safe yield is preferable but several may give almost equally good results. Absolute merit does not lie in any one. It also appears that the method is not the only determinant. Judgment enters into the matter to such an extent that it requires considerable experience to apply any method. An important point to consider is that the books should balance. Calculated supply and disposal should be equal, and no estimate can be considered valid unless the balance is made.

Under the general direction of the writer, attempts were made in the early 1930's to determine the effect of the weight of the overlying alluvium on the porosity of various classes of sediments (27). The results are not conclusive because the range in values is large. Nevertheless, curves were plotted through the scatter points. The values in Table 3 are taken from them. These data indicate far less compaction with depth than those cited by Mr. Forbes in the case of the well of the City of Lodi if the decrease in that well is all charged to

TABLE 3.—PERCENTAGE POROSITIES AT THREE LEVELS (GROUND SURFACE EQUALS 0)

Description	0	−50	−1,000
Unweathered silts and sedimentary clays	43	37	32
Unweathered fine sands	43	38	32[a]
Nongritty residual clays	34	29	26
Reddish-brown gritty residual clays	30	27	21

[a] For this material there were no tests at depths greater than − 800 ft; at this depth porosity was 32.5%. The value shown was found by projecting the curve to the 1,000-ft depth.

compaction due to overburden. Mr. Forbes, however, does not state that the sands at depth had the same make-up as those at a higher level.

Certain data concerning the Palo Alto situation from Mr. Forbes' discussion are cited in Table 4 for better comparison. On its face this would indicate a yield per foot of recession, in 1943–1944, only 7% as great as the yield when the aquifers were first drawn on. Such diminution seems impossible and the real cause should be sought along other trails. However, diminutions of much less magnitude have been found in isolated cases. It would seem impossible to have diminution of this type without a settling of the earth's crust. Mr. Forbes cites one example. Three others come to the writer's mind—one in Central Valley and two in Southern California. These are quite local; and there is no indication so far of any widespread subsidence although the water table in most of the ground-water basins of California has varied widely in elevation since about 1930.

TABLE 4.—CHANGE IN RECESSION OF WATER TABLE AT PALO ALTO, CALIF., PER MILLION GALLONS PUMPED

Period	Normal replenishment (%)	Pump draft (million gallons)	RECESSION OF WATER TABLE	
			Ft	Ft per million gal
Average, 1932–1937..................	70.8	819.7	0.8	0.1
Total, 1943–1944....................	68.5	38.8	5.5	1.4

Legal Phases.—Mr. Baker very ably outlines the legal problems which may occur in ground-water developments of the future. It is unfortunate that the courts have developed many of their precedents from the inadequate hydrological knowledge of a half century ago. Solutions of the problems noted by Mr. Baker, and other problems which will arise, will be sadly handicapped by these precedents. There is in this circumstance, material for a paper which might be of aid to jurists.

Mr. Sopp discusses the legal phases of rights to the use of ground water, and indicates the differences between law as applied to ground water and as applied to surface water. These differences are unfortunate and were made because of lack of knowledge. Of late years, the legislatures of various western states have rescued the situation by placing all water under administrative control, that is, under the same kind of law. In California, the courts have applied the same law to both surface and underground water. Under the fundamental law of California, which is the riparian doctrine, access to a water supply gives right of use without application to the state. The individual with such access takes water under his vested right and is not termed an appropriator. The individual without such access who takes water from a source is termed an appropriator. The legislature requires that the individual who does not have access (the would-be appropriator) must apply to the state for a permit to appropriate surface water; but the legislature has not made such application a prerequisite to appropriation of ground water. Even if the legislature made application to the state a prerequisite to appropriation of ground water it would apply only to the exporter to distant lands. The overlying owner would continue to take it without application to the state.

In addition, the test of "adverse user" is not whether the invader is upstream or downstream but whether his taking limits the taking of another user. If a ground-water stream is deep enough and sluggish enough the downstream user might invade the right of the upstream user.

The foregoing short discussion is made in the fear that Mr. Sopp's able discussion might be misinterpreted in certain minor respects.

Mr. Drummond discusses briefly the excellent results secured in New Mexico by careful administration of the 1931 Act which makes underground water subject to appropriation in the same way that surface water is. This law has been assumed to be a model; and passage of a similar one has been urged on the several legislatures of the western states.

The law is an improvement over conditions which existed before its passage. It could probably be improved still further but with wise administration it should be workable as it is, for the present at least. Such a law would not be effective in California unless the constitution were changed.

CONVERSION OF KINETIC TO POTENTIAL ENERGY IN FLOW EXPANSIONS

By A. A. Kalinske,[1] Assoc. M. Am. Soc. C. E.

With Discussion by F. T. Mavis, J. C. Stevens, Boris A. Bakhmeteff, E. R. Van Driest, A. R. Thomas, and A. A. Kalinske.

Synopsis

Information on the energy changes that occur when fluids flow in expanding conduits is presented in this paper. Specific data are presented on mean velocity distribution, turbulence, and pressure changes for 7.5°, 15°, 30°, and 180° expansions from 2.75-in. to 4.75-in. pipes. The velocity and turbulence measurements were made by photographing, on motion-picture film, the flow in transparent conduits. The water therein had suspended in it small, immiscible droplets which formed streaks on the pictures, from which the direction and magnitude of the velocity at any instant in two dimensions could be obtained.

The analysis of the data for mean velocity distribution, variation of turbulence, and pressure changes gives considerable information on the mechanics of the energy conversion and dissipation processes. It is found that the total loss of energy is considerably greater than the total energy of turbulence that is produced, thus indicating that a major portion of the energy is lost by direct conversion into heat at the regions of high, local shear in the fluid. The turbulence created is a by-product of the energy dissipation process; however, it plays an important rôle in the shaping of the mean velocity distribution curve in and beyond the expansion. Data are presented on the energy loss and efficiency of the energy conversion for two rates of flow through the four expansions studied.

A. Introduction

Examples of fluid flow in conduits where the cross-sectional area increases, with a resultant decrease in velocity and increase in pressure, are common wherever fluids are carried and controlled. Specific examples range all the

way from small pipe fittings, known as "reducers," to draft tubes on turbines, and the loss of head occurring in any such expansion may be only of minor importance to the engineer; or it may be of considerable importance. Throughout the years, considerable data have been accumulated, relating to losses in various types of such expansions, and in general hydraulic engineers have a fair idea of the pressure losses involved. Therefore, this paper is not concerned with the mere presentation of further pressure loss data, but rather with supplying data that will shed some light on the internal mechanics of the energy changes that occur in the fluid flowing in and beyond expansions.

The experimental data presented herein have been an outgrowth of a study relating to the general problem of the hydraulic conversion of kinetic to potential energy, which was started by the Society's Committee on Hydraulic Research in 1935 at the Iowa Institute of Hydraulic Research. In order that quantitative information might be available relating to the conversion process, it was necessary that all the elements entering into the process be measured. Therefore, for each expansion studied the mean velocity distribution was determined at several sections in and beyond the expansion. Since the conversion process involves transformation of a part of the kinetic energy into turbulence energy, it was desirable to have some measurements relating to the intensity of turbulence at various sections. This, of course, proved to be the most difficult part of the experimental study; however, some very significant data were secured. The change in the pressure along the conduit in which the expansion was installed was also determined.

Before the experiments and results are discussed in detail, a brief review will be given of some of the fundamental facts known about flow in expansions and pertinent past work on this subject. Also, since certain items relating to fluid turbulence are basic to this particular study, a short description will be given of the relation of turbulence to the energy changes that occur in flowing fluids.

B. Mechanics of Fluid Flow in Expansions

From a practical standpoint the principal item of interest is the pressure loss that occurs when fluids flow through expansions. However, in order to understand exactly what causes this extra pressure loss and where it takes place along the conduit, it is necessary that the flow mechanism be examined in detail. This paper is concerned only with incompressible fluids; therefore, density and temperature changes will be neglected.

Visual observations of flow in conical expansions reveal that there is an appreciable increase in the angularity of the velocity of fluid particles near the boundaries as they pass through an expansion. In other words, the flow becomes more eddying, and the eddies created near the boundaries gradually "eat" into the center stream which for a while after leaving the smaller conduit is relatively free of turbulence. The eddies coming from the wall naturally have relatively low forward velocities, and, as they intermingle with the rapidly moving central part of the stream, the fast-moving fluid is gradually slowed down. As the mean velocity decreases there is a gradual pressure rise, and the efficiency of the conversion process of kinetic to potential energy depends on how much of the initial kinetic energy is used in forming eddies and in direct frictional loss.

---

[2] ASA—Z10.2—1942.

The loss in any expanding section can be divided into two parts—that due to friction on the boundaries and the extra loss due to the shape and form of the conduit. Except for slow expansions (those having total angles less than about 10°) the frictional loss is negligible compared to what might be called "form loss." Both analytical work and experimental data indicate that the total expansion angle giving the least loss varies between 5° and 10°, the exact value being dependent on the velocity ratio and the initial velocity distribution. As the expansion angle is increased, the form loss increases rapidly, as it is associated with the flow separation that occurs at the boundaries; that is, as the expansion angle becomes large, the fluid near the boundaries does not have sufficient kinetic energy to move against the pressure gradient; instead a backward flow occurs. There is thus created a discontinuity inside the fluid with the result that high shearing stresses occur in the fluid and violent turbulence is generated.

Some extensive data on the loss in expansions varying from 3° to 180° (sudden expansion) between circular pipes of 1.5 and 3.0 in. in diameter were obtained by A. H. Gibson.[3] He expressed the loss in terms of the Borda loss for sudden expansions, and showed that the total loss was a minimum for an expansion of 5.5°, being about 13.5% of the Borda loss; it reached a maximum of 121% when the angle was 63°, and then diminished to 102% for a 180° expansion. Extensive experiments on the loss in sudden expansions were reported by W. H. Archer,[4] who expressed the loss as

$$h_i = \frac{1.098\,(\bar{U}_{m1} - \bar{U}_{m2})^{1.919}}{2\,g} \quad \text{...................} (1)$$

in which $\bar{U}_{m1}$ and $\bar{U}_{m2}$ are the mean velocities in the upstream and downstream conduits, respectively.

In his work on conversion of energy in cross-sectional divergences, H. Peters[5] emphasized the influence of the conditions of inflow on the efficiency of the conversion process. He stated that complete conversion requires a discharge length beyond the expansion which depends on the angle and the velocity distribution at the entrance to the expansion. He defined the efficiency of conversion as the ratio of the actual rise in pressure, corrected for wall friction, to the difference in the initial and final kinetic energies. The kinetic energy was calculated by integration of the actual velocity distribution across any section. Mr. Peters showed that superimposing a spiral motion on the flow entering any expansion increased the efficiency markedly. It appears that the rotational motion delays separation, and thus decreases the energy loss.

[5] "Conversion of Energy in Cross-Sectional Divergences Under Different Conditions of Inflow," by H. Peters, *Technical Memorandum No. 737* (Translation), National Advisory Committee for Aeronautics, 1934.

A. P. Kratz and J. R. Fellows[6] conducted detailed experiments on pressure losses resulting from changes in the cross-sectional area of rectangular air ducts, and among their findings is the conclusion that diverging sections having included angles greater than 60° give losses at least as great as those in a sudden expansion, and that no material advantage is gained by use of angles greater than 30°.

J. Nikuradse[7] made velocity distribution measurements in two-dimensional diverging sections up to angles of 5°, and it is apparent from his data that the shape of the velocity curves depends on the angle of divergence, the curves becoming more pointed for the larger angles. He noted that separation occurred at a 5° divergence and that, for slightly larger angles, there was a tendency for asymmetrical velocity distribution and a switching of the flow from wall to wall.

Some analytical work has been done in regard to retarded and accelerated flows by extension of the knowledge relating to turbulent boundary layers to conditions where a pressure gradient exists. Calculations for such conditions indicate whether a given velocity distribution and pressure gradient are possible without separation of the boundary layer. A detailed discussion of this is given by L. Prandtl.[8]

C. CERTAIN CONCEPTS RELATING TO TURBULENCE

Since the energy dissipation in conduit expansions is closely related to the fluid turbulence, an understanding of some of the basic ideas relating to turbulence is essential. Certain aspects of the statistical theory of turbulence have been presented in a previous paper.[9] The important items relating to turbulence are its origin, designation of its intensity and energy, its diffusing power, and its dissipation.

In general, for various dynamic conditions, regions of high shearing stress, where instability develops, occur in moving fluids, with the result that "rollers" or "eddies" are created. Such regions can occur near solid boundaries in a moving fluid, at boundaries of jets entering a slower-moving or still fluid, and at surfaces between two fluids of different density when a sufficient relative velocity exists. As the vortices or eddies develop, they move away and enter other parts of the fluid. Although the motion of an isolated vortex, such as of the ring or helical type, might be analyzed, when large numbers of such vortices move into a mass of fluid their mutual interactions become so complex that it becomes impossible to predict the behavior of a particular eddy. When a mass of fluid has a large number of eddies of varying size and strength, it is said to be turbulent. It has been accepted by various workers in the field of fluid turbulence that the term would be used only to describe fluid motion that is entirely haphazard in character and which can only be described quantitatively in the statistical sense. Thus the well-ordered system of vortices one sees immediately behind a cylinder immersed in a moving fluid stream is not considered as true turbulence.

Intensity and Energy of Turbulence.—The notation to be used for velocity is as follows: The velocity at any instant will be designated by the three rectangular components U, V, and W. The direction of U will be in the direction of mean flow, or, in this paper, along the conduit axis. The components V and W will be at right angles to U. The value of U can be considered as equal to $\bar{U} + u$, in which $\bar{U}$ is the mean axial velocity with respect to time at any point, and u is the fluctuating part due to the turbulence. Since the mean flow is in the direction of $\bar{U}$, $\bar{V}$ and $\bar{W}$ are zero. The turbulence components at any instant perpendicular to the u-component are v and w. Borrowing the concept of "standard deviation" from statistics, the intensity of the turbulence in each of the three directions will be defined as $\sqrt{\overline{u^2}}$, $\sqrt{\overline{v^2}}$, and $\sqrt{\overline{w^2}}$.

The total kinetic energy of the fluid at any point in the section, expressed in foot-pounds per pound of fluid, will then be equal to

$$e = \frac{\bar{U}^2}{2\,g} + \frac{\overline{u^2} + \overline{v^2} + \overline{w^2}}{2\,g} \qquad (2)$$

The first term is the kinetic energy per pound due to the mean velocity (referred to in hydraulics as velocity head), and will be designated by e_m. The sum of the other terms is the kinetic energy of the turbulence and will be designated by e_t.

An item to keep in mind is that similar values of $\overline{u^2}$, $\overline{v^2}$, and $\overline{w^2}$ for two flow conditions do not necessarily mean that the turbulence is identical. The intensity of the turbulence only characterizes the rotational velocity of the eddies. For a complete description of the turbulence, some measure of the average eddy size is necessary. The diffusing power of the turbulence is directly proportional to both the intensity and the scale.

Turbulence Energy Diffusion and Dissipation.—For a fluid moving under shear, the energy producing the flow is continually being transformed into heat. The work done by the shear, per unit volume of fluid, per unit time, for parallel flow, is equal to $\frac{\tau\, d\bar{U}}{dy}$, in which τ is the unit shear stress, and $d\bar{U}/dy$ is the mean velocity gradient transverse to the flow. For viscous flow this rate is equal to $\mu \left(\frac{d\bar{U}}{dy}\right)^2$, in which μ is the coefficient of dynamic viscosity. In turbulent flow the rate at which the mean shear does work is not necessarily equivalent to the rate of energy conversion into heat. Part of the work done by the shear results in the creation of turbulence; that is, the energy producing flow is in part transformed into energy of turbulence, which is eventually converted into heat through the action of viscosity. Of course, in the laminar boundary layer of smooth conduits, an appreciable portion of the energy is directly converted into heat since the value of $d\bar{U}/dy$ is very high in this region. Since turbulence is so diffusive in character, the turbulence energy created at one point is not necessarily dissipated into heat at that point.

The dissipation of turbulence energy is an extremely complicated phenomenon from an analytical standpoint because of its three-dimensional character. A general expression for the dissipation of turbulence energy by viscosity has been derived by G. I. Taylor[10] and it contains terms of the type $\overline{(\partial u/\partial x)^2}$, $\overline{\left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\right)^2}$, etc. These terms are the mean of the squares of the instantaneous velocity gradients due to the fluctuating velocity components. For isotropic turbulence, ($\overline{u^2} = \overline{v^2} = \overline{w^2}$), such as that generated in the throat of a wind tunnel due to a regular system of grids, the rate of turbulence energy dissipation, as shown by Mr. Taylor, reduces to a simple expression because of the simple relation that exists between the fluctuating velocity gradients in the different directions. The rate of dissipation per unit volume is then equal to:

$$e_d = 7.5\,\mu\,\overline{\left(\frac{\partial u}{\partial y}\right)^2} \qquad \text{(3)}$$

Of course, in conduit flow the turbulence is far from isotropic. The practical significance of Eq. 3 is that it gives a clue as to what factors affect the rate of turbulence energy dissipation. The term $\overline{(\partial u/\partial y)^2}$ can be set proportional to $\overline{u^2}/\lambda^2$, in which λ is a scale of turbulence associated with the dissipation process. Thus, as the size of the eddies decreases, for a given intensity of turbulence, the rate of dissipation increases. Therefore, turbulence can be dissipated more rapidly by breaking up the larger eddies. There is experimental evidence that as turbulence decays, owing to dissipation of its energy, the average scale tends to increase, since the smaller eddies are dissipated more rapidly. The larger eddies are "ground down" in a process that is not as yet clearly understood. There seems to be a stretching of the vortex filaments; for instance, Mr. Taylor[11] shows that the rate of dissipation by viscosity of the vorticity is several times greater than the rate at which vorticity actually disappears. This means that vorticity is being produced through the process of stretching the vortex filaments with a resultant decrease in size of eddies but an increase in the angular velocity, which follows from the law of conservation of angular momentum.

The foregoing ideas will serve as a background for analyzing the data on turbulence that were obtained in the flow through conduit expansions.

D. EXPERIMENTAL AND ANALYTICAL PROCEDURES

A complete study of the energy conversion and dissipation processes in the flow in expanding conduits involves a study of the mean pressure change along the conduit, the distributions of mean velocity at various sections, and measurement of the turbulence. So far as the turbulence is concerned, the obtaining of complete information regarding it presents formidable experimental difficulties. It was decided that, if its intensity could be measured at various points in several sections along the conduit, this would be all that could be attempted.

---

[10] "Statistical Theory of Turbulence," by G. I. Taylor, *Proceedings*, Royal Soc. of London, Vol. 151A, 1935, p. 430.

[11] "Production and Dissipation of Vorticity in a Turbulent Fluid," by G. I. Taylor, *ibid.*, Vol. 164A, 1938, p. 15.

Since this entire investigation extended over several years, changes in regard to general experimental procedures and apparatus occurred as information was obtained relating to experimental difficulties, and also as the general emphasis of the study was altered. The first studies were made on a 15° expansion between pipes of 3-in. and 5-in. diameters. The conical section was constructed of transparent pyralin and the straight pipe of pyralin sheets. Studies on this expansion perfected the experimental techniques, and some useful data were secured. However, after this expansion was in use about a year, it warped and had to be abandoned, thus preventing the collection of a complete set of data for several rates of flow. Since at that time transparent lucite pipe and sheet material had become available, it was decided to complete the studies using various expansions between lucite pipes of 2.75-in. and 4.75-in. diameters. Time permitted obtaining velocity and turbulence data for at least two rates of flow for expansions of 7.5°, 30°, and 180°. Pressure data were obtained on these expansions and also on a 15° expansion between 2.75-in. and 4.75-in. pipe.

The general setup used in the experimental work consisted of a constant-level supply tank, calibrated orifice, approach piping, and regulating valve. After considerable preliminary work, it was decided to obtain the velocity data photographically by use of motion pictures. The technique was as follows: Into the flowing water, about 30 ft upstream from the expansion, a mixture of carbon tetrachloride and benzine was injected, the proportions being adjusted so that the mixture had a density equal to that of the water. Powdered anthracene was suspended in the mixture to give it a milky appearance. The mixture was injected into the flowing water by means of a water-pressure operated injector. The mixture was thus broken up into droplets the size and number of which could be controlled by adjusting the rate of injection and by varying the water pressure on the injector. The size of the particles considered suitable for this work varied between one and two millimeters. The water temperature in these experiments varied from 50° to 65° F.

At sections where velocity data were desired, the flow with the suspended droplets was illuminated with a carbon-arc light by focusing an intense beam through a double-slit barrier, which gave a plane of light about $\frac{1}{8}$ to $\frac{1}{4}$ in. thick. This horizontal plane of light was directed through the center line of the conduit, and particles entering this plane of light were brilliantly illuminated. A 16-mm, motion-picture camera was mounted above the conduit and focused on the plane of light in the conduit. The shutter opening and speed of the camera were adjusted for any run, so that for the given water speed the particles would, on an average, produce streaks about $\frac{1}{2}$ in. long when the film was projected to the actual size of the conduit. A scale was inserted next to the conduit in the field of view to give the linear dimension. The field of view was only large enough to take in the width of the conduit and the scale. For each run, about 15 ft of motion-picture film was taken, giving about eight hundred individual frames. The time interval for this footage varied with the camera speed, but on the average was about 1.5 min. For each shutter opening and camera speed used, the camera was calibrated for exposure time by photographing bright particles attached to a belt which was run by a constant-speed motor.

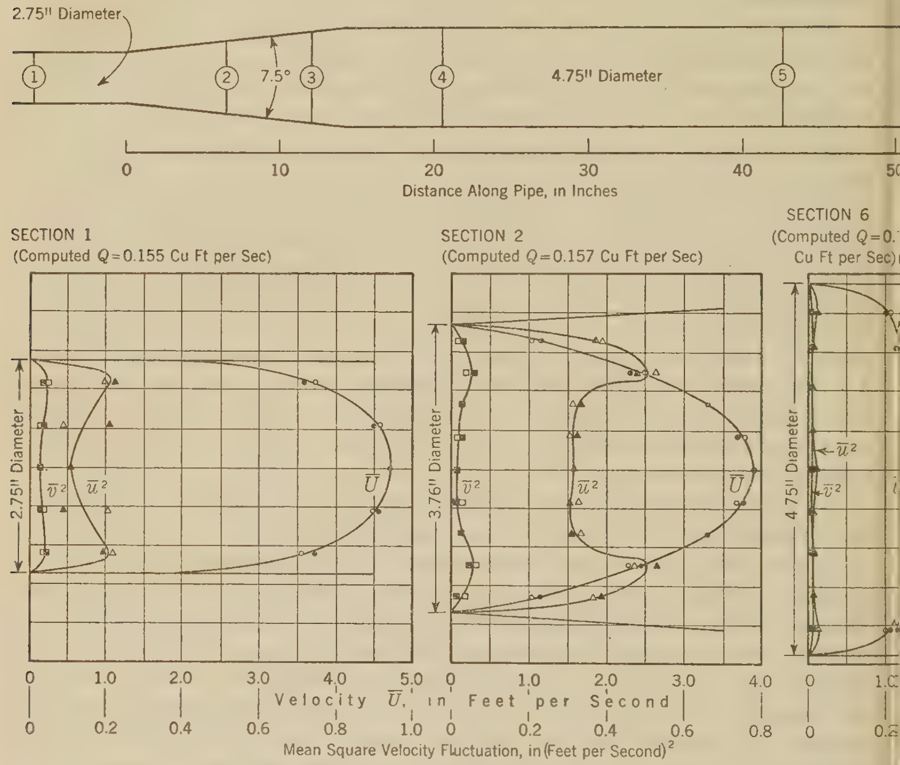

FIG. 1.—DISTRIBUTIONS OF MEAN VELOCITY AND MEAN SQUAR

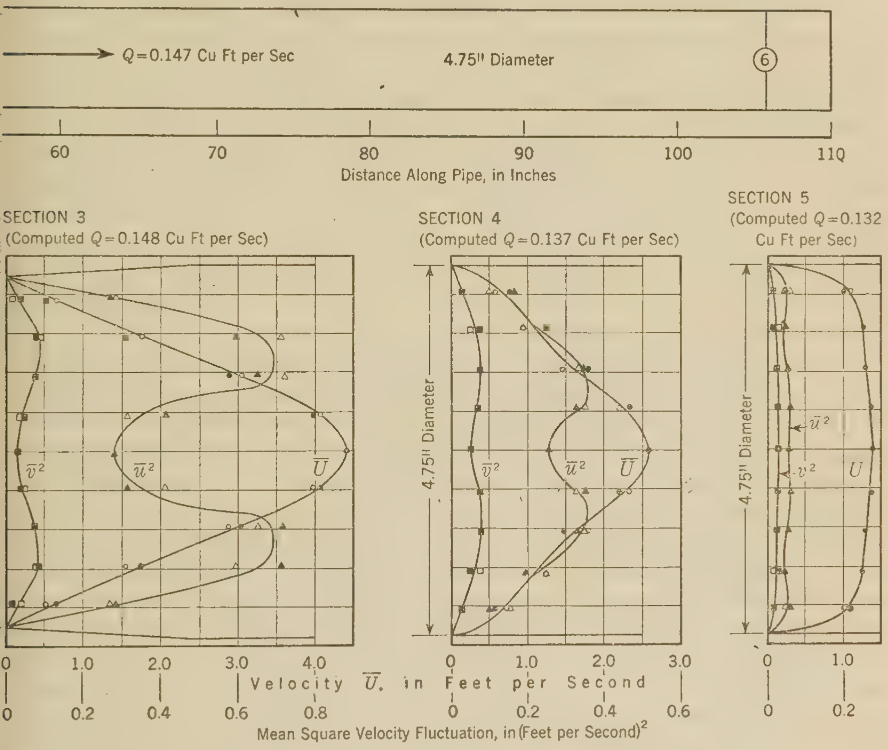
The pictures were analyzed by projecting the film to somewhat larger than full scale and measuring the length of the streaks in the following manner: At the section of the conduit where velocity data were required, some seven to nine points were selected across the conduit. At these points on the screen, squares were drawn about 1/25th of the conduit diameter in size. Streaks falling on these squares were taken as giving the velocity at that point at that instant, or, more accurately, the average velocity for the instant of time required for the droplet to move the distance of the streak. This time varied with the water speed, but was between 1/20th and 1/80th of a second. Three measurements were taken for each streak—the length components along and perpendicular to the conduit, and the width. The length of the streak in the direction of the conduit minus the streak width (droplet size) gave the velocity component in that direction at that instant. The average of such lengths gave the mean axial velocity at any point. This is designated by the symbol $\overline{U}$. Subtracting $\overline{U}$ from the individual velocity values at various instances gave u, and from these the value of $\overline{u^2}$ could be obtained.



ocity Fluctuations for 7.5° Expansion (Q = 0.147 Cu Ft Per Sec)

The length component of the streak perpendicular to the conduit gave the velocity component, V, and then, from $(\overline{V} - V)$, values of the turbulent component v could be obtained, and finally $\overline{v^2}$. Thus the streak data permitted the calculation, at each point, of the values of $\overline{U}$, $\overline{u^2}$, and $\overline{v^2}$. The number of motion-picture frames analyzed varied from 500 to 1,000. The number of readings obtained averaged about 300. As can be imagined, the taking of the data from the pictures and their evaluation were very time consuming. However, since such data had never been obtained before, it was thought worth while to do the necessary work, since it seemed that some significant information could be obtained.

The pressure-variation data were obtained by installing wall piezometers along the conduit and connecting these to a tube bank. Colored water was put into the top of the columns so as to make them more visible, and a motion picture was taken of the water levels in all the tubes. The average value of the pressure was determined by projecting the picture and reading the water-column heights from several hundred frames distributed over a time interval of about 2 min.

E. MEAN VELOCITY AND VELOCITY FLUCTUATION DATA

The distribution of the mean velocity and velocity fluctuations across several sections of a conduit was first obtained for a flow of 0.082 cu ft per sec through the 15° conical expansion between 3-in. and 5-in. pipes. A detailed plotting or tabulation of the values of $\overline{U}$, $\overline{u^2}$, and $\overline{v^2}$ for all the tests would require considerable space; therefore only typical detailed data will be shown for a few of the runs. Figs. 1 and 2 contain data obtained for the 7.5° and 180° expansions for a flow of 0.147 cu ft per sec. From visual observations it appeared that on the average the flow was symmetrical; therefore, the actual values obtained on one side of the conduit were also reflected to the other side to assist in drawing in the average curve. The actual measured values are shown by solid symbols, and the points reflected from the opposite side are open symbols.

Similar data were obtained for the 30° expansion and also for a rate of flow of 0.210 cu ft per sec in the 7.5°, 30°, and 180° expansions, and in addition for a flow of 0.082 in the 180° expansion. All these data will be used in calculating the turbulence energy and in studying its variation along the conduits.

From an examination of the data in Fig. 1 for the 7.5° expansion it is apparent that, at a distance of 100 in. beyond the start of the expansion, normal flow conditions had definitely been attained. All the data indicated that the $\overline{u^2}$-values are always larger than the $\overline{v^2}$-values. The highest $\overline{u^2}$-values and $\overline{v^2}$-values occur beyond the sudden expansion. Relative changes from section to section of $\overline{u^2}$-values and of $\overline{v^2}$-values for any expansion are not comparable; in other words, one of the turbulence components may change differently from the other. The highest values of turbulence intensity occur near the boundaries in the expansion, whereas beyond the expansion the turbulence gradually diffuses into the center of the stream. For the sudden expansion (Fig. 2), backflow near the walls is apparent. It was also observed at the end of the 30° expansion. Only a slight backflow very near the walls was visible for the 15° expansion, and none was noted for the 7.5° expansion.

Values of the discharge were computed by numerical integration of the mean velocity curves and are shown in Figs. 1 and 2. In analyzing the large amount of data it was necessary to use different people at various times, and, since considerable personal error can enter into the readings of the streak lengths from the motion-picture film, it is believed that this explains the discrepancy between the actual and calculated values of Q. In comparing values of $\overline{u^2}$ and $\overline{v^2}$ from section to section, it would be well if these values were corrected by the square of the ratio of calculated discharge to actual discharge. This will be done when the values for the turbulence energy are calculated.

Whether the values of $\overline{u^2}$ and $\overline{v^2}$ that were obtained are correct in absolute magnitude is problematical; however, in any case the relative values should be as indicated. The actual values obtained for normal flow in the straight

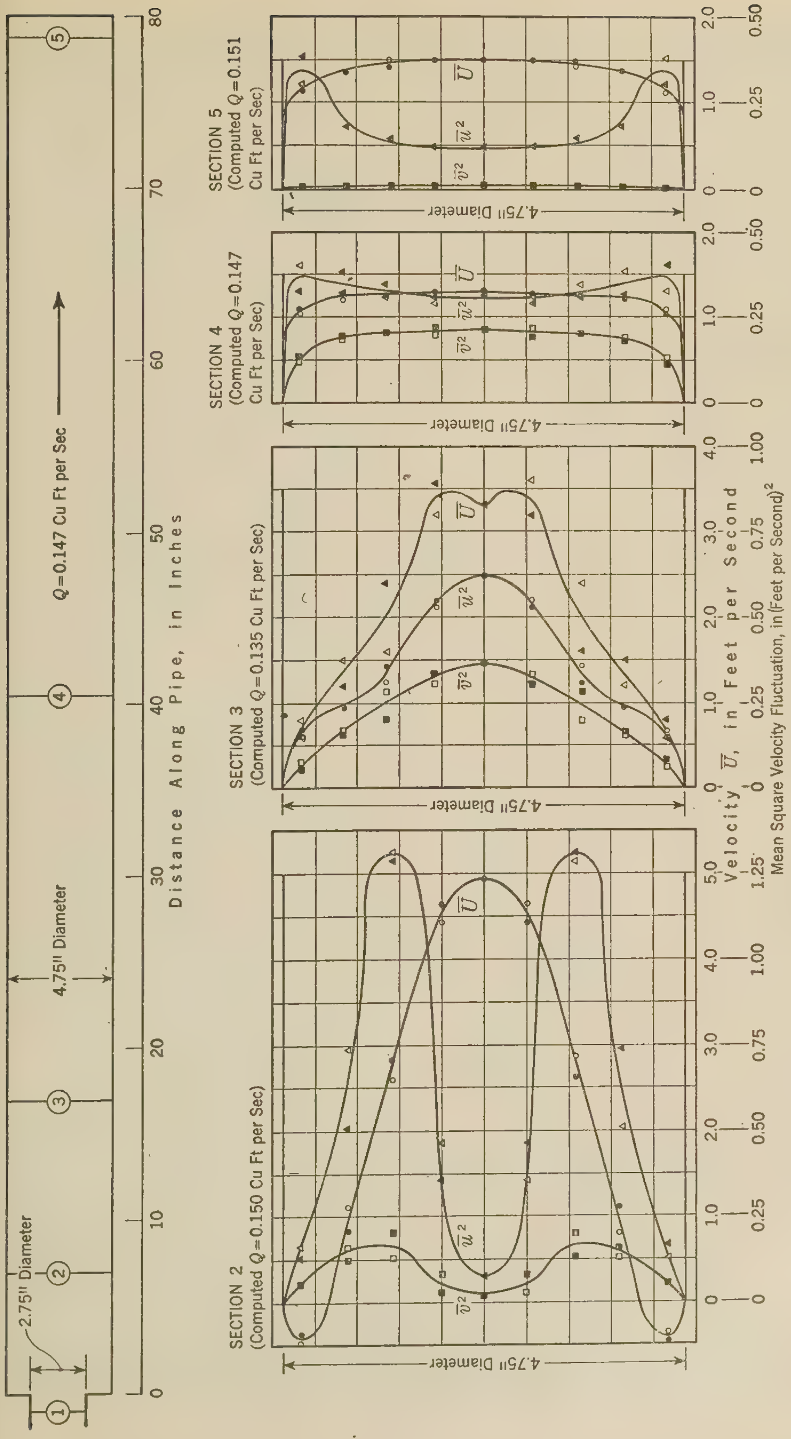


FIG. 2.—DISTRIBUTIONS OF MEAN VELOCITY AND MEAN SQUARE OF VELOCITY FLUCTUATIONS FOR 180° EXPANSION ($Q = 0.147$ CU FT PER SEC)

conduits seem to be of the order of magnitude obtained by H. C. H. Townend[12] for flow in a square pipe. Also, as the present data indicate, the value of $\overline{u^2}$ tended to be larger than that of $\overline{v^2}$ in Mr. Townend's studies. He measured the w-component and found it to be of the order of the v-component, except near the wall, where the v-component (perpendicular to the wall) tended toward zero, whereas the w-component did not.

[a] The location of the section is given as the distance in inches from the beginning of the expansion. The values given at zero distance are in the small conduit, although not necessarily just at the end of the small conduit.

Significant items to be noted from Fig. 2 are the manner in which the mean center velocity is reduced and how the turbulence gets into the center stream in the 180° expansion. In the case of the 30° expansion at a distance of 0.5 ft beyond the end of the expansion, the center velocity was reduced from a maximum of 4.7 ft to 2.5 ft per sec. Also, it was noted that at this distance the turbulence created at the boundaries of the expansion had already permeated into the center of the stream. The foregoing reduction in center velocity and permeation of the turbulence do not occur, for the 180° expansion, until a distance of 1.5 ft beyond the expansion (see Fig. 2). Evidently the turbulence created in the 30° expansion is of a larger scale and has greater diffusive power, and thereby penetrates and slows down the center portion of the stream in a shorter distance than in the 180° expansion.

In order to indicate the variation of the relative intensity of the turbulence in the conduits with the various expansions, Table 1 contains values of the ratio of maximum value of $\sqrt{\overline{u^2}}$ to the center velocity in the cross section, $\overline{U}_c$. Data shown in this table are for all the measurements made in these experiments. It is noted that the maximum value of this ratio occurs for the 30° expansion and is about 0.50 for the flow of 0.210 cu ft per sec. This ratio seems to have about the same value in the 2.75-in. pipe and in the 4.75-in. pipe, when normal flow is again developed. It seems that it took a distance of about 125 in. or about twenty-five diameters from the start of the expansions for this ratio to attain a constant value in the large pipe. For any expansion and at any given section this ratio, in general, has a smaller value for the smaller rate of flow.

---

[12] "Statistical Measurements of Turbulence in the Flow of Air Through a Pipe," by H. C. H. Townend, *Proceedings*, Royal Soc. of London, Vol. 145A, 1934, p. 180.

An examination of the typical detailed data shown in Figs. 1 and 2 and the values in Table 1 offers a fairly complete picture of the variation of the turbulence in conduit expansions.

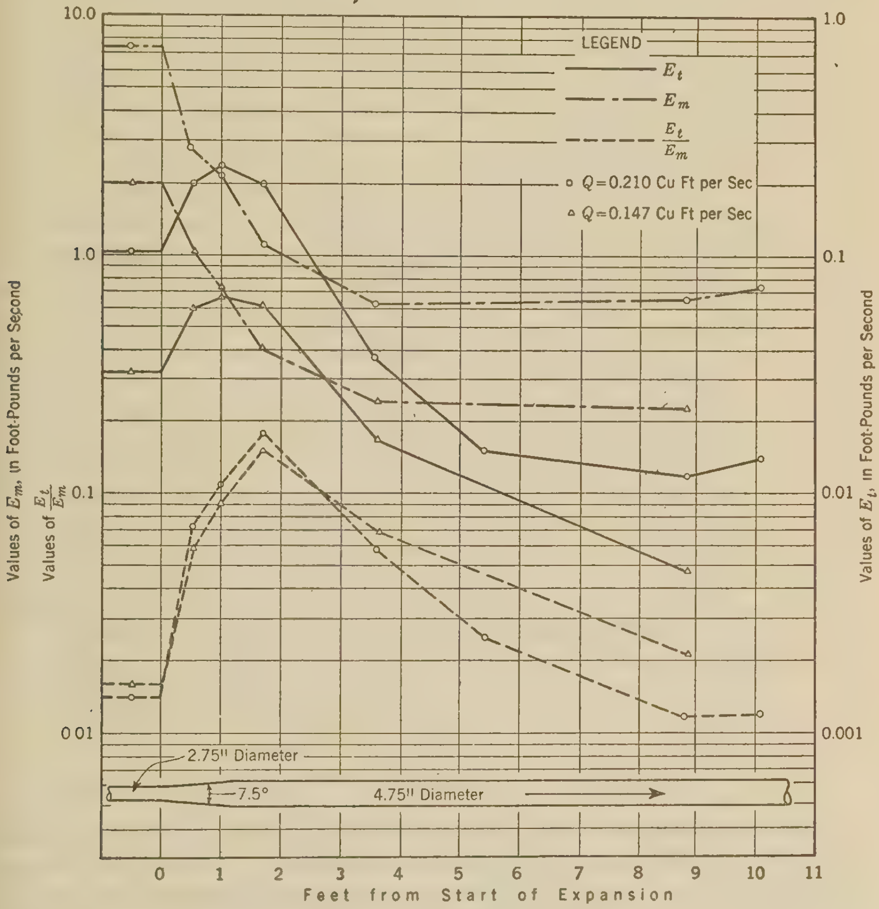

Fig. 3.—Kinetic Energy of Mean Flow and of Turbulence for 7.5° Expansion

F. Mean Kinetic Energy and Turbulence Energy

To indicate the changes occurring in the kinetic energy of the mean flow and of the turbulence energy along the conduit for the several expansions, the total value of these energies was calculated by numerical integration of data such as those shown in Figs. 1 and 2. The total kinetic energy of the mean flow in foot-pounds per second was obtained from the following expression:

$$E_m = \frac{\pi \gamma}{g} \int_0^r \overline{U}^3 \, y \, dy \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which γ is the weight of water per unit volume, r is the radius of the pipe section, and y is the distance from the center. If the distribution of the mean velocity was uniform, E_m could be expressed as $\frac{Q \gamma \overline{U}^2_m}{2g}$, in which $\overline{U}_m$ is the mean velocity in a cross section. For normal turbulent flow in a circular conduit, the values given by Eq. 4 are several per cent greater than the values obtained by using the mean velocity in the cross section. However, for velocity distribution in and immediately beyond expansions, the correct value of E_m may be several times the value obtained by using the mean velocity in the cross section. The total kinetic energy of the turbulence per pound of fluid flowing is equal to

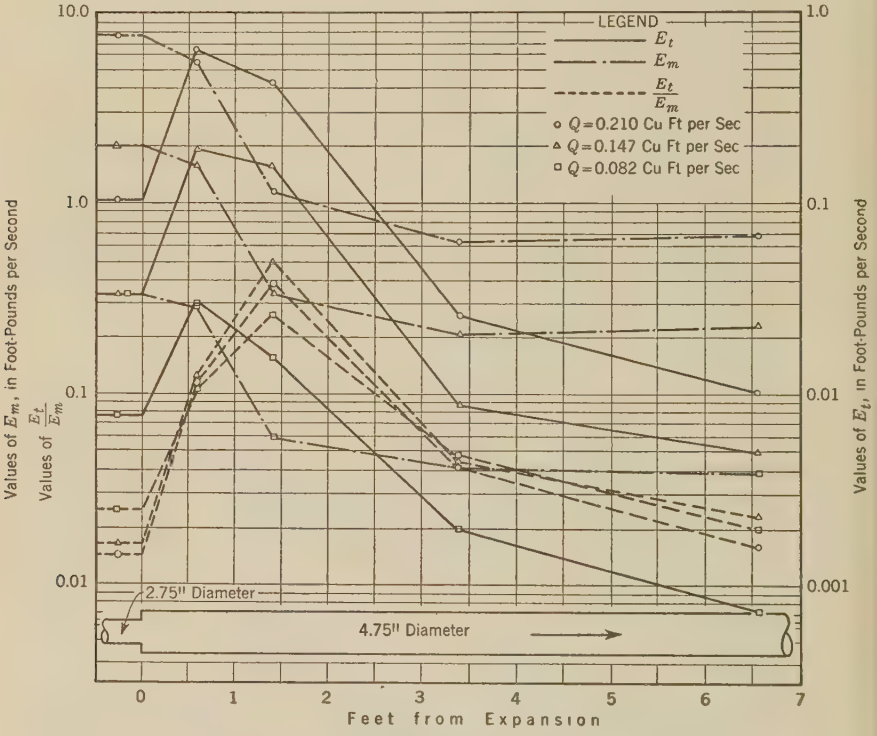

FIG. 4.—KINETIC ENERGY OF MEAN FLOW AND OF TURBULENCE FOR 180° EXPANSION

$$e_t = \frac{\overline{u^2} + \overline{v^2} + \overline{w^2}}{2g} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The total kinetic energy of the turbulence in the water flowing per unit of time past any section is then given by:

$$E_t = \frac{\pi \gamma}{g} \int_0^r \overline{U}(\overline{u^2} + \overline{v^2} + \overline{w^2})\, y\, dy \ldots\ldots\ldots\ldots\ldots (6)$$

In the present studies the value of $\overline{w^2}$ was not determined; however, in the evaluation of E_t, $\overline{w^2}$ was taken equal to $\overline{v^2}$. This appears to be a fairly good approximation except near the walls of the conduit. The values of E_t were obtained by numerical integration of data such as those shown in Figs. 1 and 2.

The ratio of calculated to actual discharge at any section was assumed to indicate the error in the streak length or in the length of velocity scale used. The calculated values of E_m or E_t were therefore corrected by the cube of this ratio. In Figs. 3 and 4 and in Table 2 are shown the values of E_m, E_t, and the ratio E_t/E_m for all the data obtained in these studies. Several pertinent items might be mentioned regarding these data: The maximum value of E_t occurs right at the end of the 7.5° expansion; for the 15° expansion it occurs slightly beyond; and, for the 30° and 180° expansions, the maximum value of E_t is about 0.60 ft beyond the expansion. The maximum value of the ratios E_t/E_m always occurs beyond the end of the expansions; the distances beyond the various expansions were 1.4 ft for 180°, 0.65 ft for 30°, and 0.50 ft for 7.5°. The turbulence energy appears to have ceased changing in the 4.75-in. conduit at a distance of 9 ft or about twenty-three diameters from the start of the 7.5° expansion. However, the change in E_m is fairly small beyond about ten diameters from the start of the expansions.

TABLE 2.—KINETIC ENERGY OF MEAN FLOW AND OF TURBULENCE

Location of section[a] (see Figs. 2 and 3)	Kinetic Energy, in Foot-Pounds Per Second		Ratio, E_t/E_m

5.35	0.622	0.031	0.050
6.75	0.570	0.013	0.023

[a] The location of the section is given as the distance, in feet, from the beginning of the expansion. Values given at zero distance are in the small conduit.

The approximate maximum values of E_t/E_m for the various expansions tested are as follows: 7.5°, 0.17; 15°, 0.28; 30° and 180°, 0.50. The values appear to be somewhat higher for the lower rates of flow. The actual values of E_t for the 30° expansion are slightly greater than those for the 180° expansion. The rate of decrease of E_t beyond the expansion is apparently most rapid for the 180° expansion, indicating that the turbulence is probably finer grained for the 180° than for the 30° expansion and thus dissipates faster. This was mentioned in Section E in connection with another item. The fact that the 30° expansion appears to have as much total turbulence energy as the 180° expansion does not necessarily mean that the head loss through it is as great. The intensity of the turbulence at a point in the fluid corresponds somewhat to the magnitude of the friction or shear stress. If this intensity is high, even if it is quite localized, the energy loss due to friction is certain to be large. It was noted that the maximum intensity of the turbulence for the 180° expansion is about 1.3 times greater than that for the 30° expansion for any given rate of flow.

[a] The location of the section is given as the distance in feet from the beginning of the expansion (see Fig. 5). The flow Q is in cubic feet per second.

The aforementioned items seem to be the principal information that can be obtained from an examination of the E_m-curves and E_t-curves. These quantitative data give some information relating to the changes in the mean kinetic and turbulence energy that take place in the flow through expanding conduits.

G. PRESSURE DATA

To complete the picture of the energy conversion process for flow through expanding conduits it is necessary to have data on the variation of the pressure. Pressures were measured for the 7.5°, 15°, 30°, and 180° expansions in the manner described in Section *D*. The pressure variation data for these expansions are shown in Fig. 5 and Table 3.

The very appreciable drop in the wall pressure at the start of the larger conduit for the sudden expansion, as shown in Fig. 5(*b*), is quite characteristic of this type of expansion. The maximum pressure is reached at distances beyond the start of the expansions which seem to increase with decrease in angle; thus, for the 7.5° expansion this distance is about 4.0 ft, for 15° it is 3.3 ft, for 30° it is 2.8 ft, and for 180° it is 2.5 ft.

In order to indicate the change in the total energy, exclusive of the turbulence energy, along the conduits, the quantity $(E_p + E_m)$ was calculated and is plotted in Fig. 6. The value of E_p was obtained by taking the values of pressure head, h, and multiplying by $62.4\,Q$. It is worth noting that the change that occurs in this total energy in the 180° expansion is much more gradual than that in the 30° expansion. In other words, as was mentioned previously, the energy conversion occurs more gradually in the sudden expansion than in the 30° expansion due to the fact that the relatively small-scale turbulence that is generated at the edges of the high-velocity stream is not so effective in "eating into" the stream and slowing it down. The diffusive power of the turbulence depends on both its intensity and scale and evidently

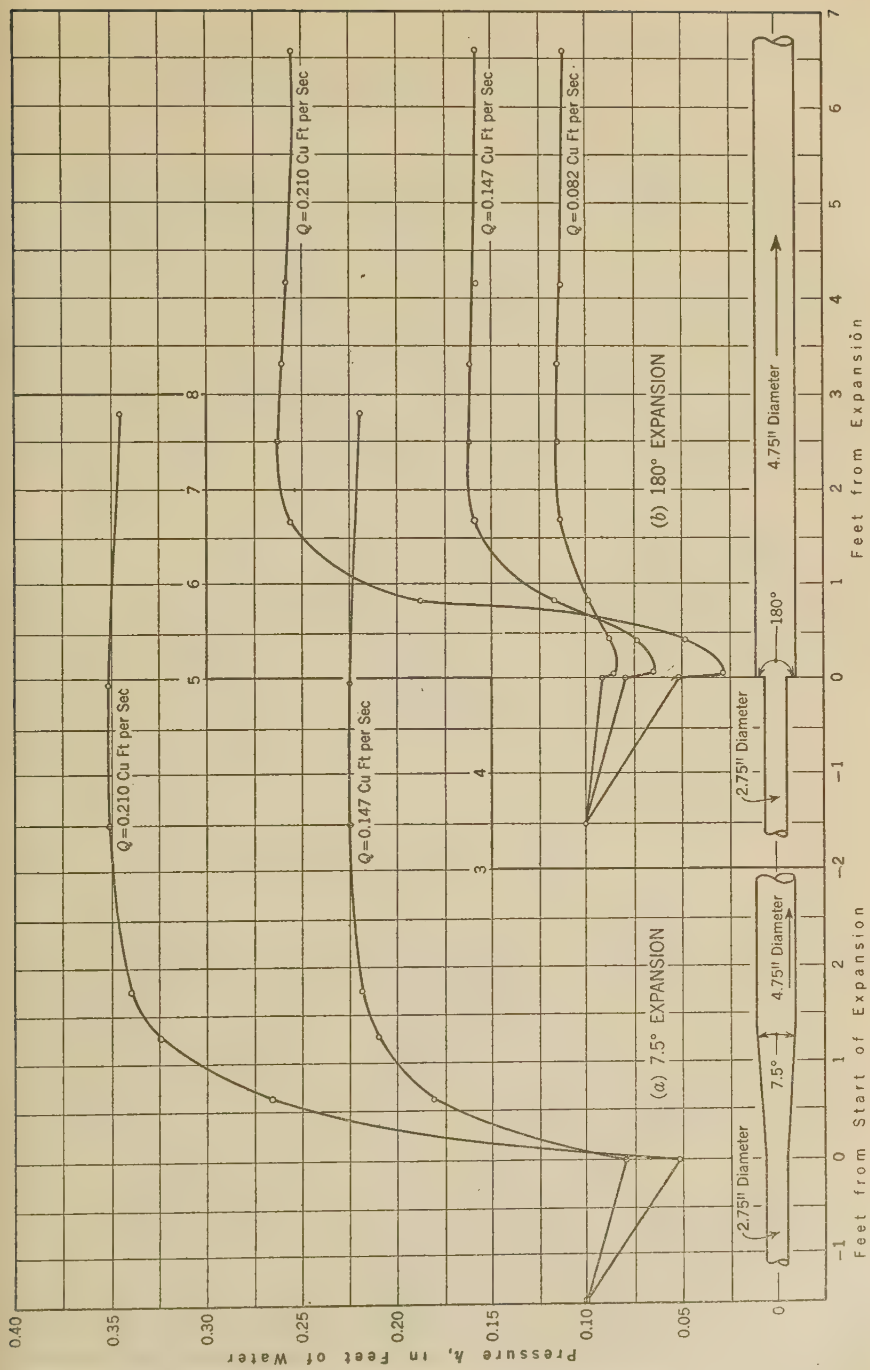

FIG. 5.—CURVES OF PRESSURE VARIATION

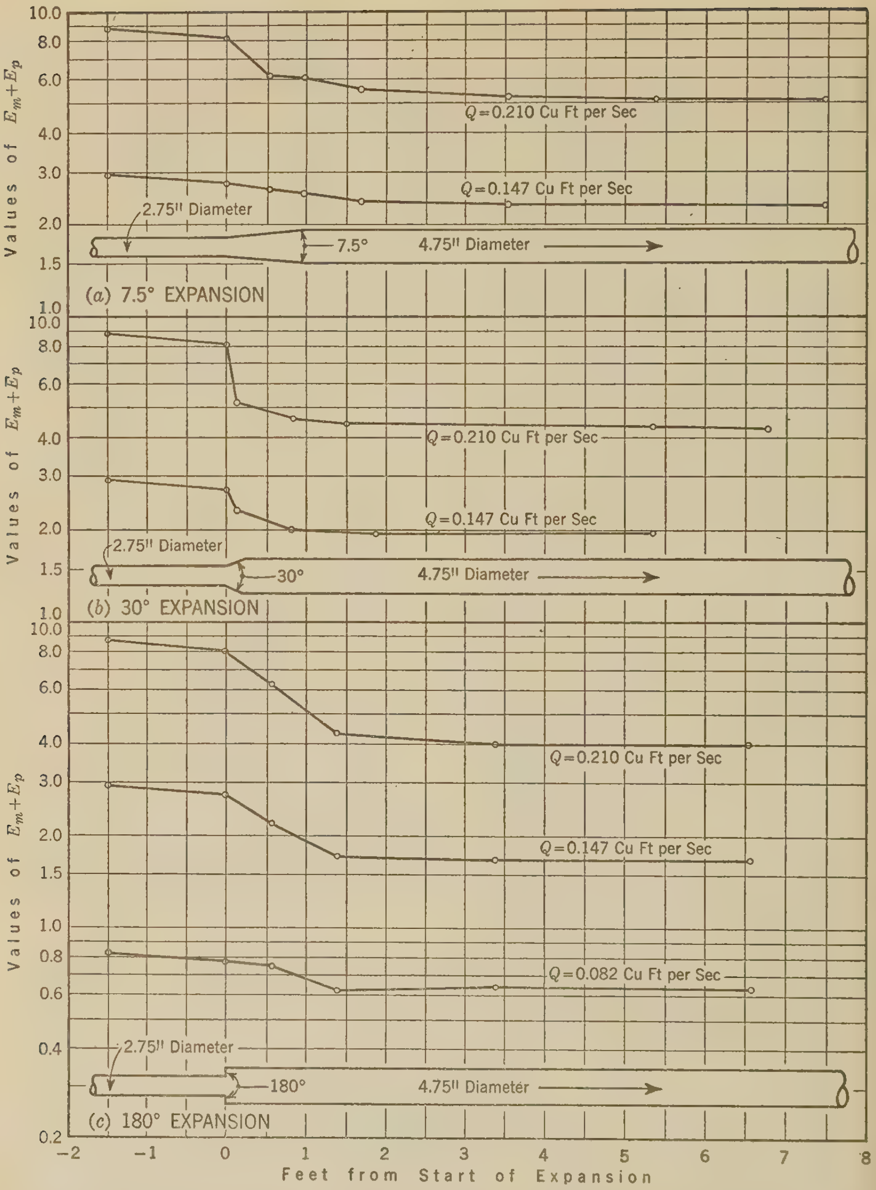

FIG. 6.—VARIATION OF KINETIC PLUS POTENTIAL ENERGY OF MEAN FLOW

the turbulence generated in the more gradual 30° expansion is of larger scale and thus gets into the main stream more quickly.

If the values of E_t are added to $(E_m + E_p)$ it will be seen that changes in the turbulence energy are minor in comparison to the changes in $(E_m + E_p)$. In other words, the total energy loss occurring is several times the maximum amount of turbulence that is generated in any of the expansions. This appears to be one of the most significant facts coming out of these studies. What, then, is the exact rôle played by the turbulence? It appears that the major portion of the kinetic energy of mean flow is lost directly due to the locally high, and quite variable, shear stresses that are set up in the fluid on the outside of the high-velocity jet. The turbulence created is a kind of by-product which, of course, uses up some of the kinetic energy of the mean flow. Although a by-product of the major energy-loss process, the turbulence, none the less, has an important influence on slowing down the high-velocity water and in shaping the velocity distribution curve.

From the values of $(E_m + E_p)$ it was possible to calculate the actual loss of energy. This was done by taking the difference between the values of $(E_m + E_p)$ at the start of the expansion and at about twenty to thirty diameters beyond the expansion and subtracting from this the normal friction in the conduit between the two points. In the conical expansions the friction loss was calculated by summing the loss for increments along the expansion. The values of the energy loss, expressed in feet of water, are shown in Table 4. Also, the efficiency of the energy conversion is given, which is expressed as:

$$\eta = \frac{(h_2 - h_1)\, Q\, \gamma}{E_{m1} - E_{m2}} \qquad \text{(7)}$$

in which $(h_2 - h_1)$ is the rise in pressure head (after correction for friction loss), and the denominator is the difference in the mean kinetic energy.

TABLE 4.—ENERGY LOSS, h, AND EFFICIENCY, η, OF VARIOUS EXPANSIONS FROM 2.75-IN. PIPE TO 4.75-IN. PIPE

Flow (cu ft per sec)	7.5° Expansion		15° Expansion		30° Expansion		180° Expansion	
	h (ft)	η (%)	h (ft)	η (%)	h (ft)	η (%)	h (ft)	η (%)
0.082	....	....	....	....	....	....	0.027	51
0.147	0.037	81	0.058	70	0.081	59	0.108	45
0.210	0.211	60	0.238	54	0.277	48	0.296	43

The energy-loss values, as given in Table 4, do not appear to vary consistently with rate of flow. Checking the loss figures given for the 180° expansion with the values obtained from the Borda formula indicates that for the higher rates of flow the figures given are appreciably larger. The reason for these apparent discrepancies is that the kinetic energy of the mean flow in the small pipe is considerably greater than that which would be obtained using the mean velocity in the cross section. For instance, for the flow of 0.210 cu ft per sec, the ratio of the actual to approximate total kinetic energy in the 2.75-in. pipe is 1.42; for the flow of 0.147 cu ft per sec, it is 1.11; and, for 0.082 cu ft per sec, it is 1.02. The variation in this ratio accounts for the fact that the loss does not vary as the square of the rate of flow. For 0.082 cu ft per sec, the loss in the sudden expansion checks that obtained from the Borda equation very well, and the reason is apparent. It is thus obvious that the energy loss in an expansion will depend on the velocity distribution at the inlet side, and this distribution must be taken into account if the actual loss is to be correctly evaluated. It is noted that the efficiency of energy conversion in the 30° expansion is not much better than in the 180° expansion.

H. CONCLUSIONS

Analysis of experimental data obtained in this investigation leads to the following conclusions relating to the energy conversion and dissipation processes in circular pipe expansions:

1. The largest energy changes occurring in the flow through any expansion are those due to the reduction in velocity and change in shape of the mean velocity distribution curve.

2. The maximum total turbulence energy is a small part of the total energy change taking place. However, at any particular section the turbulence energy may be a considerable part of the total kinetic energy. For the 30° expansion and 180° expansion, the maximum value of the ratio of turbulence energy to mean kinetic energy, E_t/E_m, rises to 0.50. For the 7.5° expansion it is only 0.17.

3. The maximum ratio between the root-mean-square value of the axial velocity fluctuation, $\overline{u^2}$, and the mean center velocity occurs in the 30° expansion, and is 0.50. The transverse velocity fluctuation is always appreciably less than the axial.

4. The loss of energy occurs more rapidly in the 30° expansion than in the sudden expansion.

5. The principal loss of energy occurs at the outside of the high-velocity stream as it passes into the expansion due to the very high shear developed. This loss is represented by a direct conversion into heat of the mean kinetic energy of the flow. The turbulence produced is but a by-product of this energy conversion process. Of course, the turbulence created also represents lost energy, since eventually it is dissipated into heat.

6. The turbulence created in the expansion plays an important rôle in helping to reduce the velocity of the center portion of the stream. Larger scale turbulence is more effective in this than in fine-grained turbulence.

7. The energy lost in an expansion and the efficiency of the conversion process are influenced considerably by the distribution of the mean velocity at the inlet to the expansion. High ratios of center velocity to the mean velocity in the cross section produce poor efficiencies and large energy losses.

I. ACKNOWLEDGMENTS

Since the experimental work reported herein extended over a period of six years, it is natural that many individuals should have contributed their efforts. This project was sponsored by the Hydraulic Research Committee of the Society, and financial aid was provided by the Engineering Foundation. The work was done in the hydraulics laboratory of the Iowa Institute of Hydraulic Research.

F. T. Mavis, M. Am. Soc. C. E., formerly head of the Department of Mechanics and Hydraulics at the University of Iowa, at Iowa City, is responsible for starting this investigation, and for his advice, suggestions, and encouragement the writer is very grateful. Graduate students who assisted at various times with the laboratory and analytical work were: E. R. Van Driest and C. L. Pien, Assoc. Members, Am. Soc. C. E., A. R. Luecker, J. M. Robertson, and Claude Lomax, Jr., Juniors, Am. Soc. C. E., and W. M. Wachter. The National Youth Administration provided a considerable number of assistants for the statistical work.

DISCUSSION

F. T. Mavis,[13] M. Am. Soc. C. E.—In a direct fashion by patient compilation and analysis of statistical data, Professor Kalinske has presented a paper which is based on a staggering number of photographs.

Whenever water decelerates in a conduit under conditions of steady flow, there is a conversion of kinetic to potential energy. This conversion is not made without loss in excess of that induced by the surface of the conduit. The losses which accompany this conversion of energy have been studied intensively and the methods of study can be classified broadly into two categories:

(1) Quantitative experiments on a particular installation or model from which over-all losses incident to the conversion can be deduced; and
(2) Mathematical analyses of general and often abstract motions of an idealized fluid.

Category (1) is the usual engineering method. It can lead to valid engineering deductions and can contribute much directly to the fundamental understanding of the mechanism of energy conversion. Both approaches to the study of the conversion of kinetic to potential energy have yielded significant contributions.

The engineering approach is usually to seek a particular solution of a problem—leaving to others the related problems of correlating, generalizing, and rationalizing the data into a general pattern. The mathematical approach usually begins with an idealized problem, leads to a general hypothesis, and leaves to others the task of applying these generalizations to particular cases. Too often these two approaches to the problem—springing from opposite sides of a chasm of unknowns—do not meet to form a well-integrated structure of theory and experiment. The investigation reported by Professor Kalinske was directed toward studying the internal mechanism of energy conversion in conduits with straight axial expansions and toward forging another link in this integrated rational structure.

The purpose of this discussion is (*a*) to classify the elementary phenomena of conversion of kinetic to potential energy in hydraulic engineering, and (*b*) to present selected bibliographic data which may suggest the course of further laboratory studies and illumine the weakness or strength of the mathematical theory.

Table 5 classifies the fundamental problems of the hydraulic conversion of kinetic to potential energy and the significant geometrical variables for each case. Common to all the problems listed are such physical variables as rate of discharge, roughness of conduit, state of motion, head loss, and velocity distribution. There are but two major classes of flow. Within the reach of the conduit under consideration the flow is either fully confined by the walls of the conduit (Table 5(*b*)), or not fully confined (Tables 5(*c*) and 5(*d*)), in which case there is a free water surface in the reach. The interplay of unbalanced forces and accelerations of liquid elements is maintained in the first case by changing pressures along fixed boundaries, and in the second case by an aperiodic pulsating free water surface or by a complex zone of air-entrained water.

---

[13] Prof. and Head, Civ. Eng. Dept., Carnegie Inst. Tech., Pittsburgh, Pa.

A conduit which fully confines the flow within a reach under consideration may induce deceleration of the liquid by reducing the velocity of flow or by changing its direction. There are four primary elements:

1. A straight axial expansion which is represented in its simplest form by the lower leg of a venturi meter, by a straight, conical draft tube, and by similar diffusers;[14]

2. An axial-to-radial expansion of which the spreading draft tube is an example;[15,16,17,18,19,20,21]

3. An elbow in which the flow can be decelerated by changing the direction of flow only, or by a combination of changes in direction and changes in average velocity. Elbows may, therefore, be subdivided further into—

   (*a*) Prismatic elbows in which the cross section and shape of the conduit remain unchanged;

   (*b*) Bisymmetrical elbows in which the cross section or shape is symmetrical with reference to two planes—one in the plane of the elbow axis and the other normal to that plane and bisecting the straight approach and outlet conduits; and

   (*c*) Expanding elbows represented by elbow draft tubes.

4. A manifold which may be represented by the filling and emptying conduit system of the more common American type of navigation locks. (In the sense that the water is discharged into a lock chamber through submerged ports during the filling stage, the manifold may also be classified as an example of a partly confined jet.[22])

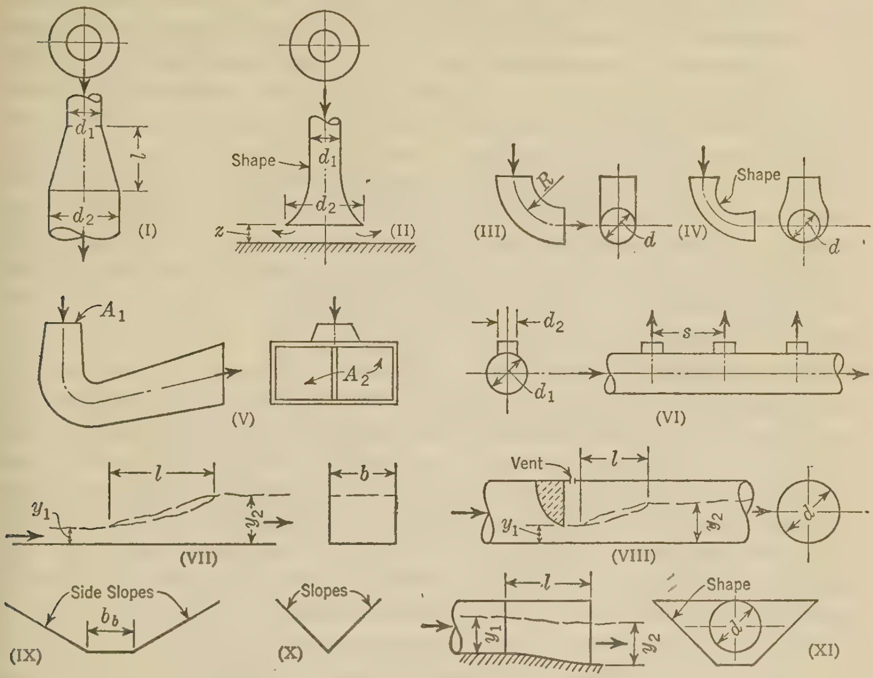
TABLE 5.—Elements of Hydraulic Conversion of Kinetic to Potential Energy



(*a*) Sketches of Pipe and Channel Sections

Element		Geometrical variables (see sketches in Table (*a*))
Description	No.	
		(*b*) Flow Fully Confined
Straight axial expansion	i	Diameters d_1 and d_2, length l, and the shape
Axial to radial expansion	ii	Diameters d_1 and d_2, the shape, clearance z, and the inserts or the vaning
Prismatic elbow	iii	Diameter d, radius r_b, and the central angle
Bisymmetrical elbow	iv	The shape and the vaning
Expanding elbow	v	Areas A_1 and A_2
Manifold	vi	Diameters d_1 and d_2, spacing s, and the shape of the passages
		(*c*) Flow Not Fully Confined; Supercritical Initial Velocity, V_o
Hydraulic Jump—		
Rectangular conduits	vii	Depths y_1 and y_2, breadth b, and length l
Circular conduits	viii	Diameter d and the venting
Trapezoidal conduits	ix	Bottom width b_b and the side slopes
Triangular conduits	x	Side slopes (special case of sketch ix)
Jets	....	(Surface, plunging, and partly confined)
		(*d*) Flow Not Fully Confined; Subcritical Initial Velocity, V_o
Transitions	xi	Depths y_1 and y_2, diameter d, length l, and the shape

Decelerating flow in a conduit with a free surface (flow not fully confined by the walls of the conduit) has two major subdivisions:[23,24,25,26,27]

I. If the velocity in a reach is supercritical (velocity head greater than half the hydraulic mean depth), the water either passes through an hydraulic jump, or continues in some form of jet. The hydraulic jump has been studied intensively in rectangular conduits, circular conduits, trapezoidal conduits, and conduits of other sections. Surface waves and plunging jets have been studied in open channel flow and submerged weirs chiefly.

II. If the approach velocity in an expanding conduit is subcritical (velocity head less than half the hydraulic mean depth), the hydraulic problem of the transition becomes primarily a matter of backwater curves. This topic has received extensive experimental and mathematical study. Practical problems in this category can be handled quite satisfactorily by combinations of laboratory study and conduit analysis.

Essentials in the study of energy conversion in flowing water are Newton's laws of motion, a complete physical concept or hypothesis, exact definitions of terms, rational induction and deduction, and objective comparisons and experiments. The engineer has usually approached the study with the objective of determining over-all losses of energy rather than with the purpose of studying the internal mechanism of energy conversion. Many guide posts to engineering judgment have been established on the basis of so-called one-dimensional solutions of problems in hydraulics. Five illustrations of "one-dimensional" approaches to problems involving conversion of kinetic to potential energy in flowing water are sketched in the following paragraphs:

A. Newton's second law of motion expresses the relationship between the unbalanced force acting on a particle and its corresponding acceleration. Precisely consistent relationships can be expressed between the work done on a particle and the change in its kinetic energy, or between the impulse of a force acting on a particle and the change in its linear momentum. Consistently applied, the principles of force and acceleration, work and energy, and impulse and momentum lead to identical conclusions. Evidence that this fact is sometimes misunderstood is the inference that Bernoulli's theorem (essentially work and energy) "applies" in some cases and that the momentum principle "applies" in others. When all factors are considered in any given problem, identical conclusions follow the logical application of the principle of work and energy or the principle of impulse and momentum. Students of hydraulics sometimes do not realize fully that apparent "differences" are but logical deductions which follow from differences in viewing the complete physical picture or concept.

[27] "Hydraulics of Steady Flow in Open Channels," by Sherman M. Woodward and Chesley J. Posey, John Wiley & Sons, Inc., New York, N. Y., 1941.

B. The principle of work and energy applied to the flow of a liquid in a stream tube leads directly to Bernoulli's theorem. If real water flows in a real conduit, the walls of the conduit exert a drag on the flowing liquid which opposes the motion. In mathematical derivations and algebraic manipulations, if the physical pictures are incomplete or inconsistently simple, "other factors" are sometimes introduced presumably as logical conclusions rather than as hypotheses whose validity must eventually be tested by experiments.

C. The principle of impulse and momentum applied to declerating flow of water in a level open conduit leads to an expression for depths of flow adjacent to the hydraulic jump. Simplé assumptions lead to an expression for head loss in terms of alternate or sequent depths of flow which is in substantial agreement with laboratory and field observations. Suffice it to state that, if the principle of impulse and momentum is logically applied to accelerating flows of water in a level open channel, the valid conclusion must be reached that the water surface promptly becomes level as a consequence of the basic definition of a fluid. On any horizontal plane the fluid cannot indefinitely resist shearing stresses which must be set up by unbalanced pressures parallel to the plane.

D. The principle of impulse and momentum applied to decelerating flow in a 90° expansion leads to differences in pressure above and below the expansion which depend on the assumed pressure distribution on the face of the expanding section. Reasonable assumptions of this pressure distribution lead to computed head losses which are in substantial agreement with laboratory observations.

E. The principle of impulse and momentum applied to "nonresilient impact" of two particles moving in the same direction with different initial velocities leads to an expression for head loss which is identical with the expression for head loss in a 90° expansion in a closed conduit. In the over-all analysis of head loss in a sudden expansion, nothing need be assumed as to the detailed mechanism of conversion. Particles at the boundary of the jet approaching the expansion come in contact with slower moving particles to emerge—after mixing—with reduced velocity. The term "inelastic impact," often used to designate this phenomenon, implies an inexact concept since a confined liquid is "elastic" in the sense that it has a well-defined bulk modulus of elasticity. Individual globules of an unconfined liquid are not resilient, however, in the sense that mechanical energy can be stored in an unconfined globule by virtue of its elastic deformation. Hence, the term nonresilient impact seems more descriptive. This nonresilient impact of liquid masses may be viewed as a physical basis for analyzing the conversion of kinetic to potential energy, and it may throw added light on the author's second conclusion that "The maximum total turbulence energy is a small part of the total energy change taking place."

Professor Kalinske has outlined briefly certain concepts relating to turbulence and he has referred to selected literature. The engineer will doubtless feel a void between these concepts and their application to even an elementary engineering situation. If statistical methods of studying the phenomena of turbulence and the nonrecoverable components of kinetic energy in a stream are to be applied to a given conduit, one must know the primary pattern of flow through the conduit, the intensity of turbulence at any given point in the conduit, and the scale of turbulence at the corresponding point. At present, if not inherently, these data must be obtained experimentally and at the expense of considerable refinement in laboratory techniques. If the data are obtained from model tests with the intention of translating results from one conduit to another, it follows that the two conduits must be geometrically similar, the intensity of turbulence at corresponding points in the two conduits must be identical, and the scale of the turbulence in the two conduits must be geometrically similar.

The practical significance of the statistical approach to fluid turbulence in the study of the conversion of kinetic to potential energy has not yet reached far beyond the laboratory and the computer's desk. The engineer certainly cannot look to the analyst of turbulence problems for the design of a diffuser, a draft tube, or the hydraulic system for a lock. However, if the basic theory of fluid turbulence prompts the experimenter and the engineer to look more critically into the effect of baffles and the internal similarity of flow patterns, the mathematical approaches—as yet of limited direct application—may eventually make their effects felt in more important problems of hydraulic engineering analysis and design.

The study described in this paper was initiated by the writer in 1936 at the invitation of J. C. Stevens, President, Am. Soc. C. E., chairman of the Society's Committee on Hydraulic Research, and progress reports have been abstracted periodically in *Civil Engineering*. Between 1936 and 1939 a bibliographic study was completed by Andreas Luksch, graduate assistant in hydraulics at the State University of Iowa, and selected tests were conducted by Mr. Luksch; by Edward R. Van Driest, Assoc. M. Am. Soc. C. E., and Arthur R. Luecker, Jun. Am. Soc. C. E., research assistants in mechanics and hydraulics; and by Hsi-Hou Chang, graduate student. In 1939 and subsequently the work on the project was directed by Professor Kalinske.

Credit for prior development of the photographic technique which played such a significant rôle in the studies reported by Professor Kalinske is due to Edgar E. Ambrosius, John C. Reed, and Henry F. Irving[28] who pursued a related program of basic studies in the hydraulics laboratory of the University of Illinois at Urbana which was under the direction of M. L. Enger, M. Am. Soc. C. E.

J. C. STEVENS,[29] PRESIDENT, AM. SOC. C. E.—Some of the mental confusion that has surrounded the particular problem of converting kinetic energy to potential energy in flow expansions has been dispelled by Professor Kalinske. He has shown that turbulence, heretofore looked upon as the principal source of ultimate energy loss, is merely a by-product of the direct loss (energy conversion into heat) in the zone of shear surrounding the jet.

---

[28] "Study of the Flow of Water Through a Glass Pipe," by Edgar E. Ambrosius, John C. Reed, and Henry F. Irving, preprinted papers and program, Aeronautic and Hydr. Divs., A.S.M.E., Summer Meeting, June 19, 20, and 21, 1934, George Reproduction Co., San Francisco, Calif., pp. 83-89.

[29] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

The author found that the maximum energy of turbulence was only half the maximum energy of the mean flow; and, of course, only a part of this turbulent energy is converted into heat as the intensity diminishes downstream. For example, in the 30° expansion, the total energy lost was 4.3 ft-lb per sec for 0.210 cu ft per sec (Fig. 6); and the maximum energy of turbulence was 0.781 ft-lb per sec (Table 2). Even if all this turbulence were lost (converted into heat), it would represent only 18% of the total energy similarly lost in the expansion.

The efficiency of an expansion is subject to various interpretations. The author has used the ratio of the gain in potential energy to the loss in kinetic energy (both in foot-pounds per second) as a measure of the efficiency of the expansion. This is primarily a measure of the recovery of velocity head. It seems to the writer that efficiency is something more than this. If the pipe length from the beginning of the expansion to the point where normal flow is restored in the larger pipe (say, sixteen diameters) is considered as a mechanism for converting from one state of flow to another, the efficiency becomes the ratio of the output energy to the input energy as is the case with any other device.

Curiosity caused the writer to prepare Table 6, comparing the orthodox concepts of efficiencies with those shown by the author in Table 4. The input and output energies were taken from Fig. 6. In either expansion, and by either method, the lower the flow, the higher the efficiency would be—approaching 100% for zero flow.

The tedium of analyzing so many movie-camera frames prevented the extension of the experiments to 60° expansions and 90° expansions. It would be interesting to know what rate of expansion yields the highest rate of energy loss—in other words, the maximum scale of turbulence.

TABLE 6.—Comparison of Efficiencies

Flow (cu ft per sec)	7.5° Expansion				30° Expansion				180° Expansion

Professor Kalinske used the only method so far devised, of which the writer is aware, for measuring the components of filament velocities. It is hoped some method will be devised whereby such components can be measured with less time-consuming labor. Perhaps the method evolved at Columbia University,[30] in New York, N. Y., might be extended to the measurement of filament velocities in pipes of nonmagnetic material.

Research into these fundamental concepts should not end with this paper; this study is just a good beginning. A most excellent approach to determining the nature of hydraulic friction is that presented by Boris A. Bakhmeteff, M. Am. Soc. C. E., and William Allan, Assoc. M. Am. Soc. C. E., in February, 1945.[31] The findings in the researches by Professor Kalinske and by Professors Bakhmeteff and Allan dovetail most admirably and open new vistas for the hydraulician.

As noted by the author (see heading, "Acknowledgments"), the project reported in the paper was sponsored by the Hydraulic Research Committee of the Society which, in 1938, became the Committee on Hydraulic Research of the Hydraulics Division. The Committee is convinced that little further progress may be expected in the solution of many hydraulic problems until the internal mechanics of hydraulic friction and energy conversions in flowing water are better known. In this respect the committee is justly proud of the work Professor Kalinske has done and of the results he has obtained.

BORIS A. BAKHMETEFF,[32] M. AM. SOC. C. E.—Professor Kalinske's paper marks a serious advance in the science of fluid mechanics. It reveals facts, relating to turbulence in "form resistance" patterns, wholly unknown before and which substantially further present-day knowledge in this obscure and generally uncharted realm. The most significant result is the disclosing of the quantitative inner relations between the over-all energy loss E_r, occurring in the course of expansion, and the turbulent energy E_t, apparent and measurable in the turbulent fluctuations. Although the paper deals with flow expansions only, the facts, as established, seem to be typical in all probability of other "form" or "local" resistances.

The aforesaid terms are meant to designate the concentrated losses of energy known to accompany the abrupt variations of flow geometry, such as the losses in bends, knees, valves, back of bluff bodies, etc. It is generally recognized that the generic cause conducive to "form" losses is "separation," with the highly strained and labile "discontinuity sheets" serving as seats of concentrated turbulence engendering activity. It is accepted further that the turbulent eddying composite, featured by the energy E_t, represents the final phase of a complex process by the force of which flow energy is withdrawn from the store inherent to the streaming, and is subjected to "conversion" into vortical eddying form. It has been surmised, finally, that, in the course of the cyclic deformations of the free discontinuity sheet which accompany "transition" from the laminar to the turbulent regimen, only a portion of the used up flow energy reappears in the ostensible turbulent manifestations, and that the remainder of such energy is dissipated in loco in the process of conversion, constituting what may be termed a "conversion loss."[33] However, all prior inferences regarding the possible energy balance in the turbulent process were necessarily conjectural, as no factual evidence existed to permit reliable quantitative interpretations. It is only now, in the light of Professor Kalinske's findings, that the actual situation has been ascertained reliably.

[32] Prof., Civ. Eng., Columbia Univ., New York, N. Y.

[33] "The Mechanism of Energy Loss in Fluid Friction," by Boris A. Bakhmeteff and William Allan, *Proceedings*, Am. Soc. C. E., February, 1945, pp. 143–147.

It would seem that the situation is best illustrated by expressing the different pertinent quantities in terms of the initial kinetic energy E_{m1}, at the mouth of the small conduit. In fact, since the denominator in Eq. 7 may be represented with sufficient approximation by

$$E_{m1} - E_{m2} = E_{m1}\left[1 - \left(\frac{D_1}{D_2}\right)^4\right] \dots\dots\dots\dots\dots\dots (8)$$

the over-all relative loss E_r/E_{m1} may be expressed by

$$(1 - \eta)\,[D_1 - (D_1/D_2)^4] \dots\dots\dots\dots\dots\dots\dots\dots (9)$$

—or, for the 2.75-in. to 4.75-in. expansion, by 0.89 $(1 - \eta)$. The data required for the calculations may be taken from Tables 2 and 4, as well as from Fig. 4. One also finds therein the information for establishing the ratio E_t (max)$/E_{m1}$ of the maximum measured turbulence energy to the initial E_{m1}, and with this the final ratio of E_t (max)$/E_r$. The values are assembled in Table 7.

TABLE 7.—VALUES OF ENERGY RATIOS

Flow (cu ft per sec)	30° EXPANSION			180° EXPANSION		
	$\frac{E_r}{E_{m1}}$	$\frac{E_t\text{ (max)}}{E_{m1}}$	$\frac{E_t\text{ (max)}}{E_r}$	$\frac{E_r}{E_{m1}}$	$\frac{E_t\text{ (max)}}{E_{m1}}$	$\frac{E_t\text{ (max)}}{E_r}$
0.082	....	....	....	0.425	0.090	21%
0.147	0.365	0.115	31%	0.470	0.095	19%
0.210	0.474	0.105	22%	0.506	0.082	16%

With all possible allowances for experimental uncertainties devolving (as the author states) from the colossal observational difficulties, the order of magnitude is established beyond doubt. The turbulent energy E_t at its maximum is but a small portion of the total loss E_r. No wonder the author is prompted to refer to the turbulence created as a "kind of by-product," attributing the major loss to the intense and variable local shearing stresses, set up on the outside of the high-velocity jet. The description fits the rather striking circumstances, provided the wording is not misinterpreted. The fact is, of course, that the mechanism of energy loss is an entity, a composite whole, no constituent portion of which should be considered separate and alone. Turbulence is engendered ultimately for the very reason that separation originates intensive local stresses, initially of viscous nature. In the inevitable sequence of events, these local stresses lead to vehement deformations, transforming the discontinuity sheets into eddying patterns, with the latter in turn breaking up into inordinate turbulent "swarming." In other words, the first and the last phases in this process, characterized respectively by the highly strained viscous sheets and by the ostensible turbulent fluctuations, constitute inseparable links of an organic whole. In this light, the findings of the paper, in so far as the small numerical ratios of E_t/E_r are concerned, could be qualified as having disclosed the surprisingly low efficiency of energy exchange in the turbulence producing mechanism.

In reflecting on these properties, one gains the impression that perhaps the feature of having relatively small manifestations reflect the presence of momentous processes, deeply affecting the essence of things, is rather typical of turbulence phenomena in general. For instance, consider the case of so-called established turbulence, in uniform motion in conduits. The measured turbulent energy in pipes, etc., constitutes on the average only a few per cent of the kinetic energy of the main motion. Nevertheless, the transverse mixing, concomitant to such turbulence, increases the stress structure, and with that the over-all energy loss, to many hundreds if not thousands of times the shearing forces and the losses, which would prevail if the motion at the same flow rate were to remain laminar. Again in this case, the measurable E_t is only a part of the total energy E_r withdrawn from the flow and spent on conversion.[34] In fact, the writer feels that the possible (E_t/E_r)-ratios in uniform motion, when actually measured, may prove to be even lower than the values shown in the paper for flow expansions.

In uniform motion the production of turbulence and all other features of the energy spending process unfold in equal measure in each of the successive cross sections. In other words, all the functions of the energy-loss mechanism are uniformly distributed along the length of the conduit. In the case of form resistances, on the other hand, the consecutive functions, started by separation, unfold in successive fashion over a certain distance range along the axis. Naturally one is tempted to seek, in the factual evidence presented in the paper, possible clues which would help to disclose, even if conjecturally, the physical nature of the energy-loss mechanism. Note, in this connection, that in Fig. 4, for the 180° expansion, turbulence reaches its maximum in the very first measured station at a distance of about 0.55 ft from zero. It is true that, in the case of the 30° and particularly with the 15% expansion (see Table 2), the locus of maximum E_t is shifted somewhat downstream. This could be explained, however, by the fact[35] that, in divergent cones, the separation is somewhat delayed. These facts are quite significant. Obviously, in the initial stage of separation, when the live jet first comes into contact with the "roller," friction in the discontinuity sheet is viscous, so that the shearing stresses are shaped by the Newton law $\left(\frac{\mu\, du}{dy}\right)$. Furthermore, as these viscous discontinuity sheets are highly unstable, the rolling up process to form eddying patterns is begun almost at once. In other words, the over-all distance from the beginning of separation to transition must be rather short. Beyond the transition reach, where the turbulent regimen has established itself, the high local stress may continue by force of convective transverse mixing. The pertinent question however is whether, in this post-transition stage, there is any further production of turbulence, in the sense of further investment of flow energy into vortical turbulent form; or, perhaps the conversion process, with the inherent concentrated absorption of flow energy, is confined to the short pre-transition stage. Within the latter, of course, flow energy is spent by way of viscous deformation in accordance with the generic Stokes formulation $\mu \zeta^2$, in which ζ denotes vorticity. The abrupt drop of the energy line in Fig. 6 would seem to point in the direction of the latter hypothesis. If such is the case, and if no further turbulence is engendered beyond the transition reach, then subsequent losses of flow energy would occur by reason of the transverse turbulence mixing. The dynamics of this particular loss, concomitant to "turbulent diffusion," have been discussed elsewhere.[36] In uniform flow such diffusion loss is comparatively low. The rather gentle slope of the total energy lines in Fig. 6, beyond the first abrupt drop, seems to point toward analogous conditions in the case of flow expansions.

[35] "Versuche über die Strömungsvorgänge in erweiterten und verengten Kanälen," by H. Hochschild, *Forschungsarbeiten des Vereines Deutscher Ingenieure*, Heft 114, 1912.

Another point, to which the writer would like to draw attention, is the prevailing custom of qualifying the losses in flow expansions, as losses of kinetic energy. Actually, in a closed conduit the mean velocities U_1 and U_2 in the initial and final sections are prescribed by continuity. Accordingly, except for the secondary effect of local velocity distributions, the corresponding kinetic energies of the average flow are predetermined and cannot be either increased or reduced. What is actually lost is pressure, for the eventual gain in potential energy, which theoretically should accompany the reduction in velocity, is consummated only partly, to the extent of $\eta\,(E_{m1} - E_{m2})$. One may take account of what happens by resorting to the basic Euler equation

$$\frac{dp}{ds} = -\rho \frac{d}{ds}\left(\frac{u^2}{2}\right) - F_r \qquad (10)$$

featuring the dynamic balance along a filament s. The eventual pressure increase developing from the inertial force, $-\rho\, u \frac{du}{ds}$, is reduced to the extent of the resultant friction traction F_r, forthcoming from the high local stresses. Note, in particular, that the F_r resultant is determined not by the absolute value of the local stress but by the transverse gradient of the latter; and, of course, it is typical of separation sheets to evidence highly concentrated stress changes. If and when separation (which is the source of high local shear) can be reduced by that or other means, the process of restoring pressure is correspondingly remedied. The paper indicates certain means to that effect, cited by H. Peters.[5] The writer would like to supplement the reference by drawing attention to some earlier research by K. Andres[37] and by H. Hochschild.[35] Both of these exceptionally complete and valuable monographs on flow expansion deal in detail with the physical and dynamical features of the phenomenon.

---

[36] "The Mechanism of Energy Loss in Fluid Friction," by Boris A. Bakhmeteff and William Allan, *Proceedings*, Am. Soc. C. E., February, 1945, p. 153.

[37] "Versuche über die Umsetzung von Wassergeschwindigkeit in Druck," by K. Andres, *Forschungsarbeiten des Vereines Deutscher Ingenieure*, Heft 76, 1909.

In particular, the Andres experiments reveal the extent to which pressure restoration is affected by the degree of turbulence in the oncoming streaming. Restoration is at its lowest when the initial flow is smooth and the inherent turbulence intensity small. The higher the disturbances, imposed by artificially increasing the turbulence, the smaller will be the effects of the forthcoming separation and with that the higher the rate of the gained pressure. At the time when the Andres report was written (1909), the science of fluid mechanics was in its infancy and the aforesaid results might have appeared paradoxical. At present, one sees at once the analogy with the well-known effect of a turbulent boundary layer delaying separation and thus reducing the form resistance of an immersed sphere or of a cylinder. The best remedy for counteracting pressure losses, as found by Mr. Andres, was to impose a rotary motion on the expanding jet. Through such means he raised the restoration rate to more than 90%. A similar effect is achieved, of course, by removing the reversed flow film next to the solid boundary, by artificial suction.[38]

The Hochschild experiments are especially valuable in that they offer detailed velocity and pressure distribution profiles in the diverging sections. Characteristic is the lack of symmetry in the expanding flow, and the fact that the actual expansion of the jet extends in many instances far beyond the end of the diverging tube. On the whole, the different Hochschild diagrams, featuring the energy distribution in flow expansions, complement most usefully the over-all flow pictures presented in Figs. 1 and 2.

The sole intention prompting these remarks is to possibly add toward clarifying the different topics, presented in pioneer fashion in Professor Kalinske's excellent paper. Indeed, the engineering profession is deeply indebted to the author for a contribution which raises so many new and fascinating questions to be attacked by future research.

E. R. Van Driest,[39] Assoc. M. Am. Soc. C. E.—The chief advantage of this paper is that it gives a quantitative description of the distribution of turbulence in, as well as the variation of pressure along, a fluid as it moves through an expanding conduit. Such information is of great concern to the fluid flow analyst.

The author's findings concerning the relative amounts of molecular internal energy and turbulence energy are very interesting and prompt one to calculate the rise in temperature if no turbulence energy appeared. For the high flow through the sudden expansion, a simple calculation leads to a temperature change of about 0.0004 F. The measurement of such a small change would require a most sensitive thermocouple. Although the author states that temperature changes are to be neglected during the expansion process, these changes do occur for a real fluid in spite of the incompressibility.

That turbulence is a by-product of shearing action is a fact that all fluid technicians should know. It is only through shear that instability of flow and resulting turbulence arise. The effect of turbulence on shaping the ensuing velocity distribution by diffusion is well exemplified by the change in the distribution through the transition region in flow along a flat plate.

[38] For reference to Ackeret's work on diffusers and other experiments on boundary layer control, see "Applied Hydro- and Aeromechanics," based on lectures by L. Prandtl, by O. G. Tietjens, McGraw-Hill Book Co., Inc., New York, N. Y., 1934, p. 81.

[39] Asst. Prof., Mech. Eng., Mass. Inst. Tech., Cambridge, Mass.

Although, as the author states, it was not the purpose of the paper to present further pressure-loss data, nevertheless, owing to its practical importance, it may be of interest to compare the efficiencies of the energy conversion as computed from the author's data with efficiencies determined by other experimenters. The conventional efficiency formula is

$$\eta = \frac{p_2 - p_1}{\frac{\gamma \bar{U}^2_{m_1}}{2g}\left[1 - \left(\frac{A_1}{A_2}\right)^2\right]} \qquad \text{(11a)}$$

which differs from Eq. 7 in that the velocity distribution is assumed uniform across the initial and final sections. For sudden expansions, Eq. 11*a* becomes (upon insertion of the Borda loss formula):

$$\eta = \frac{2}{1 + \frac{A_2}{A_1}} \qquad \text{(11b)}$$

From the very comprehensive paper by G. N. Patterson,[40] the writer has replotted, in Fig. 7, data obtained by H. Peters and A. H. Gibson. Calculated efficiencies are plotted in Fig. 7, using Eq. 11*a* and the author's data in Table 3 and Fig. 5. It is seen that the author's efficiency data are somewhat higher in general than would be expected from Eq. 11*b* (with which the Peters and Gibson results agree well) and somewhat lower than the test data of Messrs. Peters and Gibson at small angles of divergence.

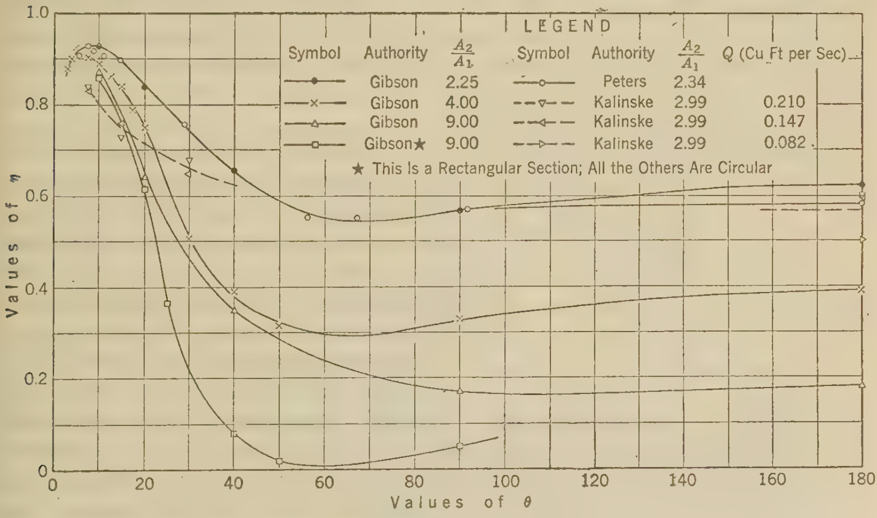

FIG. 7

---

[40] "Modern Diffuser Design," by G. N. Patterson, *Aircraft Engineering*, September, 1938, p. 267.

Dimensional analysis shows that

$$\eta = f\left(\frac{\bar{U}_{m1} D_1 \rho}{\mu}, \frac{A_2}{A_1}, \theta\right) \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

if the density ρ and the viscosity of the fluid are assumed to be effective. In Eq. 12, D_1 is the diameter of the small pipe and θ is the total angle of divergence. However, Mr. Gibson[41] stated that he found no systematic variation of his results with the Reynolds number, which was always greater than about 50,000 in his experiments. It is probably true that the variation of the author's data with discharge is also not an effect of the Reynolds number which was greater than 50,000 for the two highest discharges.

The writer is very happy to have assisted in the development of the photographic technique used in these studies and to have helped in the collection of some of the turbulence data.

A. R. THOMAS,[42] ESQ.—The need for data on the characteristics of turbulence in flow expansions has long been evident and Professor Kalinske's observations and analysis are of great interest and value.

The data presented refer to circular pipes, but the problem of designing expansions in open channels is even more complex and is of considerable importance where the channel downstream of the expansion is erodible, because a poor design often results in the creation of a return eddy which plays havoc with the side banks. The main principles are the same in open channels as in circular pipes, and, although there are added complexities due to cross-sectional shape and a free water surface, many of the conclusions drawn for the one case should be applicable to the other.

In the experiments described, the flow appears to have been symmetrical about the central axis. The existence of an adverse pressure gradient in the expansion, however, may result in instability of flow pattern, due to which the main stream moves to one side, with the formation of slack water or a return eddy on the other, as shown in Fig. 8.

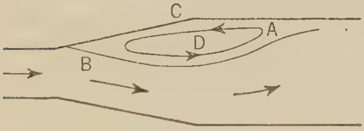

FIG. 8.

The maintenance of the return eddy depends on a balance of forces which may be expressed in a simplified form as follows:[43] Because of the conversion of kinetic energy into pressure energy, the pressure is greater at point A than at point B, creating conditions favorable to flow from points A to B. Considering the eddy as a whole, its equilibrium is maintained by the balance between the force due to this pressure gradient, acting upstream, the force due to the lateral influx of momentum from the main stream between points A and B, due to turbulence, acting downstream, and the resistance of the side wall and bed, acting against the flow. Local pressure differences are created by the curvature of flow, determined to some degree by the shape of expansion, and the shape of eddy adjusts itself to maintain the balance.

---

[41] "On the Flow of Water through Pipes and Passages Having Converging or Diverging Boundaries," by A. H. Gibson, *Proceedings*, Roy. Soc. of London, Series A, Vol. 83, 1910, p. 366.

[42] Secretary, Central Board of Irrig., Simla, India.

[43] "Flow in Expansions in Open Channels," by A. R. Thomas, *Proceedings*, Punjab Eng. Cong., Lahore, Paper No. 236, 1940, p. 179.

The influx of momentum has greatest effect on the outside of the eddy, decreasing toward the side wall. If its effect at point D, the center of the eddy, is not sufficient to outbalance the adverse pressure gradient, flow at that point will be upstream; and the width of eddy will increase, contracting the main stream, raising its velocity, and so increasing the influx of momentum until equilibrium is reached. On the other hand, if the influx more than outbalances the adverse pressure gradient at point D, flow at that point will be downstream, and the eddy will contract until equilibrium is reached. If the influx of momentum is so great that it outbalances the adverse pressure gradient even at the side wall, the eddy will disappear and the entire flow will be in the downstream direction.

This is another way of describing how the lateral transmission of momentum determines the velocity distribution, but it facilitates the drawing of certain conclusions; namely: (1) The greater (*a*) the angle of divergence, (*b*) the expansion ratio, (*c*) the depth-width ratio, or (*d*) the Froude number ($U^2/2\,g\,D$), the greater is the pressure gradient—hence the larger is the eddy; and (2) the greater the turbulence, the greater is the influx of momentum—hence the smaller is the eddy.

As conclusion (1) assumes turbulence to be independent of the variables considered (which, as shown in the paper, is not generally true) it may have limitations. Conclusion (2) explains why measures taken to increase turbulence (such as a cross grid, or blocks on the bed) improve the flow. The effect of such measures is increased by the loss of head caused, which reduces the pressure gradient. It also explains why, turbulence being subject to scale effect, models of flow expansions do not accurately represent larger prototypes.

It is also clear that, in addition to the angle of divergence, the expansion ratio, depth : width ratio, Froude number, and intensity of turbulence determine the behavior of expanding flow, so that results obtained with a given angle of divergence cannot be applied indiscriminately to other cases.

These conclusions, however, are only qualitative and do not give much assistance in practical design. For example, they do not indicate the maximum permissible angle of expansion in a given case or the most suitable side curves. A quantitative expression in terms of the discharge and channel dimensions can be derived for pressure gradient, modified by loss of head based on empirical data, but it has not so far been possible to derive an expression for the lateral transfer of momentum due to turbulence in expanding flow. It is here that experimental and analytical work, such as is presented by Professor Kalinske, will be of value, and it is hoped that he will be able to extend his researches to other cases.

A. A. KALINSKE,[44] ASSOC. M. AM. SOC. C. E.—The data presented in this paper were given in considerably abbreviated form because of space requirements; and, therefore, careful study of the paper is necessary in order that the reader may obtain a proper picture of the variations in turbulence, mean velocity, pressure, and energy for the different expansions. Complete graphical representation of all the data would have been desirable. Most of the discussers were acquainted with the general nature of the investigation, and the results obtained, through personal correspondence and contacts and progress reports. Doubtless, the practical hydraulic engineer concerned solely with over-all pressure losses in conduits may not have appreciated completely some of the basic facts uncovered in this study.

---

[44] Director of Fluid Mechanics, Appliance Corp. of America, Milwaukee, Wis.

The author would like to reemphasize what he considers the most important fact revealed by this study. Professor Bakhmeteff's discussion very effectively elucidates this item—namely, that, although form resistance in fluids is accompanied by the generation of considerable visual turbulence, the energy represented by this turbulence is relatively small compared to the total loss. The major portion of the energy is lost by direct conversion into heat through viscous action in the so-called "surfaces of discontinuity" where the turbulence originates. It appears that this phenomenon also occurs for flow in straight pipes and in turbulent boundary layers along straight surfaces. However, although no direct evidence is available to prove this theory definitely, it is hoped that the fundamental idea, as to how energy is converted into heat (lost) in fluid flow, may form the basis for other studies and analyses that will increase knowledge of fluid flow under turbulent conditions still further.

The paper revealed some information relating to the over-all efficiency of the energy conversion process in conical expansions. Messrs. Bakhmeteff, Stevens, and Van Driest commented on this particular item. The significant fact seems to be that the shape of the mean velocity distribution across the section of the entrance to the expansion has considerable influence on the efficiency of the energy conversion process, and must be taken into account in any efficiency calculations. Since roughness of the approaching conduit influences the velocity distribution, it appears that this is another variable that must be added to those given in Eq. 12. The author does not agree with Mr. Stevens that the efficiency of an expansion is subject to various interpretations. The efficiency must be calculated on the basis of what proportion of the initial kinetic energy is converted into pressure. The ratio of total "output energy" to "input energy" would depend on the total pressure on the system which, of course, does not control the flow phenomena in the expansion, unless cavitation conditions are approached.

Professor Mavis has outlined very completely the many hydraulic problems which concern expansion of flow. His discussion and the literature he cites form a most excellent review of practical hydraulic phenomena. In this field further knowledge relating to conversion of kinetic to potential energy would be helpful. Mr. Thomas stresses some items that must be considered if engineers are to understand flow expansion phenomena in open channels more fully. He states correctly that similarity of Froude numbers does not necessarily mean similar turbulence conditions, since the formation of eddies is not controlled by gravity forces.

The writer thanks the discussers for their comments and the additions to the subject covered by the paper. He hopes that basic research of this type will occupy a more prominent place in the activities of hydraulic research laboratories.

INTERRELATION OF CERTAIN STRUCTURAL CONCEPTS

By Camillo Weiss,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Ralph W. Stewart, R. C. Brumfield, Max W. Strauss, Leon Beskin, Alexander Dodge, William C. Spiker, T. F. Hickerson, Dean F. Peterson, Jr., A. A. Eremin, and Camillo Weiss.

Synopsis

A study in restraint as it affects engineering structures is presented in this paper. Physical interpretation is given to such structural terms as "fixed point," "carry-over factor," and "degree of restraint," and their mutual relations are established.

Introduction

The analysis of stresses and bending moments in any indeterminate structure is dependent upon the sections of the members comprising this structure. Because of the rapid increase in the number and variety of structures involving indeterminate frames there has been a correspondingly rapid increase in the methods for the computation of the stresses and moments in such frameworks.

The method of moment distribution introduced by Hardy Cross,[2] M. Am. Soc. C. E., offers a relatively rapid and precise means of computation and, in the writer's opinion, is as good a method as can be devised. It permits the analysis of a framework from a unique point of view. Whereas the method of least work is based on the concepts of work and energy; the slope-deflection method on relations governing deformations comprising the geometry of flexure; the Cross method may be considered as based on a complex of concepts that can be summed up under the term "restraint."

Work and deformation imply the action of a force. Restraint, however, is entirely a function of the structure itself. In this study an attempt has been made to correlate some of the component parts that characterize restraint. It is a purely academic study and no new methods are proposed.

Note.—Published in January, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Designer, Bethlehem Steel Co., Fabricated Steel Constr., Eng. Dept., Bethlehem, Pa.

[2] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

The structural concepts primarily considered are the "fixed point," the "carry-over factor," and the "degree of restraint." "Fixed points" have been defined as points of zero bending moment, or fixed points of contraflexure, for unloaded spans.[3] Usually such points are thought of in connection with beams continuous over three or more supports; but two such "fixed points" exist in every member of any frame. They are called "fixed" because their position on the elastic curve is stationary. In this study the shorter term "node" has been used to designate these characteristic points.

For the purpose of distributing fixed-end moments, Professor Cross defined the carry-over factor as the ratio of the moment induced at the fixed end to the moment applied at the rotating end of a member which is on unyielding supports at both ends. In this study the term "carry-over factor" denotes the ratio of the moment induced at the restrained, but not necessarily fixed, end to the moment applied at the other end of a member which is on unyielding supports at both ends.

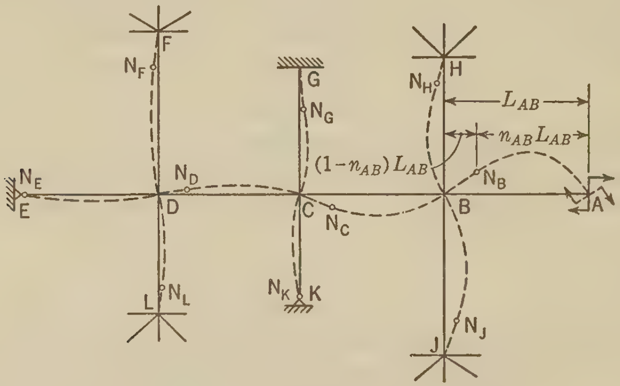

FIG. 1

"Degree of restraint" is a term which has been used loosely. A general definition of the concept is offered in this study and a law is established which states that, for m members rigidly connected to form a joint, the sum of their degrees of restraint equals $(m - 1)$. A "degree of fixation" has been defined by Thomas F. Hickerson,[4] M. Am. Soc. C. E. It is a useful concept and is a special case of this general degree of restraint. The interrelation of these three concepts is derived analytically and, to a limited extent, illustrated graphically.

NOTATION

The letter symbols used in this paper are defined where they first appear, in text or illustration, and are assembled for convenience of reference in Appendix I.

FIXED POINTS AND CARRY-OVER FACTORS

When one end of a restrained member is rotated back and forth, the wave-like elastic curves will pass through a certain node. In the special case of the beam continuous over several supports, this node is one of the "fixed points" of the given span. A similar node will occur in a member AB of any framework when one end A is rotated as illustrated in Fig. 1. Its location on the axis of the member is stationary and is a function of the stiffness of the member and of the restraint at the far end. The node (points N, Fig. 1) caused by end rotation is at the far end of the member when that end is not restrained, or at some point between the far end and the third point nearest that end, this latter position being the position for full fixity at that end. Hence the nodal intercept measured from the generating end (end A in member AB; end B in members BC, BH, and BJ, etc.) is generally more than twice the nodal intercept measured from the restrained end.

---

[3] "Continuous Bridges," by D. B. Steinman in "Movable and Long-Span Bridges," by G. A. Hool and W. S. Kinne, 1923, pp. 250–252.

[4] "Statically Indeterminate Frameworks," by Thomas F. Hickerson, Univ. of North Carolina Press, Chapel Hill, 1937, pp. 8–10.

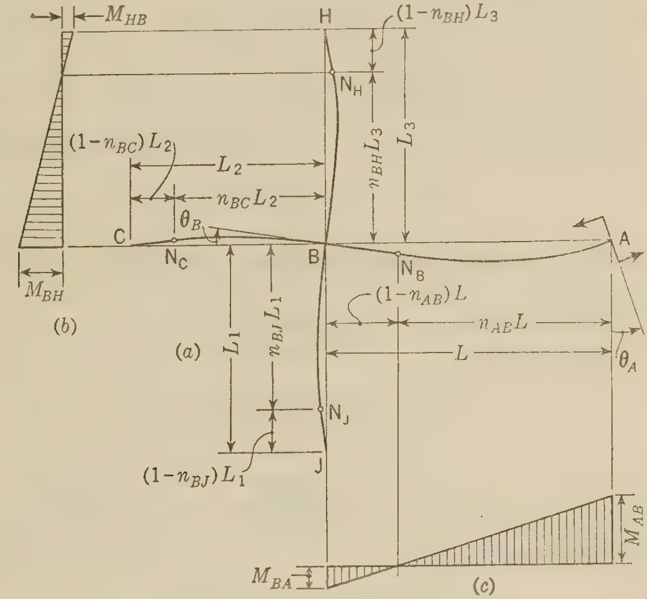

FIG. 2

The node divides each member in the ratio (n) which the generating moment bears to the induced moment. This property of the node furnishes a physical concept for a general carry-over factor f; that is, the carry-over factor is the ratio of the shorter nodal intercept to the longer nodal intercept. From end A to end B the carry-over factor is

$$f_{AB} = \frac{1 - n_{AB}}{n_{AB}} \quad \text{.........................(1)}$$

When the induced moment occurs at a fixed end, $n_{AB} = \frac{2}{3}$ and the ratio is $\frac{1}{2}$, which is defined as the carry-over factor for beams of constant cross section by Professor Cross.[2]

NODAL INTERCEPT RATIOS

The unloaded beam AB, Fig. 2(a), is restrained at point B by unloaded members BJ, BC, and BH. A moment applied at end A causes the joint to rotate through an angle θ_A. Elastic distortion of member AB induces rotations θ_B, θ_J, θ_C, and θ_H of joints B, J, C, and H, respectively, and distortion of the members meeting at those points. Assuming that no relative displacement occurs—

$$M_{BH} = 2\,E\,K_{BH}\,(2\,\theta_B + \theta_H) \qquad (2a)$$

and

$$M_{HB} = 2\,E\,K_{BH}\,(2\,\theta_H + \theta_B) \qquad (2b)$$

Dividing Eq. 2*b* by Eq. 2*a* gives the relation

$$\frac{M_{HB}}{M_{BH}} = \frac{2\,\theta_H + \theta_B}{2\,\theta_B + \theta_H} \qquad (3a)$$

Referring to Fig. 2(*b*) it follows from the similarity of triangles that

$$\frac{M_{HB}}{M_{BH}} = \frac{1 - n_{BH}}{n_{BH}} \qquad (3b)$$

By combining Eqs. 3*a* and 3*b* it is possible to express θ_H in terms of θ_B:

$$\theta_H = -\,\theta_B\,\frac{3\,n_{BH} - 2}{3\,n_{BH} - 1} \qquad (4)$$

Likewise, the slopes of the other joints adjacent to joint B can be expressed in terms of θ_B:

$$\theta_J = -\,\theta_B\,\frac{3\,n_{BJ} - 2}{3\,n_{BJ} - 1} \qquad (5a)$$

$$\theta_C = -\,\theta_B\,\frac{3\,n_{BC} - 2}{3\,n_{BC} - 1} \qquad (5b)$$

and

$$\theta_H = -\,\theta_B\,\frac{3\,n_{BH} - 2}{3\,n_{BH} - 1} \qquad (5c)$$

Similarly (compare Eqs. 3 and 4):

$$\frac{M_{BA}}{M_{AB}} = \frac{2\,\theta_B + \theta_A}{2\,\theta_A + \theta_B} = \frac{1 - n_{AB}}{n_{AB}} \qquad (6a)$$

and

$$\theta_A = -\,\theta_B\,\frac{3\,n_{AB} - 1}{3\,n_{AB} - 2} \qquad (6b)$$

The condition for static equilibrium of joint B requires that

$$M_{BJ} + M_{BC} + M_{BH} + M_{BA} = 0 \qquad (7)$$

Expressing the moments in terms of slopes similar to Eqs. 2 and utilizing Eqs. 4 and 6*b*,

$$2\,E\,K_{BJ}\,\frac{3\,n_{BJ}}{3\,n_{BJ} - 1} + 2\,E\,K_{BC}\,\frac{3\,n_{BC}}{3\,n_{BC} - 1} + 2\,E\,K_{BH}\,\frac{3\,n_{BH}}{3\,n_{BH} - 1} + 2\,E\,K_{AB}\,\frac{3\,n_{AB} - 3}{3\,n_{AB} - 2} = 0 \qquad (8)$$

Dividing by 6 E and rearranging Eq. 8,

$$\frac{1 - n_{AB}}{3\,n_{AB} - 2} = \frac{K_{BJ}}{K_{AB}} \times \frac{n_{BJ}}{3\,n_{BJ} - 1} + \frac{K_{BC}}{K_{AB}} \times \frac{n_{BC}}{3\,n_{BC} - 1} + \frac{K_{BH}}{K_{AB}} \times \frac{n_{BH}}{3\,n_{BH} - 1} + \cdots \qquad (9)$$

Eq. 9 may be considered a general equation applying to any joint of the type shown in Fig. 3. It gives the location of the node which characterizes the restraint at end B of a member AB with constant moment of inertia if the remote nodes of the restraining members are known.

Stiffness Factors and Distribution Factors

For a member with a constant ratio $K = \frac{I}{L}$, the term 4 E K is a measure of its maximum stiffness. It expresses the resistance to rotation of one end of a member if the other end is rigidly fixed. If the restraint at the far end is relaxed until it is free to turn, the resistance to rotation of the near end will diminish from 4 E K to 3 E K.

In general the resistance to rotation of the end of a member will be E times a stiffness factor or restraint factor "r." For a member with constant moment of inertia, r then varies between 3 K and 4 K.

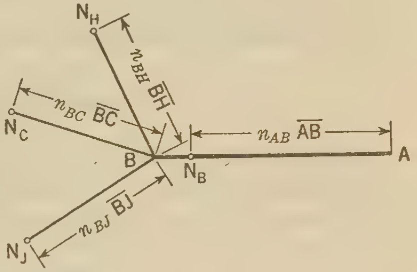

Fig. 3

Referring again to Eqs. 7 and 8 and to Figs. 2 and 3, it is evident that, provided lateral displacement of joints is prevented, each member BX which restrains end B of member AB contributes to the restraint a quantity E times r, in which the stiffness factor or restraint factor r equals

$$r_{BX} = 6\,K_{BX}\,\frac{n_{BX}}{3\,n_{BX} - 1} \qquad (10)$$

Assuming that all members are made of the same material, E is a constant. It will be omitted hereafter but should not be forgotten. Relatively, then, each member contributes to the restraint of end B of member AB a quantity:

$$r_{BJ} = \frac{6\,n_{BJ}}{3\,n_{BJ} - 1}\,K_{BJ} \qquad (11a)$$

$$r_{BC} = \frac{6\,n_{BC}}{3\,n_{BC} - 1}\,K_{BC} \qquad (11b)$$

and

$$r_{BH} = \frac{6\,n_{BH}}{3\,n_{BH} - 1}\,K_{BH} \qquad (11c)$$

The total restraint R_{BA} exerted upon end B of member AB equals the sum of the restraint factors:

$$R_{BA} = r_{BJ} + r_{BC} + r_{BH} \qquad (12)$$

The quantity

$$d_{BA} = \frac{r_{BA}}{R_{BA} + r_{BA}} \qquad (13)$$

measures the ratio in which an external moment applied at the joint B will be distributed, and has been called a "distribution factor."

Eqs. 1, 9, and 10 give the carry-over factor, the nodal intercept ratio, and the stiffness factor or restraint factor in terms of the nodal intercept ratio. Nodal intercept ratio, restraint factor, and carry-over factor can be expressed also in terms of the restraint, R, as follows: By combining Eqs. 9, 10, and 12 and solving for n_{AB}, the nodal intercept ratio is equal to

$$n_{AB} = \frac{2}{3}\frac{R_{BA} + 3\,K_{AB}}{R_{BA} + 2\,K_{AB}} \qquad (14)$$

By combining Eqs. 10 and 14, the stiffness factor or restraint factor is equal to

$$r_{AB} = 4\,K_{AB}\frac{R_{BA} + 3\,K_{AB}}{R_{BA} + 4\,K_{AB}} \qquad (15)$$

By combining Eqs. 1 and 14, the carry-over factor is equal to

$$f_{AB} = \frac{1}{2}\frac{R_{BA}}{R_{BA} + 3\,K_{AB}} \qquad (16)$$

If end B is hinged, $R_{BA} = 0$ and Eqs. 14 to 16 furnish $n_{AB} = 1$; $r_{AB} = 3\,K_{AB}$; and $f_{AB} = 0$. If end B is fixed, $R_{BA} = \infty$, and Eqs. 14 to 16 furnish $n_{AB} = \frac{2}{3}$; $r_{AB} = 4\,K_{AB}$; and $f_{AB} = \frac{1}{2}$.

Degree of Restraint

The term "degree of restraint" is generally applied very loosely. Based on the preceding discussion the degree of restraint Q_{AB} will be defined as the ratio of the restraint exerted upon the end of a member to the resistance against rotation of the entire joint:

$$Q_{AB} = \frac{R_{AB}}{R_{AB} + r_{AB}} \qquad (17a)$$

The degree of restraint can be defined also as the difference between unity and the distribution factor, because

$$Q_{AB} = \frac{R_{AB}}{R_{AB} + r_{AB}} = 1 - \frac{r_{AB}}{R_{AB} + r_{AB}} \qquad (17b)$$

It can be shown that for any rigid joint of m members the summation of their degrees of restraint as defined by Eqs. 17 must equal $(m - 1)$; that is:

$$\sum Q = m - 1 \qquad (18)$$

For instance, if four members form a rigid joint, the summation $\sum Q = 4 - 1 = 3$, and the average restraint equals 75%. If any of the four members have a degree of restraint greater than 75%, the restraint on one or more of the other three members is correspondingly reduced, and vice versa. If two members form a joint and one member restrains the other 100% (as, for instance, a member rigidly embedded in the earth), the second member exerts no restraint on the first member.

In terms of nodal intercept ratios Eq. 17*a* may be written

$$Q_{AB} = \frac{(1 - n_{BA})\,(3\,n_{AB} - 1)}{(1 - n_{BA})\,(3\,n_{AB} - 1) + n_{AB}\,(3\,n_{BA} - 2)} \quad \text{........} (19)$$

Obviously, as both n_{AB} and n_{BA} are contained in Eq. 19, the degree of restraint at one end is a function also of the degree of restraint at the other end of a member.

Degree of Fixity

"Degree of fixity" (or "degree of fixation") is another term commonly used in the study of indeterminate structures. It has been defined[4] in terms of end slopes as follows:

> Applying a rotation θ_B to end B of an unloaded member AB, the degree of fixity at end A is the difference between unity and the ratio of the slope at the restrained end A to the slope at A if the end were hinged.

From this definition the expressions for the carry-over factor, stiffness factor, nodal intercept ratio, and degree of restraint in terms of the degree of fixity are as follows:

$$f_{AB} = \frac{2\,F_{BA}}{3 + F_{BA}} \quad \text{........................} (20a)$$

$$r_{AB} = K_{AB}\,(3 + F_{BA}) \quad \text{...................} (20b)$$

$$n_{AB} = \frac{1}{3}\,\frac{3 + F_{BA}}{1 + F_{BA}} \quad \text{.....................} (20c)$$

and

$$Q_{AB} = \frac{4\,F_{AB}}{4\,F_{AB} + (1 - F_{AB})\,(3 + F_{BA})} \quad \text{............} (20d)$$

Some Mutual Relations

By definition the degree of fixity F_{BA} may vary between zero and unity. From Eq. 20*d* it can be seen that the degree of restraint, Q_{AB}, may vary, therefore, between $\dfrac{4\,F_{AB}}{3 + F_{AB}}$ and F_{AB}. In other words, $Q'_{AB} = F_{AB}$ when $F_{BA} = 1$. In terms of the nodal intercept ratio this means that $Q'_{AB} = F_{AB}$ when $n_{AB} = \frac{2}{3}$ (see Eq. 20*c*) and, from Eq. 19, it follows that

$$Q'_{AB} = F_{AB} = \frac{3 - 3\,n_{BA}}{3\,n_{BA} - 1} \quad \text{..................} (21)$$

It is further interesting to note that, if end B is hinged and $n_{AB} = 1$, Eq. 19 reduces to

$$Q''_{BA} = \frac{2\,(1 - n_{BA})}{n_{BA}} \quad \text{...................} (22a)$$

Referring to Eq. 1 it is seen that

$$Q''_{AB} = 2 f_{BA} \qquad \text{(22b)}$$

This can be demonstrated also as follows: Let C_{AB} be the fixed-end moment at end A due to an external moment M_B at end B. Then $C_{AB} = \frac{1}{2} M_B$. The end moment at end A is $M_{AB} = Q_{AB} C_{AB}$ and by definition

$$f_{BA} = \frac{M_{AB}}{M_B} = \frac{Q_{AB} C_{AB}}{2 C_{AB}} \qquad \text{(23)}$$

from which $Q_{AB} = 2 f_{BA}$.

Eqs. 21 and 22 have been plotted in the chart in Table 1, which shows graphically the restraint characteristics of the joint. If for a given member AB the nodal intercept ratio n_{BA} is determined, which is a function of the characteristics of joint A only, the following information is known:

(1) The degree of fixity at joint A, as this lies on the lower curve;

(2) The carry-over factor from joint B to A, which is one half the value of the ordinate of the upper curve; and

(3) The fact that the degree of restraint (and, therefore, the distribution factor) for end A of a member AB for any external moment at joint A is the ordinate of a point A somewhere between the two curves depending on the restraint at end B. This very narrow range demonstrates the well-known fact that (especially with increasing remoteness) adjacent restraints do not affect, materially, the distribution of an external moment at a joint.

MOMENT FLOW

An external moment (such as an unbalanced fixed-end moment) is held in equilibrium by all the members forming the joint at which it is acting and is distributed among all of these members in the ratio of their distribution factors. A moment that has been carried over to a joint by any one member is held in equilibrium by the other members of that joint and is distributed to these other members.

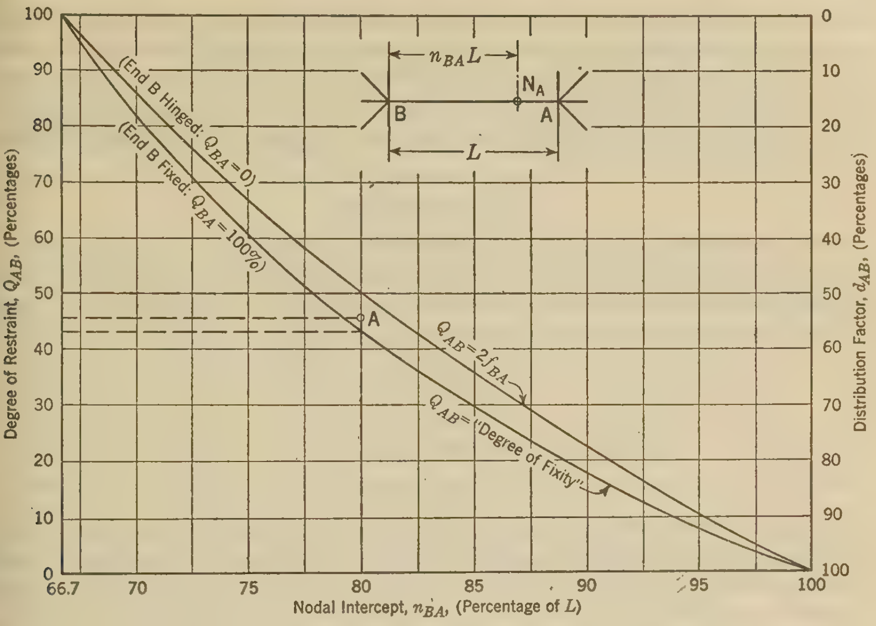
An unbalanced fixed-end moment or an external moment thus flows from joint to joint, diminishing as it spreads and leaving each joint in equilibrium. In a closed frame the result is an infinite series of waves. It is well known that convergence is so rapid, however, that for all practical purposes it is permissible to insolate a part of a frame by assigning arbitrary restraints to the marginal joints. In an open frame the necessary constants can generally be determined and the moments obtained by one distribution.

Some of the relations established in this paper are illustrated in Table 1. Attention is called to the fact that all functions are based on constant moments of inertia and on absence of joint displacements.

SUMMARY

In an attempt to generalize and correlate certain concepts used in the analysis of structures, and assuming constant cross sections, simple algebraic relations were found to exist between some of these terms which in effect reduce them to a "common denominator."

TABLE 1.—Interrelation Between the Node, Degree of Restraint, Degree of Fixity, and Carry-Over Factor



Structural concept	Symbol	Structural Concept in Terms of:		
		Degree of fixity	Restraint factors	Nodal intercept ratio
Nodal intercept ratio	n_{AB}	$\frac{1}{3}\frac{3+F_{BA}}{1+F_{BA}}$	$\frac{2}{3}\frac{R_{BA}+3K_{AB}}{R_{BA}+2K_{AB}}$	(See Eq. 9 and Fig. 3)
Distribution factor	d_{AB}	$\frac{(1-F_{AB})(3+F_{BA})}{(1-F_{AB})(3+F_{BA})+4F_{AB}}$	$\frac{r_{AB}}{R_{AB}+r_{AB}}$	$\frac{n_{AB}(3n_{BA}-2)}{n_{AB}(3n_{BA}-2)+(1-n_{BA})(3n_{AB}-1)}$
Carry-over factor	f_{AB}	$\frac{2F_{BA}}{3+F_{BA}}$	$\frac{1}{2}\frac{R_{BA}}{R_{BA}+3K_{AB}}$	$\frac{1-n_{AB}}{n_{AB}}$
Degree of restraint	Q_{AB}	$\frac{4F_{AB}}{4F_{AB}+(1-F_{AB})(3+F_{BA})}$	$\frac{R_{AB}}{R_{AB}+r_{AB}}$	$\frac{(1-n_{BA})(3n_{AB}-1)}{(1-n_{BA})(3n_{AB}-1)+n_{AB}(3n_{BA}-2)}$
Degree of fixity	F_{AB}	....	$\frac{R_{AB}}{R_{AB}+4K_{AB}}$	$\frac{3-3n_{BA}}{3n_{BA}-1}$
Restraint factor (or stiffness factor)	r_{AB}	$K_{AB}(3+F_{BA})$	$4K_{AB}\frac{R_{BA}+3K_{AB}}{R_{BA}+4K_{AB}}$	$K_{AB}\frac{6n_{AB}}{3n_{AB}-1}$

The approach to the subject matter being essentially mathematical, a problem incidental thereto, but important none the less, presents itself. It is the question of adopting some form of uniform mathematical language—algebraic letter symbols—for the expression of commonly recognizable terms. In Appendix I, the writer has attempted to conform essentially with standard lists now in process of formulation. It is acknowledged that the effort is imperfect, and that there is need for objective thought in the compilation of such a "dictionary."

In the hope that some readers may have suggestions to offer in discussion, a list of Tentative American Standard Letter Symbols for Structural Analysis, being perfected currently under the chairmanship of Albert Haertlein, M. Am. Soc. C. E., is added to the paper as Appendix II. It is not intended to open for discussion the entire field of structural symbols, but any suggestions for adapting the symbols of the present paper to the proposed standard will be a contribution to this subject.

ACKNOWLEDGMENT

This study was submitted in draft form to W. H. Jameson and J. L. Walmsley, Members, Am. Soc. C. E., and George L. Gray, Assoc. M. Am. Soc. C. E., and their helpful comments are gratefully acknowledged, as is the assistance given by Sidney Liu in preparing the copy.

APPENDIX I

NOTATION

The following letter symbols, used in this paper, conform essentially with American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials[5] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932.

Subscripts.—Capital letter subscripts are used to specify a given location on the frame. For example, M_{AB} denotes the moment at end A of a beam AB; or K_{AB} denotes the stiffness ratio I/L for the beam AB.

d = distribution factor for an unbalanced moment;
E = modulus of elasticity in tension and compression;
F = degree of fixity at the points indicated by subscripts;
f = carry-over factor = the ratio of the shorter nodal intercept to the longer nodal intercept (Eq. 1);
I = moment of inertia;
K = a constant ratio = I/L, or stiffness ratio;
L = length; total span length between joint intersections;
M = external moment;
n = ratio of the longer of two nodal intercept distances, to the length L; for brevity this ratio is called "the nodal intercept ratio";
Q = degree of restraint (see Eq. 17a);
R = summation of restraint or stiffness factors r, of all beam ends exerting a restraint on the end of a given beam (see Eq. 12);
r = restraint factor or stiffness factor at the end of a given beam (see Eq. 10);
θ = change in the slope of the tangent to the elastic curve at the end of a given beam.

[5] ASA—Z10a—1932.

APPENDIX II

Proposed American Standard Letter Symbols for Structural Analysis

In the following the general principles of Letter Symbol Standardization were formulated by a Committee of the American Standards Association, with Society representation, and have been adopted by the Association as a guide for the selection of letter symbols in all fields. The list of structural symbols is a tentative one, approaching final action by the Association.

General Principles of Standardization

1. Manuscript.—In preparing manuscripts, it is suggested that authors give careful attention to the use of symbols from this and other standard lists and to the principles here given. Symbols used should be defined clearly. When a table of symbols is not given, it is desirable to make reference to the standard lists from which the symbols are taken. The many numbers, letters, and signs which are similar in appearance should be distinguished carefully.

2. Letter Symbol.—A letter symbol is a single character, with subscript or superscript if required, used to designate a physical magnitude in mathematical equations and expressions. Two or more symbols together always represent a product.

Letter symbols are to be distinguished from abbreviations, mathematical signs and operators, graphical symbols, and chemical symbols:

(*a*) Abbreviations are shortened forms of names and expressions employed in texts and tabulations and should not be used as symbols in equations.
(*b*) Mathematical signs and operators are characters used with letter symbols to denote mathematical operations and relations.
(*c*) Graphical symbols are conventionalized diagrams and letters used on plans and drawings.
(*d*) Chemical symbols are letters and other characters designating chemical elements and groups.

3.—The same symbol should be used for the same physical magnitude regardless of the units employed and regardless of special values occurring for different states, points, parts, times, etc. Units or special values may be distinguished when necessary by subscripts, superscripts, or by upper-case and lower-case letters when both are specifically included as symbols in a standard list. The units used should be indicated when necessary. Sometimes different symbols are used for the components of a vector.

4. Subscript.—A subscript preferably should be a simple character. It is commonly employed to indicate constancy of a particular physical magnitude, such as pressure or temperature, when there are other variables. A multiple subscript, sometimes divided by a comma, refers to more than one state, point, part, time, etc. A subscript should not be attached to a subscript. Further uses of subscripts are listed in Principles 3 and 6.

5. Superscript.—A symbol with a superscript, such as a prime (′) or a second (″), should be enclosed in parentheses, braces, or brackets before affixing an exponent. A complicated exponent (or any other expression frequently repeated) may be replaced by a single symbol selected to represent it. Reference marks should not be attached to symbols. Further uses of superscripts are listed in Principles 3 and 6.

6. Conflicts.—Conflicts which would occur when different physical magnitudes are assigned the identical symbol in the same or different standard symbol lists may be resolved in one of the following ways:

(*a*) For one or more of the conflicting uses, the given symbol may be employed with subscript or superscript selected by the author.
(*b*) If one of the magnitudes has an alternate symbol in a standard list, it may be used.
(*c*) A slight change in the name of the magnitude may remove the conflict. For instance, one may use L for "length of radius" when r for "radius" conflicts with r used for another magnitude.

7. Unlisted Magnitudes.—To symbolize a special value of a listed magnitude, see Principle 3. The symbol chosen by an author for a physical magnitude not appearing in any standard list should be one that does not have already a different meaning in the field of the text.

8. Typography.—Letter symbols, letter subscripts, and letter superscripts, whether upper case or lower case, should be printed with italic type unless definitely specified otherwise. On manuscript this is indicated by underlining each symbol which is to be italicized. Special types, such as Old English and type that is currently used for vector magnitudes, should be avoided for scalar magnitudes. When special type is used for vector magnitudes, the same italic letter should be used for the corresponding scalar magnitude. Vertical Arabic numerals should be used as coefficients in equations and in subscripts and exponents. Bars, dots, and other modifying signs and operators should be used in the manner currently recognized by mathematicians.

TENTATIVE LIST OF SYMBOLS

General Letter Symbols.—

A = area;
b = breadth or width;
D = diameter;
E = modulus of elasticity (Young's modulus);
e = eccentricity;
F = force (see also P);
f = coefficient of sliding friction;
G = modulus of elasticity in shear, or rigidity;
g = acceleration of gravity;
h = height, depth, or thickness;
I = inertia, rectangular moment of (area); I_{xy} = product moment of inertia;

J = polar moment of inertia.
k = radius of gyration.
l = length.
M = moment of forces, bending moment.
P = forces or loads, concentrated (see also P).
p = pressure, normal force per unit area.
Q = moment of area, statical, or first moment.
R = modulus of rupture.
r = radius.
s = normal stress per unit area.
s_s = shear stress per unit area.
T = torque.
t = temperature.
V = volume.
W = weight, total.
w = load, or weight per unit distance.
x = coordinate distance measured parallel to an x-axis.
y = coordinate distance measured parallel to a y-axis; deflection, or ordinate to the elastic line of a beam at distance x.
Z = section modulus.
α = coefficient of linear expansion, linear.
γ = weight per unit volume.
δ = total elongation.
ϵ = unit linear deformation, normal strain.
η = efficiency.
μ = Poisson's ratio.
ρ = density; mass per unit volume, $\frac{\gamma}{g}$;
ϕ = total angular deformation.

her Symbols *Primarily for Reinforced Concrete.*—

C = total compressive force.
c = distance from the neutral axis to the extreme fiber.
d = depth from the compression face of a beam or slab to the center of the longitudinal tensile reinforcement.
f = unit stress, f_c = compressive stress in concrete and f_s = tensile stress in steel reinforcement.
j = ratio of the distance between the resultant compressive stress and the resultant tensile stress to the distance from the outer compression fiber to the resultant tensile stress in a reinforced concrete beam.
n = ratio, modulus of elasticity of steel to modulus of elasticity of concrete.
p = ratio, area of steel reinforcement to area of concrete.
T = total tensile force on the steel reinforcement.
u = unit bond stress.
v = unit shearing stress.

Letter Symbols Primarily for the Analysis of Frameworks, Arches, and Cables.—

c = distance from the neutral axis to the extreme fiber;
h = rise of an arch or sag of a cable;
K = stiffness factor = $\frac{I}{\text{span}}$;
M = moment of a force; bending moment;
m = moment at any section of a beam due to a unit load or to a unit moment applied at a given point;
R = reaction;
s = linear distance, or length measured along an arc;
u = force at any bar of a framed structure due to a unit load applied at a given point in a given direction;
V = shearing force in a beam section;
y = deformation; total displacement of a panel point of a truss or a point on the elastic line of a beam;
Z = section modulus;
γ = shear strain;
δ = total elongation;
ϵ = unit linear deformation; normal strain;
θ = angular distance in slope deflection;
ϕ = total angular deformation.

Letter Symbols Primarily for Mechanics of Solid Bodies.[6]—

a = linear acceleration;
E = energy, E_k being kinetic energy and E_p being potential energy (use T and V, respectively, when there is a conflict with E = modulus of elasticity);
f = frequency;
K = stress concentration factor;
T = kinetic energy (E_k is preferred except when there is a conflict with E = modulus of elasticity);
t = time;
V = potential energy (E_p is preferred except when there is a conflict with E = modulus of elasticity);
v = linear velocity;
W = work;
α = angular acceleration;
ω = angular velocity.

---

[6] See also American Standards Association Letter Symbols for Mechanics of Solid Bodies, ASA—Z10.3—1942.

DISCUSSION

Ralph W. Stewart,[7] M. Am. Soc. C. E.—The flexure of a continuous structure exhibits a number of interrelated phenomena both in the structure as a whole and in the individual spans. These phenomena comprise what are known as the "beam constants" and the "load constants," as well as a variety of other constants or properties that can be derived from the beam constants and the load constants. Each of the various methods for computing the bending moments in a continuous structure is contrived by selecting a limited number of these properties and using the properties chosen in a more or less regimented manner. A conversion table showing the interrelationship between the constants used in a number of systems of analysis has been presented by Fang-Yin Tsai.[8] The table covers the general case—namely, members with variable cross sections.

The final test of a structural concept is its usefulness in computing the stresses in a structure. The author's concept features nodal distances, restraint factors, and final carry-over factors. These terms may be applied to the solution of a continuous structure such as that shown in Table 2, which gives the computations for the relative moments at end E of the frame analyzed. For any moment applied at point E, 2/347 of the moment will be transmitted to end A, 3/347 of it to end G, etc. This frame was selected because a very thorough exposition of its analysis by the concept of end moment distribution is available for reference.[2] Fig. 4 shows the additional work required to determine the effect at all joints of an applied moment at point D. Restraint factors are computed as follows:

$$r_{DC} = \frac{6 \times 0.7666}{3 \times 0.7666 - 1} \times 5 = 17.7$$

and

$$r_{DE} = \frac{6 \times 1}{3 \times 1 - 1} \times 3 = 9.0$$

The moment M_{DE} equals $9/17.7 \times 115 = 58.5$; and the total fixed-end moment is $58.5 + 115 = 173.5$. Fig. 4 then indicates that 2/173.5 of a moment applied at point D is transferred to end A, etc.

The solutions of Eq. 9 to obtain the nodal intercepts for members CD and DE require an appreciable length of time. Also, the nodal distances in this structure and other continuous structures are different for each member and are different for the ends of the same member. This makes the nodal distances inferior to the moment-area constants as bases for analyzing a structure.

Fig. 5 shows a solution which uses the moment-area constants delineated in the form of an elastic curve traverse. All angles of flexure are at the one-third points of the span. They do not move in response to changes in restraint as do the nodal distances. Thus, any labor or difficulties in computing the locations of the angles are eliminated.

An angle of flexure multiplied by the stiffness of the member involved gives a moment, and a moment divided by the stiffness of the member gives the appurtenant flexure angle. By using these properties of Fig. 5 in connection with simple geometry, the arithmetical computations for Fig. 5(*a*) (which yields the same result as Table 2) can be performed in much less time than that required for the example in Table 2. This condition is also true for Fig. 5(*b*) which corresponds to Fig. 4. Fig. 5(*c*), which shows the final carry-over factor to all joints for an applied moment at point B, furnishes an automatic check of the computations for Figs. 5(*a*) and 5(*c*) by noting that Fig. 5(*a*) gives an applied moment of 347 at end E for a joint rotation of unity at point

FIG. 5

B and that the computations for Fig. 5(*c*) for a rotation of unity at end E yield a moment of 347 at point B, as required by Maxwell's theorem of reciprocal deflections. The computations for Fig. 5(*d*) require only one setting of a slide rule from which two readings are taken, followed by a moment summation about joint C. Fig. 5(*d*) gives the final carry-over factors at all joints for a moment applied at joint C. All the necessary arithmetical work is shown directly in Fig. 5. For a solution based on nodal distances the additional work represented by Table 2, and scratch-paper work not shown, are necessary.

The foregoing solutions demonstrate how the structural concepts which the author presents can be appraised as tools for practical analytical work. An extension of the study to structures having tapering members would show even greater relative adaptability for the moment-area constants.

The paper is well written and will be of value to computers who make analyses of structures based on the position of the points of contraflexure of the members.

R. C. BRUMFIELD,[9] M. AM. SOC. C. E.—In this paper Mr. Weiss has discussed primarily five terms which are applicable in connection with the solution of indeterminate structures composed of interlocking beams, the distortions of which structures are essentially due to bending moment. The five terms, with the definitions assigned to them in the paper, are given by the author as follows:

Carry-Over Factor.—See "Introduction":

> "In this study the term 'carry-over factor' denotes the ratio of the moment induced at the restrained, but not necessarily fixed, end to the moment applied at the other end of a member which is on unyielding supports at both ends."

(By unyielding supports it is obvious that the author means supports that allow no movement of translation although the beam may rotate.)

Stiffness or Restraint Factor.—See "Stiffness Factors and Distribution Factors":

> "* * * the resistance to rotation of the end of a member will be *E* times a stiffness factor or restraint factor '*r*.' For a member with constant moment of inertia, *r* then varies between 3 *K* and 4 *K*."

Distribution Factor.—See sentence containing Eq. 13:

> "[The distribution factor] measures the ratio in which an external moment applied at the joint B will be distributed [to a particular member of the joint]"

Degree of Restraint.—

> "* * * the degree of restraint Q_{AB} will be defined as the ratio of the restraint exerted upon the end of a member to the resistance against rotation of the entire joint."

---

[9] Associate Prof., Civ. Eng. Dept., Cooper Union, New York, N. Y.

Degree of Fixity.—

> "Applying a rotation θ_B to end B of an unloaded member AB, the degree of fixity at end A is the difference between unity and the ratio of the slope at the restrained end A to the slope at A if the end were hinged."

It seems clear from the context that the author has in mind the use of these terms largely in connection with the Cross method[2] of solving indeterminate structures by distribution through successive approximations. This appears to be evident from the statement in the "Introduction" and from the fact that, in deriving an expression for the distribution factor (Eq. 13), only that one is derived for an artificial moment applied to the joint externally, this being the one required in the Cross method of distribution.

The justification for such terms as those listed must lie wholly in the relative number of cases in which they are found useful, such as (*a*) the services that they may be made to render in computing the bending effects of loads applied to an indeterminate structure; (*b*) the allocation of these effects to the separate members of the structure; and (*c*) the evaluation of the distortions induced in the structure. Of these purposes the first two will ordinarily be the more important. Concepts that serve these purposes adequately and with a maximum of simplicity should be adopted and used. Those which do not meet these tests eventually will be discarded.

As a basis for deriving his various formulas, the author uses the concept of the "fixed point," or "node point" as he terms it. This concept has long been in existence and is used to express the fact that, in any beam whose bending-moment diagram consists exclusively of the effects of the bending moment introduced at one end of a span and that induced by it at the opposite end of the same span, the point of zero bending moment remains at a fixed point along the beam regardless of the size or sense of the inducing moment.

The selection of the term "node point" for this position of zero bending moment is unfortunate, particularly when taken in connection with the context of the paper in which the term "elastic curve" is used to identify this point. In vibratory motion, the most important characteristic of a node is that there is no movement of the vibrating body at the node. This is not true of the "fixed point" of a beam. In fact, there is always lateral movement at its fixed point, when the beam is only under the influence of a moment at one end and its induced moment at the opposite end. The casual reader is likely to form quite an opposite impression in the paper from the statement (see heading, "Fixed Points and Carry-Over Factors"): "* * * the wave-like elastic curves will pass through a certain node."

The idea of fixed point might well be eliminated entirely from the considerations, in connection with the five definitions listed at the beginning of this discussion. Although the author has used the concept as a basis for his derivations, it need not have been so used. Every equation in the paper could have been derived with equal or greater simplicity if the concept had not been introduced, using as a basis well-established ideas that have long existed. Judging the term, then, from the standpoint of service it seems to be superfluous.

The author uses the terms "stiffness factor" and "restraint factor" interchangeably as measures of the bending moment required to be applied to the end of a beam, resting on a free support, in order to rotate that end through a unit angle under the influence of the restraints that may exist at the opposite end of the same beam. Such a beam might be span AB, Fig. 2, the restraints that influence the beam being those at joint B.

The writer would suggest a change in this concept. Stiffness is characterized by movement or, rather, capacity to resist movement. The author measures this movement by the bending moment required to cause it. This has one virtue and one fault. It represents a stiff beam in terms of a large number and so appeals to the natural instinct that this should be so. Its fault lies in the fact that the stiffness is not measured in terms of movement, but rather, in an auxiliary fashion, in terms of the moment required to cause movement.

If the movement itself is used as a measure of stiffness, the term "stiffness factor" or preferably "stiffness index" may be defined as a measure of the angle of rotation caused at the end of a beam by the application there of a unit couple. Such a definition allows stiffness to be measured directly in terms of movement or rotation. The fact that it is now an inverse measure of the movement (that is, a large "stiffness index" represents a relatively flexible member) does not mitigate against the definition since by it a true concept is obtained of the movement of the beam end. Thus the word "index" is used instead of the word "factor" which ordinarily is thought of as a multiplier.

One should also distinguish sharply between the terms "stiffness factor" (or "stiffness index") and "restraint factor" (or "restraint index") which terms the author uses interchangeably. Stiffness is a function that is (and should be) influenced largely by the characteristics of the beam itself. Restraint, on the other hand, is something applied from without and beyond the beam, which is applied only to the beam end. In such a beam as span AB, Fig. 2, the term "stiffness index" should be applied to end A, whose rotation is influenced largely by beam AB, and the term "restraint factor" (or "index") to the far end of beam B, where rotation is influenced by the three restraining beams, BJ, BC, and BH. Thus, when a moment is transmitted from point A to point B, the rotation of end A of the beam is measured by the stiffness index, and that of the same beam at end B, by its restraint index. Such a concept leads to simple expressions for the various terms under discussion.

Referring to Fig. 2, if a unit couple is applied to span AB at end A, the angle of rotation at end A is:

$$6\,E\,\theta_A = \frac{2 - f_{AB}}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots (24)$$

From Eq. 24, one may define "stiffness factor" (or "index") by the equation:

$$i_{AB} = \frac{2 - f_{AB}}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Thus, the index is shown to be a measure of angular rotation. Without giving the derivations that lead to the conclusion, the expression for the restraint index for span AB, at B, is given by the expression:

$$R_{AB} = \frac{1}{\dfrac{1}{i_{BJ}} + \dfrac{1}{i_{BC}} + \dfrac{1}{i_{BH}}} \qquad (26a)$$

or

$$R_{AB} = \frac{i_{BJ}}{1 + \dfrac{i_{BJ}}{i_{BC}}\left(1 + \dfrac{i_{BC}}{i_{BH}}\right)} \qquad (26b)$$

The right-hand quantity of either Eq. 26*a* or Eq. 26*b* is usable, but Eq. 26*b* is preferable since it is adaptable to slide-rule use without any other mathematical work except mental additions. The usefulness of this restraint index is apparent from the fact that the bending moment arriving at joint B, from end A, divides to the three restraining members according to the following expressions:

$$M_{BJ} = M_{BA}\frac{R_{AB}}{i_{BJ}} \qquad (27a)$$

$$M_{BC} = M_{BA}\frac{R_{AB}}{i_{BC}} \qquad (27b)$$

and

$$M_{BH} = M_{BA}\frac{R_{AB}}{i_{BH}}, \qquad (27c)$$

or, in general:

$$M_n = M\frac{R}{i_n} \qquad (28)$$

It is seen that Eq. 28 has a close relationship to the distribution factor given in Eq. 13. It differs from this factor in that it gives the division, to the restraining members, of moment arriving at the joint through the transmitting member or actuating member AB, rather than the division of the moment to the members when an artificial torque is applied to the joint and all radiating members are acting as transmitting members.

From Eqs. 24 and 28 it is clear that, if the bending moment which arrives at joint B, through span AB, is unity, the angle of rotation of joint B induced thereby is

$$6\,E\,\theta_{BJ} = 1 \times \frac{R_{AB}}{i_{BJ}} \times i_{BJ} = R_{AB} \qquad (29)$$

Thus R_{AB} becomes a direct measure of the rotation of the end B of beam AB, just as i_{AB} was a direct measure of the rotation at the opposite end. The expression R_{AB} involves only the characteristics of the restraining members and thus becomes a true restraint index, whereas i_{AB} involves mostly the characteristics of the beam, restraint being only included through the expression f_{AB}. Thus "stiffness index" is a proper name for this term.

With these concepts in mind the author's expression for the carry-over factor, freed from its special application in the Cross method of analysis as explained in the paper, becomes:

$$f_{AB} = \frac{1}{2 + K_{AB}\, R_{AB}} \qquad (30)$$

which compares with Eq. 16.

In the writer's opinion the term "degree of restraint" discussed in the paper is not especially useful. In terms of the foregoing concepts and the author's definition it would be the ratio of the restraint index of member AB to the restraint index of the joint as a whole, against the artificial torque applied to it. Thus

$$Q_{AB} = \frac{\dfrac{1}{\dfrac{1}{i_{BJ}} + \dfrac{1}{i_{BC}} + \dfrac{1}{i_{BH}}}}{\dfrac{1}{\dfrac{1}{i_{BA}} + \dfrac{1}{i_{BJ}} + \dfrac{1}{i_{BC}} + \dfrac{1}{i_{BH}}}} = 1 + \frac{R_{AB}}{i_{BA}} \qquad (31)$$

The degree of fixity, using the definition of the paper, may be derived as follows, using the beam noted in the definition and assuming a unit couple applied at joint B: With the beam as restrained, Eq. 24 yields—

$$6\, E\, \theta_A = \frac{2\, f_{BA} - 1}{K} \qquad (32a)$$

With end A assumed resting on a support that permits perfect freedom of rotation—

$$6\, E\, \theta'_A = \frac{2 \times 0 - 1}{K} \qquad (32b)$$

Then:

$$F_{AB} = 1 - \left(\frac{2\, f_{BA} - 1}{K} \times \frac{K}{-1}\right) = 2\, f_{BA} \qquad (33)$$

These examples serve to show that the introduction of the idea of "restraint index" for the beam as differentiated from "stiffness index" permits the mathematical delineation, in quite simple forms, of all the concepts listed in the paper. The elimination of the idea of "fixed point" (or "node point" as it is called) in no way hinders the work, and the derivations leading to the results are, in most cases, simpler than those listed in the paper.

The author's project of codifying the nomenclature used in connection with indeterminate structures is praiseworthy. It should lead to beneficial results if properly handled. Such standardization, if well done, will be an assistance in clarifying thought and mutual understanding in the engineering profession. There is one danger to be noted, however: If too rigidly applied and if there is too great insistence upon the letter of the standard rather than the spirit, the result may be that engineering thought is put into a "strait jacket" and initiative stifled. The number of concepts involved is large when indeterminate structures are to be considered in their broadest sense. A noncoplanar frame, involving not only beams of variable section but also curved beams, is a case in point. In such a structure, the number of interrelated factors is sufficient to exhaust the letters in the ordinary alphabet as well as those in the Greek alphabet. Every one in a position to influence standardization should be patient and move cautiously until the literature on these matters is much more nearly crystallized than at present.

Max W. Strauss,[10] Jun. Am. Soc. C. E.—In the "Introduction," the author makes the statement that "The method of moment distribution introduced by Hardy Cross,[2] M. Am. Soc. C. E., * * * is as good a method as can be devised." That this is open to question is suggested by the author himself by the fact that he introduces the concept of an exact carry-over factor. This concept is not a new one. The writer has seen it traced back to Maurice Lévy who developed it about 1880.[11] Since then it has frequently been employed by others. However, beyond implying this concept, the development of the thesis of the paper seems to fall short of its logical conclusion. For instance, if Eq. 1 is substituted in Eq. 9, the latter may be rewritten:

$$f_{AB} = \frac{1}{2 + \dfrac{K_{AB}}{\dfrac{K_{BJ}}{2 - f_{BJ}} + \dfrac{K_{BC}}{2 - f_{BC}} + \dfrac{K_{BH}}{2 - f_{BH}}}} \qquad (34)$$

Thus, to determine the carry-over factor for any span toward a joint, it is only necessary to know the carry-over factors away from that joint for all other spans. Starting at a fixed or free-end support, all other carry-over factors may be determined rather easily. This is the basic principle long advocated by R. C. Brumfield, M. Am. Soc. C. E.[12]

For continuous beams, Eq. 34 reduces to:

$$f_X = \frac{1}{2 + \dfrac{K_X}{K_{X-1}}(2 - f_{X-1})} \qquad (35a)$$

which, for continuous beams of constant moment of inertia and equal spans throughout, becomes:

$$f_X = \frac{1}{4 - f_{X-1}} \qquad (35b)$$

Because of the very rapid convergence, f_X approaches f_{X-1}; and, starting at either a free or fixed support, $f_X \approx f_{X-1} \approx 2 - \sqrt{3} = 0.268$. For all practical purposes, this convergence can be assumed to take place in three or four spans. The writer's attention has been called to a short table compiled by Bertrand de Fontviolant which illustrates this effect.[13]

Moment Transmission and Distribution.—Eq. 13 is an expression for the distribution of a moment applied externally at joint B to the various spans at that joint. The terms in the right-hand side of the expression are defined by Eqs. 11 and 12. Instead of an external moment, consider a moment in span BA at joint B, arriving from joint A, which is to be distributed to the other spans at joint B. This moment will be distributed to each span in the ratio of its distribution factor to the sum of the distribution factors of the receiving members. Thus,

---

[12] "Moving Loads on Restrained Beams and Frames," by R. C. Brumfield, *Proceedings*, Am. Soc. C. E., May, 1945, p. 627.

[13] "Resistance des Matériaux," by Bertrand de Fontviolant, J. B. Bailliere & Fils, Paris, France, 1923, p. 452.

$$M_r = M_s \frac{d_r}{1 - d_s} = M_s \frac{r_r}{R_s} \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

in which the subscripts r and s indicate the receiving member and the sending member, respectively.

Referring to Fig. 3, consider member AB loaded in such a manner that the fixed-end moments are FEM_{AB} and FEM_{BA}. Then the moment in span BJ at joint B is

$$M_{BJ} = \text{FEM}_{\text{BA}}\, d_{BJ} + \text{FEM}_{\text{AB}}\, d_{AB}\, f_{AB} \frac{d_{BJ}}{d_{BJ} + d_{BC} + d_{BH}} \ldots\ldots (37)$$

Factoring out the moment split[12] for member BJ:

$$M_{BJ} = \frac{r_{BJ}}{R_{BA}} [\text{FEM}_{\text{BA}}\, (1 - d_{BA}) + \text{FEM}_{\text{AB}}\, d_{AB}\, f_{AB}] \ldots\ldots (38)$$

Comparing Eq. 38 with Eq. 36:

$$M_{BA} = \text{FEM}_{\text{BA}}\, (1 - d_{BA}) + \text{FEM}_{\text{AB}}\, d_{AB}\, f_{AB} \ldots\ldots\ldots (39a)$$

Similarly,

$$M_{AB} = \text{FEM}_{\text{AB}}\, (1 - d_{AB}) + \text{FEM}_{\text{BA}}\, d_{BA}\, f_{BA} \ldots\ldots\ldots (39b)$$

Illustrative Problem.—To illustrate the foregoing, the writer has chosen a frame (see Fig. 6) that has been solved previously by the Cross method of successive approximations.[14] The expressions for the carry-over factor and the distribution factor are given in Table 3 as are the moments at the supports due to the various loads. A usual sign convention is followed. A positive moment indicates a clockwise resisting moment acting on the span and a negative moment indicates a counterclockwise resisting moment. Thus, a moment transmitted from one end of a span to the other will not change sign; but, in passing through a joint, a moment will change sign before it is distributed to the other spans.

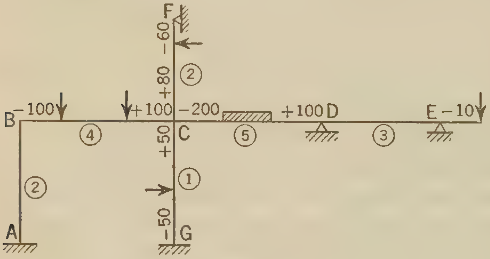

Fig. 6

The K-values are shown circled on each span in Fig. 6 and the fixed-end moments are indicated at the end of each span. Since $f_{BA} = \frac{1}{2}$, $r_{BA} = \frac{2}{1.5}$

---

[14] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Fig. 1, p. 5.

$= R_{BC}$, which results in $f_{CB} = \frac{1}{5}$ and $r_{CB} = \frac{4}{1.8}$. Similarly, $r_{CF} = \frac{2}{2}$ and $r_{CG} = \frac{1}{1.5}$, so that $R_{CD} = \frac{4}{1.8} + \frac{2}{2} + \frac{1}{1.5} = \frac{7}{1.8}$ and $f_{DC} = \frac{7}{23}$. Therefore,

$r_{DC} = \frac{115}{39} = R_{DE}$ and $f_{ED} = \frac{115}{347}$. Beginning at the other end, $f_{DE} = 0$ and $r_{DE} = \frac{3}{2.0} = R_{DE}$, so that $f_{CD} = \frac{3}{16}$. Also, $r_{CD} = \frac{80}{29}$ and $R_{CB} = r_{CD} + r_{CG}$

$+ r_{CF} = \frac{80}{29} + \frac{1}{1.5} + \frac{2}{2} = \frac{385}{87}$ and $f_{BC} = \frac{385}{1{,}118}$. Therefore, $r_{BC} = \frac{4{,}472}{1{,}851} = R_{BA}$ and $f_{AB} = \frac{4{,}472}{12{,}646}$.

The moment splits (m) are obtained by Eq. 36. At a joint such as C, they are computed separately for each member acting as a transmitting member. Thus, for example, for the moment transmitted from joint B to joint C: $m_{CG} = \frac{r_{CG}}{R_{CB}} = \frac{1}{1.5} + \frac{385}{87} = \frac{174}{1{,}155}$; $m_{CF} = \frac{r_{CF}}{R_{CB}} = \frac{2}{2} \times \frac{87}{385} = \frac{87}{385}$; and $m_{CD} = \frac{80}{29} \times \frac{287}{385} = \frac{6{,}960}{11{,}165}$.

The distribution factors are obtained by Eq. 13. For example, $d_{CD} = \frac{1}{1 + R_{CD}/r_{CD}} = \frac{1}{1 + 7/1.8 \times 29/80} = \frac{144}{347} = 0.4150$.

Actual end moments of each loaded span due to the loads in the span are obtained by Eqs. 39; thus:

$$
\begin{aligned}
M_{BC} &= -\,(100 \times 0.3556 + 100 \times -\,0.3343 \times 0.200) = -\,42.24\\
M_{CB} &= +\,(100 \times 0.6657 + 100 \times 0.6444 \times 0.3444) = +\,88.76\\
M_{GC} &= -\,(50 \times 1 + 50 \times 0.1003 \times 0.500) = -\,52.51\\
M_{CG} &= +\,(50 \times 0.8997 + 50 \times 0) = +\,44.98\\
M_{CF} &= +\,(80 \times 0.8496 + 60 \times 1 \times 0.4248) = +\,93.45\\
M_{CD} &= -\,(200 \times 0.585 + 100 \times 0.6628 \times 0.3043) = -\,137.17\\
M_{DC} &= +\,(100 \times 0.3372 + 200 \times 0.4150 \times 0.1875) = +\,49.28
\end{aligned}
$$

These moments are distributed to the frame by the calculated carry-over factors and distribution factors as shown.

Conclusions.—In view of the obvious similarity of the Cross method to the method of successive approximations and the fact that the Cross method is derived from the basic slope-deflection equations, it seems fair to question the author's assertion that the Cross method is based on a concept of "restraint" whereas the slope-deflection method is based "on relations governing deformations comprising the geometry of flexure." Actually, use of the Cross method is equivalent to solving the simultaneous slope-deflection equations by successive approximations. On the other hand, the method indicated by the author is truly based on the concept of "restraint." By recognizing that "restraint" is a function solely of the structure and is entirely independent of the loading and by proper evaluation of "restraint," a method is provided for the distribution of moments in a framework of restrained beams by a single operation.

LEON BESKIN,[15] ASSOC. M. AM. SOC. C. E.—The structural concepts reviewed by the author cover the efforts of engineers, over a period of seventy years, to simplify the analysis of frameworks. By restricting the problem to that of a framework with no joint displacement, the unknowns are limited to joint rotations and to beam-end moments. Two expressions can be written defining the relation between the moments and the rotations at the two ends of each beam of a framework. The analysis of the framework is equivalent to the solution of the system of simultaneous equations represented by these expressions. All the so-called "methods of analysis" are only various procedures for the solution of the system of simultaneous equations. This explains why there is so little fundamental difference between all existent methods, and why the coefficients introduced by one writer can be reduced so easily to those derived by another writer. Practically every stress analyst has computed such relationships at one time or another, and it is improbable that, in this paper, any new physical interpretation is given to structural terms. The relationship between fixed points, carry-over factors, and stiffness factors, known in principle since the fundamental works of O. Mohr and Maurice Lévy,[11] can be found in various forms in more recent papers.[16]

---

[15] Senior Stress Analyst, Eng. Dept., Consolidated Vultee Aircraft Corp., Nashville, Tenn.

The concept of node (fixed point) seems to have been introduced by Mr. Mohr for the special case of continuous beams. Later, it was extended to frameworks. A common practice—especially in Europe—is the analysis of frameworks by determining the locations of the fixed points.[17,18] For instance, Professor Campus has taught these methods at Liége University in Liége, Belgium, for many years. These facts challenge the remark in the "Introduction" that "Usually such points are thought of in connection with beams * * *." The author's definitions of the fixed points are misleading. It is incorrect, for example, to state (see "Introduction") that "their position on the elastic curve is stationary," and (see heading, "Fixed Points and Carry-Over Factors") that: "When one end of a restrained member is rotated back and forth, the wave-like elastic curves will pass through a certain node." The amplitude of displacement of a node is different from zero, and, characteristically, a node is a point of inflection. From the principle of superposition, this point is fixed when there is only one applied end moment.

The relation between intercept ratios is well known in the form of an expression for carry-over factors. For continuous beams it is:

$$f_{BC} = \frac{K_{BC}}{2\,(K_{BA} + K_{BC}) - f_{AB}\,K_{BC}} \dots\dots\dots\dots\dots (40a)$$

or

$$\frac{K_{BA}}{2 - f_{AD}} + \frac{K_{BC}}{2 - \dfrac{1}{f_{BC}}} = 0 \dots\dots\dots\dots\dots\dots\dots (40b)$$

The corresponding relation for frameworks is also well known.[17,18] The writer, for example, has shown[18] that a simple derivation of the formula can be established, and that the formula can be written in a symmetric form:

$$\sum_X K_{BX} \frac{1}{2 - f_{BX}} = 0 \dots\dots\dots\dots\dots\dots\dots (41a)$$

or, using the author's notation and defining all the intercept ratios from the common joint:

[17] "Analysis of the General Two-Dimensional Framework," by Yves Nubar, *Transactions*, Am. Soc. C. E., Vol. 110 (1945), p. 905.

[18] *Transactions*, Am. Soc. C. E., Vol. 110 (1945), p. 933.

$$\Sigma K_{BX} \frac{n_{BX}}{3\, n_{BX} - 1} = 0 \ldots\ldots\ldots\ldots (41b)$$

In general, the use of carry-over factors leads to simpler formulas than those written in terms of nodal intercept ratios. For instance (compare Table 1):

$$d_{AB} = \frac{2 - f_{AB}}{2 + f_{BA}\,(1 - f_{AB})} \ldots\ldots\ldots\ldots (42a)$$

$$Q_{AB} = 1 - d_{AB} \ldots\ldots\ldots\ldots (42b)$$

$$F_{AB} = \frac{3\, f_{BA}}{2 - f_{BA}} \ldots\ldots\ldots\ldots (42c)$$

$$r_{AB} = \frac{6\, K_{AB}}{2 - f_{AB}} \ldots\ldots\ldots\ldots (42d)$$

and

$$n_{AB} = \frac{1}{1 + f_{AB}} \ldots\ldots\ldots\ldots (42e)$$

In the light of these remarks, it is fair to state, contrary to the author, that the so-called "Cross method" does not permit the analysis of frameworks from a different or novel point of view. The basic relations between end moments and end rotations can be established, either by geometric considerations based on the relation between moment and curvature, or by strain energy methods. All methods have the same basis, and, although the wording is different, the mathematical process is the same. For instance, consider the formula giving the end rotation of a beam as a function of the moments in the beam:

$$\theta_{AB} = \int_A^B \frac{(L - x)\, M}{E\, I}\, dx; \ldots\ldots\ldots\ldots (43)$$

From geometric considerations, it appears that the curvature $\frac{M}{E\,I}$ produces a rotation $\frac{M\,dx}{E\,I} = d\phi$ between the two ends of an infinitesimal element dx, so that the deflection at one joint B, in reference to the tangent at the other joint A, is:

$$\delta_B = \int_A^B (L - x)\, d\phi \ldots\ldots\ldots\ldots (44)$$

If the reference line is rotated by an angle θ_{AB}, equal to the rotation at point A, the deflection at point B is equal to zero, which defines θ_{AB}:

$$\theta_{AB} = \frac{\delta_B}{L} \ldots\ldots\ldots\ldots (45a)$$

By application of strain energy methods, a dummy couple equal to 1 is placed at A, which produces moments $m = (L - x)/L$ at each point of the beam, and the rotation is:

$$\theta_{AB} = \int_A^B m\, d\phi \qquad (45b)$$

Eqs. 45*a* and 45*b* lead to the same relation (Eq. 43). In the "Introduction," Mr. Weiss states:

> "Whereas the method of least work is based on the concepts of work and energy * * * the Cross method may be considered as based on a complex of concepts that can be summed up under the term 'restraint.'"

This statement ignores the fact that Eq. 43 is the starting point for the Cross method as well as for other methods. Continuing, the author states: "Work and deformation imply the action of a force. Restraint, however, is entirely a function of the structure itself." This seems to imply that the concept of restraint can be defined without introducing into it the concept of force. Paradoxically, the author defines restraint thus (see heading, "Stiffness Factors and Distribution Factors"): "In general the resistance to rotation * * * will be E times a stiffness factor or restraint factor 'r.'" In other words, far from being exclusively a function of the structure, restraint is nothing but the ratio of an externally applied load (generally a couple) to a displacement (generally a rotation), multiplied by E.

The author's opinion (see "Introduction") that "The method of moment distribution * * * is as good a method as can be devised," accepted without question by many structural engineers, should nevertheless be challenged. The following summary is intended to clarify the comparison between various methods.

Methods of solving simultaneous equations can be divided into three main groups—succession elimination of unknowns, determinants, and successive approximations. Determinants require an excessive amount of computations when there are more than three or four unknowns, and this method is of little practical interest. The best solution by successive elimination was that presented by Karl F. Gauss, and it has been applied to the problem of continuous beams as the method of conjugate points.[11,16] The relationship between these two methods is easy to establish. To make the problem more general, beams of variable sections are considered. Numbering the supports by even numbers $2\,j$, and the spans by odd numbers $2\,j + 1$, the three-moment equation is:

$$B_{2j-1}\, M_{2j-2} + C_{2j}\, M_{2j} + B_{2j+1}\, M_{2j+2} = H_{2j} \qquad (46)$$

The quantities B, C, and H are defined by the following relations, in which x is the abscissa in each span, measured in the direction of increasing j; ζ is the ratio x/L, and m is the statical moment in each span:

$$B_{2j-1} = L_{2j-1} \int_0^1 \frac{\zeta\,(1-\zeta)\, d\zeta}{I_{2j-1}} \qquad (47a)$$

$$C_{2j} = L_{2j-1} \int_0^1 \frac{\zeta^2\, d\zeta}{I_{2j-1}} + L_{2j+1} \int_0^1 \frac{(1-\zeta)^2\, d\zeta}{I_{2j+1}} \qquad (47b)$$

and

$$H_{2j} = \int_0^1 \frac{\zeta\, m_{2j-1}\, d\zeta}{I_{2j-1}} + \int_0^1 \frac{(1-\zeta)\, m_{2j+1}\, d\zeta}{I_{2j+1}} \ldots\ldots\ldots\ldots (47c)$$

Eliminating unknowns, successively, to the moment M_{2j-4}, inclusive, Eq. 46 (written for the support $2j - 2$) is transformed into:

$$C'_{2j-2}\, M_{2j-2} + B_{2j-1}\, M_{2j} = H'_{2j-2} \ldots\ldots\ldots\ldots (48a)$$

The moment M_{2j-2} is eliminated by the linear combination of Eqs. 46 and 48*a* and leads to an equation similar to Eq. 48*a*:

$$C'_{2j}\, M_{2j} + B_{2j+1}\, M_{2j+2} = H'_{2j} \ldots\ldots\ldots\ldots (48b)$$

which shows that quantities C'_{2j} and H'_{2j} are defined by the following relations of recurrence:

$$C'_{2j} = C_{2j} - \frac{B^2_{2j-1}}{C'_{2j-2}} \ldots\ldots\ldots\ldots (48c)$$

and

$$H'_{2j} = H_{2j} - \frac{B_{2j-1}}{C'_{2j-2}}\, H'_{2j-2} \ldots\ldots\ldots\ldots (48d)$$

The first member of Eq. 48*b* defines a linear relation between M_{2j} and M_{2j+2}, which shows that the carry-over factor f_{2j+1} is:

$$f_{2j+1} = \frac{B_{2j+1}}{C'_{2j}} = \frac{B_{2j+1}}{C_{2j} - f_{2j-1}\, B_{2j-1}} \ldots\ldots\ldots\ldots (49)$$

Eq. 49 can be identified easily with Eq. 40*a*, since, in the case of beams with constant sections, the following relations hold:

$$B_{2j+1} = \frac{1}{6\, K_{2j+1}}; \ldots\ldots\ldots\ldots (50a)$$

and

$$C_{2j} = \frac{1}{3\, K_{2j-1}} + \frac{1}{3\, K_{2j+1}} \ldots\ldots\ldots\ldots (50b)$$

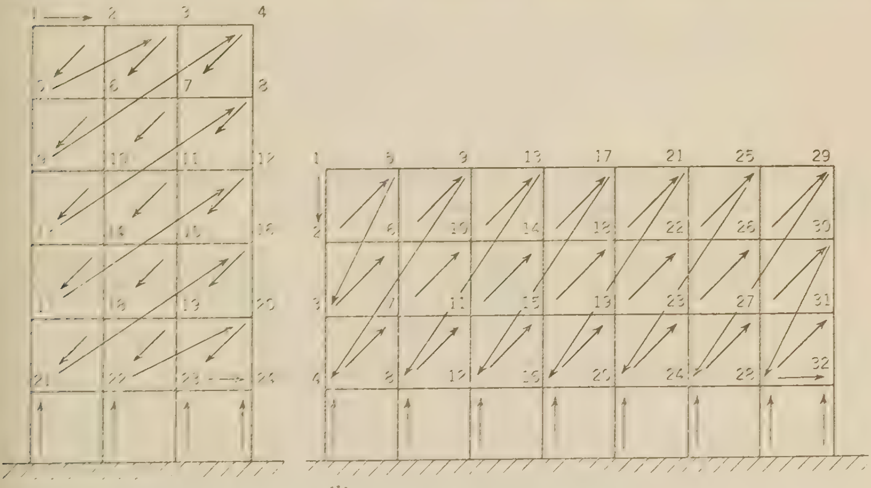
Eq. 48*b* can be written for all the spans, and the equation for the last span contains only one unknown moment, which is thus directly determined. Using Eq. 48*b* in reversed sequence, all the moments are defined, successively, by relations such as:

$$M_{2j} = -\frac{B_{2j+1}}{C'_{2j}}\, M_{2j+2} + \frac{H'_{2j}}{C'_{2j}} \ldots\ldots\ldots\ldots (51)$$

Thus, the method of successive eliminations leads to the use of Eqs. 48*c*, 48*d*, and 51, representing eight numerical operations per span, three being independent of the loading conditions (determination of the coefficients C'_{2j}).

The Cross method requires five numerical operations per span, per cycle—two distributions, two carry-over operations, and one summation. When the cycles are completed, an over-all addition, equivalent to at least one operation per cycle, is required. Thus, there are six operations per cycle, instead of a total of eight operations by the direct method. If checks are made, it can be shown that the direct method requires thirteen operations per span (additional calculation of coefficients C'' and H' from the second end of the beam), whereas the Cross method is equivalent to nine operations per span, per cycle. The preliminary operations are equivalent in both methods. For instance, the two carry-over factors in a span are $\frac{B_{2j-1}}{C_{2j-2}}$ and $\frac{B_{2j-1}}{C_{2j}}$; and the determination of the factors H is equivalent to the determination of the fixed-end moments. Thus, as two or three cycles, and very often more, are required by the Cross method, it is more expeditious, in the case of beams, to apply the direct method. In addition, three operations per span (or six operations, including checks) are independent of the loading in the direct method. Thus, for additional loading conditions, seven operations per span (including checks) are required by the direct method, whereas nine operations per span, per cycle, are required by the Cross method. In this case, the Cross method is definitely inefficient.

The direct method can be used in the case of frameworks. However, because there is no initial equation of the type of Eq. 48*a* along a closed circuit, the direct method is generally transformed into a method of successive approximations. In the initial form, complications increase with the number of parallel beams (stories) or columns (spans). For instance, for four parallel rows (spans or stories), the elimination should be made in the sequence (see Fig. 7): 1, 2, 5, 3, 6, 9, 4, 7, 10, 13, 8, 11, 14, 17, · · ·. In the case of two rows of joints, and especially when the joints are not fixed (Vierendeel beams such as high buildings with lateral load), the direct method is more advantageous



(*a*) (*b*)

FIG. 7

than methods of successive approximation, but this advantage disappears for a greater number of rows of joints. Finally, contrary to general opinion, the accuracy of the direct method does not decrease when there are many spans, because the coefficients, such as $\frac{B^2_{2j-1}}{C'_{2j-2}}$ (see Eq. 48*c*), are of the order of magnitude of one quarter of the coefficients C_{2j} so that small errors tend to disappear, instead of accumulating. This fact is precisely the cause of the rapid convergence of methods of successive approximations.

Methods of successive approximations have been developed by physicists and mathematicians, in connection with various problems in physics. The first systematic work in this field can be attributed to J. Fourier,[19] who developed his theories around 1820. However, it was not until between 1900 and 1910 that various mathematicians, principally J. Fredholm and D. Hilbert,[20] established the theory in its present form. Their work dealt mainly with equations containing an infinite number of unknowns, because physical problems generally lead to such equations. Thus, the theories are greatly simplified when applied to structural problems with a finite number of unknowns.

Methods of successive approximations can be presented as follows (see Eqs. 47). A system of linear equations can be written in the form:

$$\sum_j X_j\, a_{ij} = Y_i \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

in which X_j represents the unknowns, a_{ij} the coefficients (defined by the structure only), and Y_i the second members (defined by the structure and the loading). The matrix form of Eq. 52 is:

$$|X_j|\,|a_{ij}| = |Y_i| \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53a)$$

and the solution is:

$$|X_j| = |Y_i|\,|a'_{ij}| \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53b)$$

in which the matrix $|a'_{ij}|$ is the reciprocal of the matrix $|a_{ij}|$; thus:

$$|a'_{ij}| = \frac{1}{|a_{ij}|} = |a_{ij}|^{-1} \ldots\ldots\ldots\ldots\ldots\ldots (54a)$$

Eq. 54*a* has no significance until the numerical computation which it represents is defined. For this purpose, the matrix $|a_{ij}|$ is written as:

$$|a_{ij}| = |a_{ii}|\left|\frac{a_{ij}}{a_{ii}}\right| = |a_{ii}|\left[|E| + |b_{ij}|\right] \ldots\ldots\ldots\ldots (54b)$$

The first equality in Eq. 54*b* signifies that each column of the square matrix $|a_{ij}|$ is divided by its diagonal term a_{ii} and the resulting matrix $\left|\frac{a_{ij}}{a_{ii}}\right|$ can be multiplied by the column matrix $|a_{ii}|$ to find the matrix $|a_{ij}|$. In $\left|\frac{a_{ij}}{a_{ii}}\right|$, the diagonal terms $\frac{a_{ii}}{a_{ii}}$ are equal to unity. The second equality in Eq. 54*b* signifies that $\left|\frac{a_{ij}}{a_{ii}}\right|$ can be written in the form of a sum of the identical matrix $|E| = |e_{ij}|$ (with: $e_{ii} = 1$ and $e_{ij} = 0$), and of the matrix $|b_{ij}|$ $\Bigg($with: $b_{ii} = 0$ and

---

[19] "Théorie Analytique de la Chaleur," by J. Fourier, Didot, Paris, France, 1822.

[20] "Methoden der Mathematischen Physik," by R. Courant and D. Hilbert, Julius Springer, Berlin, 1931.

$b_{ij} = \dfrac{a_{ij}}{a_{ii}}$). It can be shown that the relation—

$$(1 + r)^{-1} = \frac{1}{1 + r} = 1 - r + r^2 - r^3 \cdots \pm r^n \cdots \ldots\ldots\ldots (55)$$

—holds for the matrix $|E| + |b_{ij}|$; thus:

$$(|E| + |b_{ij}|)^{-1} = |E| - |b_{ij}| + |b_{ij}|^2 \cdots \pm |b_{ij}|^n \cdots \ldots\ldots (56)$$

The conditions of convergence of the series in the right-hand member of Eq. 56 are satisfied in the case of equations corresponding to redundant structures. Thus, Eq. 53*b* can be written in the form:

$$|X_j| = |Y_i|\,|a_{ij}|^{-1} = \left|\frac{Y_i}{a_{ii}}\right| (|E| - |b_{ij}| \cdots \pm |b_{ij}|^n \cdots) \ldots (57)$$

Eq. 57 has a definite significance, since multiplication and addition of matrices are defined operations. This equation is the basis of the "method of relaxation" developed by R. V. Southwell,[21] of which the Cross and the Maney-Goldberg[22,23,24,25] methods are only special applications. In the case of frameworks, the latter method can be reconciled with the method of relaxation as follows:

In the Cross method, quantities that can be called "total unbalanced moments" (M_j) are the principal unknowns. These quantities are related to the fixed-end moments $M^o_{j,i}$ (moment at joint j, in beam ji), by

$$M_j + \sum_i M_i\, b_{i,j} = \sum_i M^o_{j,i} = M^o_j \ldots\ldots\ldots\ldots\ldots (58)$$

Factors $b_{i,j}$ are the products of distribution factors by carry-over factors:

$$b_{i,j} = d_{i,j} f_{i,j} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (59)$$

The final-end moments $M_{i,j}$ are defined by:

$$M_{i,j} = M^o_{i,j} - M_i\, d_{i,j} - M_j\, b_{j,i} \ldots\ldots\ldots\ldots\ldots (60)$$

The method of successive approximation can be expressed by the following relations between successive unbalanced moments:

$$M^1_j = - \sum_i b_{i,j}\, M^o_i \ldots\ldots\ldots\ldots\ldots\ldots\ldots (61a)$$

and

$$M^{n+1}_j = - \sum_i b_{i,j}\, M^n_i \ldots\ldots\ldots\ldots\ldots\ldots (61b)$$

---

so that:

$$M_j = \sum_{n=1}^{\infty} M^n{}_j \tag{62}$$

In the Cross method, Eqs. 61 are written in the following detailed form: Distribution—

$$\Delta M^{n+1}{}_{i,j} = - M^n{}_i \, d_{i,j} \tag{63a}$$

carry over—

$$\partial M^{n+1}{}_{j,i} = \Delta M^{n+1}{}_{i,j} \, f_{i,j} \tag{63b}$$

unbalance—

$$M^{n+1}{}_j = \sum_i \partial M^{n+1}{}_{j,i} \tag{63c}$$

Eq. 60 is written in the form:

$$M_{i,j} = M^o{}_{i,j} + \sum_{n=1}^{\infty} \Delta M^n{}_{i,j} + \sum_{n=1}^{\infty} \partial M^n{}_{i,j} \tag{64}$$

The method has been perfected by elimination of Eq. 63*a*, so that:

$$\partial M^{n+1}{}_{j,i} = - M^n{}_i \, b_{i,j} \tag{65}$$

whereas Eq. 64 is written as:

$$M_{i,j} = M^o{}_{i,j} - M_i \, d_{i,j} + \sum_{n=1}^{\infty} \partial M^n{}_{i,j} \tag{66}$$

The method thus developed is easily identified with Eq. 57, written as:

$$|M_j| = |M^o{}_i| \, (|E| - |b_{i,j}| + \cdots \pm |b_{i,j}|^n + \cdots) \tag{67a}$$

$$|M_j| = |M^o{}_j| - |M^o{}_i| \, |b_{i,j}| + \cdots \pm |M^o{}_i| \, |b_{i,j}|^n + \cdots \tag{67b}$$

and

$$|M_j| = |M^o{}_j| + |M^1{}_j| + \cdots + |M^n{}_j| + \cdots \tag{67c}$$

Eq. 67*c* is the result of the repeated substitution of Eq. 61*b*, written in the form—

$$|M^{n+1}{}_j| = - |M^n{}_i| \, |b_{i,j}| \tag{68}$$

—in Eq. 67*b*.

Thus, it appears that the Cross method is an application, to structural problems, of a conventional method of mathematical analysis. The slope-deflection method, developed by G. A. Maney, M. Am. Soc. C. E., and John E. Goldberg,[22,23,24,25] Assoc. M. Am. Soc. C. E., is equivalent in its initial form to the improved Cross method (elimination of Eq. 63*a*). The difference is in the choice of unknowns which are the slope deflections instead of the "total unbalanced moments." The final moments are defined by a relation similar to Eq. 60, in which $r_{i,j}$ is a restraint factor:

$$M_{i,j} = M^o{}_{i,j} - E \, \theta_i \, r_{i,j} - E \, \theta_j \, r_{j,i} \, f_{j,i} \tag{69}$$

From the relation

$$d_{i,j} = \frac{r_{i,j}}{\sum_j r_{i,j}} \tag{70}$$

it is found that

$$M_i = E\,\theta_i \sum_j r_{i,j} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (71)$$

which shows the relationship between the two methods. The Maney-Goldberg method appears to be the simpler, since it makes use of the elementary concept of joint rotation instead of the complex concept of total unbalanced moment which, in final analysis, is the external couple required to produce the actual joint rotation when the other joints are fixed and when no other load is applied.

The original Maney-Goldberg method has been improved by its authors in the following manner: Dividing the joints into two groups i and j defined in such a manner that every span connects two joints belonging to the two groups, Eq. 67*a* can be written in the form—

$$|M_j| = (|M^{\circ}_j| - |M^{\circ}_i|\,|b_{ij}|)\,(|E| + |b_{i,j}|^2 + \cdots + |b_{i,j}|^{2n} \cdots) \,.\,. (72a)$$

and

$$|M_i| = |M^{\circ}_i| + (|M^{\circ}_j| - |M^{\circ}_i|\,|b_{i,j}|) \times |b_{i,j}|\,(|E| + \cdots + |b_{i,j}|^{2n} \cdots) \ldots\ldots\ldots\ldots (72b)$$

Since the sum $|M^{\circ}_j| - |M^{\circ}_i|\,|b_{i,j}|$ forms one matrix, the number of operations required by Eqs. 72 is half of the number necessitated by Eq. 67*a*, to obtain the same approximation. This short cut is essential when the convergence is slow (as, for example, for structures with sidesway).

The Maney-Goldberg method may appear longer than the Cross method, because it necessitates the computation of moments equivalent to rotations. However, since a check of the results is indispensable, it is necessary to calculate the rotations when the Cross method is applied, to find whether the relations between rotations and end moments are satisfied by the solution. The additional operation is included in the Maney-Goldberg method which is self-checking. When this operation is added to the Cross method, the latter becomes self-checking, and the number of operations is the same by both methods, provided the Maney-Goldberg short cuts are applied to the Cross method.

Another method of successive approximations results from a different interpretation of Eq. 67*a*: If the matrix,

$$|B_{i,j}| = |E| - |b_{i,j}| + |b_{i,j}|^2 \cdots \pm |b_{i,j}|^n \cdots\ldots\ldots\ldots (73)$$

is determined, the total unbalanced moments are defined simply by:

$$|M_j| = |M^{\circ}_i|\,|B_{i,j}| \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

This method can be applied to slope deflection as well. The numerical calculation of the matrix $|B_{i,j}|$ is about as complex as the determination of one actual solution by Eq. 67*c*. On the other hand, this operation is done only once for a given structure, after which Eq. 74 defines all the total unbalanced moments with a minimum of operations for any loading condition, avoiding the tedious repetition of successive approximations in each case. This method can easily be identified with the method of conjugate points, since, in both methods, the moments at any joint are defined directly in terms of a linear combination of the fixed-end moments at all the joints.

In conclusion, the direct method of successive elimination is always the most advantageous in the case of one row of spans, and it is generally the most advantageous for two rows of spans. In all the other cases, methods of successive approximations are more powerful. When only one condition or very few loading conditions are examined, the Maney-Goldberg method is the most expeditious, although the Cross method can be improved to obtain the same efficiency. When many loading conditions are examined, the method of successive elimination, transformed into a method of successive approximations (conjugate points in frameworks), is generally the best. The section under the heading, "General Principles of Standardization," in Appendix II, will help to avoid the use of such cumbersome notations as FEM for fixed-end moments and $\overline{\text{DL}}$ and $\overline{\text{LL}}$ for dead load and live load.

ALEXANDER DODGE,[26] ASSOC. M. AM. SOC. C. E.—The slope-deflection method has been used in this paper to derive equations for members of constant moment of inertia. In appraising the work done by Mr. Weiss, it will be instructive to compare it with parallel studies by the writer[27] in 1939, which involved the development of the moment-area principle for members of varying moments of inertia. The writer's studies included the effect of sidesway and the construction of influence lines. The definition of fixity constitutes the main difference in the papers. In the writer's concept, the "end fixity" is defined as the ratio of $\frac{Z'}{Z}$, in which Z' is the exact moment at point B due to unit moment at point A, and Z is the moment at point B due to a unit moment at point A if end B is fixed. For members with a constant moment of inertia, $Z = 0.5$. Referring to Fig. 2, the "end fixity" is

$$f_{ba} = \frac{\Sigma S_p}{\Sigma S_p + S_{ba}} \qquad (75a)$$

in which S_p is the exact stiffness corresponding with the stiffness factor r in the author's concept, or

$$f_{ba} = \frac{R_{BA}}{R_{BA} + 3\,K_{BA}} \qquad (75b)$$

Eq. 75*b* will be recognized as a part of Eq. 16. The reversed subscript for the symbol K denotes that the stiffness at end B of member AB is used, which is an important distinction in analyzing a member of varying moment of inertia. The carry-over factor may be looked upon as the exact moment at joint B due to unit moment at end A. With these changes in the subscript notations as explained in Appendix I, Eq. 16 would be changed to

$$f_{BA} = \tfrac{1}{2}\,\frac{R_{BA}}{R_{BA} + 3\,K_{BA}} \qquad (76)$$

thus simplifying most of the equations derived from it. In itself, this is not an important change, but the fact that all terms in Eq. 76 refer to the same point

[27] "Solution of Rigid Frames by Coefficients of Unit Moment," by Alexander Dodge, thesis presented to the University of Washington, Seattle, Wash., in 1939 in partial fulfilment of the requirements for the professional degree of Civil Engineer.

(joint B) will certainly be appreciated by engineers who may have practical use for the concepts. The definition of end fixity expressed by Eqs. 75 has several advantages: (1) It is a linear function of the carry-over factor and, therefore, has a physical significance that can be visualized easily and clearly; and (2) it makes the expression for the exact stiffness of the member, S_p, very simple, namely:[27]

$$S_p = \frac{C'}{C} S \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

in which S is the stiffness of the member at joint B if end A is hinged; C is the ratio of stiffness S to the stiffness of the member at joint B if end A is fixed; and[27]

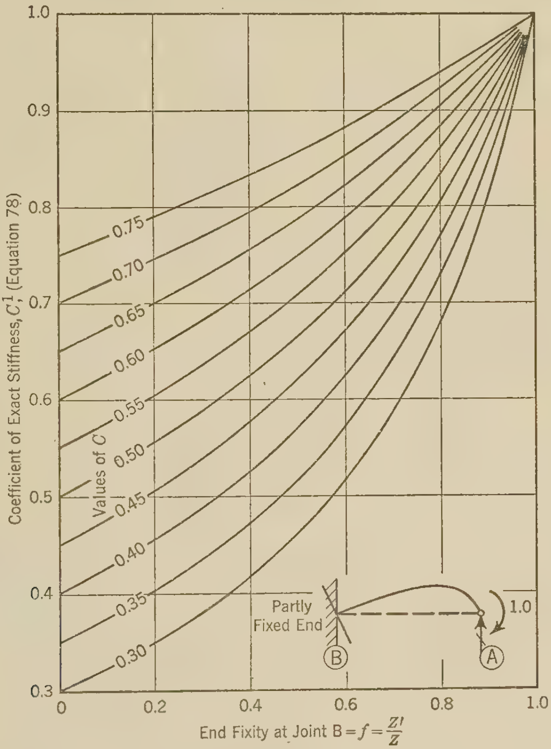

FIG. 8

$$C' = \frac{C}{1 - f(1 - C)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

Charts for the constants S and C have been prepared and published by Thorbjörn Germundsson,[28] Assoc. M. Am. Soc. C. E. Values of C' for any variation of moment of inertia can be selected from Fig. 8. For a constant moment of inertia, Eq. 77 becomes:

---

[28] "Design of Continuous Frames Having Variable Moment of Inertia," by Thor Germundsson, *Civil Engineering*, October, 1932, p. 647.

$$S_p = \frac{C'}{0.75} \times \frac{3\,I}{L} = \frac{4\,C'\,I}{L} \ldots\ldots\ldots\ldots\ldots\ldots (79)$$

In general, referring to Eq. 23, the end moment at end A is not equal to $Q_{AB}\,C_{AB}$; but, by Eq. 16, it is equal to $\frac{R_{AB}}{R_{AB} + 3\,K_{AB}}\,C_{AB}$, which is a constant that is independent of the characteristics of joint B. In Eq. 17*a*, r_{AB} has a limit of $3\,K_{AB} \leqq r_{AB} \leqq 4\,K_{AB}$, which shows that r_{AB} is a function of the characteristics of joint B also. Therefore, using Fig. 1 as an example, it should be kept clearly in mind that, for this particular frame, the relation $Q_{XY} = 2\,f_{YX}$ applies to no member except span BA, because $Q_{XY} \neq \frac{R_{XY}}{R_{XY} + 3\,K_{XY}}$.

In order to generalize the subject, the effect of varying moment of inertia should be examined. Using charts prepared by Mr. Germundsson,[28] with Eqs. 16 and 17*a*, the values in Table 4 were computed for the ratio $b = \frac{I}{I'} = 0.08$, as applying to four designs of beam AB. The values common to all beams were assumed to be: $R_{AB} = 2.0$; the stiffness factor at end A of the member AB, with end B hinged, is equal to $S_{ab} = 1.0$, and $Q_{AB} = 67\%$ when $Q_{BA} = 0$. If the values of Table 4 were plotted on the chart in Table 1, they would be found scattered over a wide area. This indicates that, in general, no simple relation exists between values of Q and n. An important modification would also be noted in Eq. 22*b*, the constant of which would be changed from 2 to 1.333, 0.908, and 3.33, respectively, for the first three beams in Table 4.

TABLE 4.—CONSTANTS FOR BEAM AB AND VARIOUS COMBINATIONS OF STRAIGHT HAUNCHES

Haunches at:	Ratio, haunch to span length[a]	f_{BA}	n_{BA}	Q_{AB} (end B fixed)[b]
A and B..............	0.4	0.5	0.667	0.462
End A................	0.8	0.734	0.572	0.568
End B................	0.8	0.2	0.833	0.568
Uniform section........	....	0.333	0.75	0.6

[a] The ratio of minimum to maximum moment of inertia is 0.08 in each case. [b] The value of Q_{AB} with end B hinged is 0.67 in each case.

The basic structural concepts are expressed fully by Eqs. 13, 16, 75, and 77, and their application to the solution of various structures, including frames with sidesway and varying moment of inertia as well as to the construction of influence lines has been demonstrated previously.[27] A typical example is demonstrated in Fig. 9. The method of tabulating the needed values in terms of symbols is shown in Fig. 9(*a*), and the numerical solution is given in Fig. 9(*b*). Recalling that constants for a beam of uniform moment of inertia are: $S = \frac{3\,I}{L}$, $C = 0.75$, and $Z = 0.5$, the computations are made starting from the left end of the frame and proceeding to the right end. By Eqs. 75, $f_{bd} = 0.375$. With this value enter Fig. 8 and read $C'_{db} = 0.827$. By Eq. 77, $S_{dbp} = 0.022$; by Eqs. 75, $f_{df} = 0.734$; $C'_{fd} = 0.918$; and $S_{fdp} = \frac{0.918 \times 0.0128}{0.75} = 0.0156$.

Beginning at the right end of the frame and proceeding to the left end:

$$f_{fd} = \frac{0.008 + 0.025}{0.008 + 0.025 + 0.0128} = 0.72;\quad C'_{df} = 0.915;\quad S_{dfp} = \frac{0.915 \times 0.0128}{0.75}$$

(b) COMPUTATIONS

FIG. 9.—SOLUTION OF A RIGID FRAME

$= 0.0156$; $f_{db} = \dfrac{0.0156 + 0.0133}{0.0156 + 0.0133 + 0.02} = 0.592$; $C'_{bd} = 0.881$; and $S_{bdp} = \dfrac{0.02 \times 0.881}{0.75} = 0.0234$. By Eq. 13, $K_{ba} = \dfrac{0.012}{0.012 + 0.0234} = 0.339$. It should be noted that factor K_{ba} corresponds to factor d_{BA} in the author's concept.

All other K-values are computed similarly. In practice, the computations are made on a slide rule and recorded directly in Fig. 9(a). It will be noted that, in addition to the foregoing computations, the coefficients J are also recorded in Fig. 9. These coefficients indicate the proportion in which the coefficient Z' received at the joint is divided between the remaining members; for example, $J_{db} = \frac{K_{db}}{K_{db} + K_{dc}} = \frac{0.432}{0.432 + 0.261} = 0.624$, etc. Noting that the coefficients K and J always carry a minus sign and that coefficients Z' have a plus sign, and assuming clockwise moments to be positive, for the loading conditions of Fig. 9(a), the final moments will be as follows: Fixed-end moments $= \frac{w\,L^2}{12} = \frac{1.2 \times 20^2}{12} = 40$ kip-ft; $M_{DF} = -40\,(1 - K_{df}) + 40\,(-K_{fd} \times Z'_{df}) = -32.43$ kip-ft; $M_{DB} = M_{DF}\,J_{db} = 20.24$; $M_{BD} = M_{DB}\,Z' = 3.78$; $M_{AB} = 3.78 \times -1 \times 0.5 = -1.89$; $M_{DC} = -32.43 \times -0.376 = 12.19$; $M_{CD} = 12.19 \times 0.5 = 6.10$; $M_{FD} = 40\,(1 - 0.321) + (-40 \times -0.307 \times 0.36) = 31.58$; $M_{FE} = 31.58 \times -0.757 = -23.91$; $M_{EF} = -23.91 \times 0.5 = -11.96$; $M_{FG} = 31.58 \times -0.243 = -7.67$; and $M_{GF} = -7.67 \times 0.5 = -3.84$. If a frame is built up of members with varying moments of inertia, the same procedure is used, except that the coefficient C' would be selected from Fig. 8 to correspond with the respective beam C-values.

The author's paper, being essentially mathematical, might be improved if its definitions and symbols were adapted to a more general case. For example, for the third beam in Table 4, the node caused by end rotation is closer to the generating end A if end B is fixed. Therefore, the definition of the carry-over factor as the ratio of the shorter nodal intercept to the longer nodal intercept would be in error. For these reasons, the definition of the "carry-over factor" as originally stated by Hardy Cross, M. Am. Soc. C. E., and so well rooted in engineering literature, should not be altered. There is an objection also to symbol r being used to designate the restraint or stiffness factor. The symbol r, designating the word "ratio," has been used to designate Professor Cross' "carry-over" factor, and tables have been prepared, published,[28] and broadly used in structural analyses. The symbol S, abbreviating a word stiffness, also has a good logical reason to be retained to represent the "stiffness" of a beam, and S_p "the exact stiffness," where the subscript p denotes "a partly fixed or partly restrained beam." As noted in Appendix II, the letter symbol $K = \frac{I}{L}$ equals the stiffness factor or a factor of proportionality of stiffness. Sometimes the letter K also denotes "the relative stiffness of a member" when compared with other members. Therefore, to avoid confusion, r_{BX} in Eq. 10 should not be referred to as "the stiffness factor," but as "the stiffness" or rather, "the exact stiffness." The meaning of "exact stiffness" may be clarified by referring to the "unit stiffness" concept which is defined thus: If a unit moment applied at the hinged end of a beam is causing unit rotation of the same end (for a given degree of restraint at the other end) the beam is said to have a "unit stiffness" at the end where the unit moment is applied. The "exact stiffness," then, is an inverse function of the true rotation angle at the end of the beam at which the unit moment is applied.

WILLIAM C. SPIKER,[29] M. AM. SOC. C. E.—A possible method is suggested by the author whereby engineers may eventually come nearer to agreement as to the simplest possible procedure for computing stresses in rigid frames. If engineers can agree on fundamental concepts and uniform symbols, progress will have been made.

The author and the writer agree that the "point of inflection" is an important and fundamental concept. Apparently they do not agree as to the importance of θ as a measure of resistance although they do agree as to the importance of resistance as a concept. The writer especially does not accept the author's symbols "d," "r," and "n" because they do not suggest what they mean and are in conflict with other symbols already well established.

Very strongly, the writer agrees with the author's idea of charting the location of points of inflection; but he is of the opinion that Table 1 is either not clear or is incorrect; and that the formulas of the paper are unnecessarily abstruse.

For computing tables and charts of θ-values, resistances, points of inflection, etc., the writer uses principles and formulas that can be deduced from the equations of the slope-deflection method and from the routine of its application. For convenience, the fixed-end moment FEM is taken equal to 100 or multiples of 100. Values of L are then equal to the square root of 1,200, when the unit load (w) is equal to 1, or multiples of 1.

Instead of using $I/L = K$ for all spans, that ratio is used only where one end of a member is actually fixed and where reference is made to the particular member along which "carry overs" are being made and for which equivalent K-values are being computed.

Reference can be made to the short cut or special case of the slope-deflection equation for beams hinged at one end; thus,

$$M_{A-B} = 3\,E\,K\,\theta_A - 3\,E\,K\,R - (\text{FEM})_1 \ldots\ldots\ldots\ldots (80)$$

in which $(\text{FEM})_1$ is the fixed-end moment of the beam when only one end of the beam is fixed or assumed to be fixed. It is the algebraic sum of FEM and the carry over. In Eq. 80, the quantity $3\,E\,K\,\theta$ is actually $4\,E\,(\frac{3}{4}\,K)\,\theta$. In other words, K would be $\frac{3}{4}\,K$ if conditions remained the same except that the other end of the beam were fixed. This reduced K may be called the true, effective, or equivalent, value of K; but whatever it is called it designates a measurable, computable (or determinable) amount of resistance to the rotation of the end of a member. It is always less than the ratio I/L except when the other end of the member is actually fixed; or when the other end of the member is being rotated in the same direction as the end in question, and carry overs are omitted. The formula for computing the reduction of effectiveness of I/L

---

[29] Cons. Engr., Atlanta, Ga.

at end of any member is taken from the slope-deflection method; thus:

$$K_{A-B}\text{ (equivalent value)} = K_{A-B} - \left[\frac{(0.5\,K)^2}{K_{A-B} + \Sigma K_B\text{ (effective values)}}\right] \ldots (81)$$

In Eq. 81, ΣK_B (effective values) is the K-value for members that are actually fixed at the other end, plus K_B (equivalent values) for members that are not fixed at the other end. The true, or effective value of K is always I/L or a percentage of that ratio.

The total carry over is always the product of $\dfrac{0.5\,K}{K_{A-B} + \Sigma K_B\text{ (effective values)}}$ and the algebraic sum of the fixed-end moment for beam AB at end B and the values of $(\text{FEM})_1$ for members meeting AB at end B.

The product $4\,\theta$ in the slope-deflection equation is always the algebraic sum of $(\text{FEM})_1$'s divided by ΣK (effective values) at the joint. Then the application of the slope-deflection equation to the known values of θ determines the moments and checks them for continuity. Also, it detects an error in the location of the point of contraflexure in columns in case the points of contraflexure in the columns have been approximated.

T. F. Hickerson,[30] M. Am. Soc. C. E.—This is an interesting and valuable paper; but these structural concepts and the interrelated exact carry-over factors do not constitute an integral part of the Cross method of moment distribution, as the casual reader might infer from the author's introduction.

To the list of algebraic relations in Table 1, one more column might be added for completeness, as indicated in Table 5. Here certain concepts are expressed in terms of "carry-over factors." The term "degree of restraint" as introduced by the author might well be omitted. It serves no useful purpose except as an approximate check on the "degree of fixity"; the K-values alone could serve the same purpose in a much simpler manner. Thus, in Fig. 3:

$$F_{BA} = \frac{K_{BJ} + K_{BC} + K_{BH}}{K_{BJ} + K_{BC} + K_{BH} + K_{BA}} \ldots\ldots\ldots\ldots\ldots (82)$$

approximately.

The letter symbols in Appendix I appear, in the main, to be well chosen. Subscripts must be added to avoid confusion. The idea of nodal intercept tends to confuse rather than clarify the concept of "carry-over factor," and should be omitted from the definition. Instead of defining $K\ (= I/L)$ as "stiffness ratio," the writer prefers "stiffness coefficient" or "nominal stiffness" inasmuch as the real stiffness (or restraint) of a structural member is dependent not only on its K-value but also on the degree of fixity at the far end of the member.

A symbol should be added for "moment split." This symbol indicates how a moment that is carried over to the end of a member is to be balanced into, or absorbed by, each of the other members at the joint. Evidently this induced moment divides itself among the receiving members in accordance

with their relative stiffness values. This "moment split" ratio is likely to be confused with the "distribution factor." As a rule, the writer prefers not even to compute the distribution factor; that is, instead of assuming the "near end" fixed—a condition that does not actually exist—just use the real degrees of fixity at each end of the loaded member as arguments (in a table compiled by the writer[31]) and write down the coefficients giving final moments in the member. These end moments are then balanced into the restraining members, and carried on to remote joints in greatly reduced quantities.

TABLE 5.—STRUCTURAL CONCEPTS IN TERMS OF THE CARRY-OVER FACTOR

Structural concept	Symbol	Carry-over factor
Nodal intercept ratio	n_{AB}	$\dfrac{1}{f_{AB}+1}$
Distribution factor	d_{AB}	$\dfrac{1-2f_{BA}}{1-f_{AB}f_{BA}}$
Degree of fixity	F_{AB}	$\dfrac{3f_{BA}}{2-f_{BA}}$
Restraint factor (or stiffness factor)	R_{AB}	$\dfrac{6f_{BA}K_{AB}}{1-2f_{BA}}$

Instead of Eqs. 39, a parallel set is as follows:

$$M_{BA} = [\mathrm{FEM_{BA}} + \mathrm{FEM_{AB}}\,\tfrac{1}{2}\,(1 - F_{AB})]\,(1 - d_{BA})\ldots\ldots(83a)$$

and

$$M_{AB} = [\mathrm{FEM_{AB}} + \mathrm{FEM_{BA}}\,\tfrac{1}{2}\,(1 - F_{BA})]\,(1 - d_{AB})\ldots\ldots(83b)$$

The only advantage that can be claimed for Eqs. 83 in comparison to Eqs. 39 is that they contain two variables, in addition to the fixed-end moments, instead of three variables.

Instead of Eqs. 83 the writer, as a rule, prefers to use the following:

$$M_{AB} = \frac{4\,F_{AB}\,H_{AB}}{D}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(84a)$$

$$M_{BA} = \frac{4\,F_{BA}\,H_{BA}}{D}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(84b)$$

in which: $H_{AB} = \mathrm{FEM_{AB}} + \frac{1}{2}\,\mathrm{FEM_{BA}}\,(1 - F_{BA})$; $D = 4 - (1 - F_{AB})\,(1 - F_{BA})$; and $H_{BA} = \mathrm{FEM_{BA}} + \frac{1}{2}\,\mathrm{FEM_{AB}}\,(1 - F_{AB})$.

If either end is fixed, $D = 4$, and Eqs. 84 are greatly simplified; but the real advantage of Eqs. 84 is their adaptability to a table of coefficients, which has been compiled.[31] Thus, with F_{AB} and F_{BA} as arguments, the moments at the ends of the loaded member can be written down most easily.

To illustrate the foregoing the writer has solved the frame shown in Fig. 10(*a*). The results are written on the members in Figs. 10(*b*) to 10(*f*). This method of solution serves also as an influence diagram indicating which combination of loads will produce maximum effects. If all the members are loaded simultaneously, the total moments are as follows: $M_A = +18.56$; $M_{BA} = M_{BC} = +37.13$; $M_{CG} = +44.25$; $M_{CB} = +114.25$; $M_{CF} = +101.44$; $M_{CD} = -259.94$; $M_{DC} = -M_{DE} = +23.17$; $M_{ED} = -M_{DE} = +10$; and $M_G = -52.87$.

---

[31] "Statically Indeterminate Frameworks," by Thomas F. Hickerson, Univ. of North Carolina Press, Chapel Hill, 1937, pp. 90–93.

The fact that the "degree of restraint" and "carry-over factors" for interior spans of continuous beams of constant moment of inertia and equal spans converge toward a fixed quantity was discovered by the writer many years ago. Thus the "degree of restraint" produced by three or more equal spans is 46% whether the far terminal be hinged or fixed.

Dean F. Peterson, Jr.,[32] Assoc. M. Am. Soc. C. E.—Using the slope-deflection equations, Mr. Weiss has developed the algebraic interrelationships between the various "structural concepts" commonly used in the method of moment distribution. The "common factor" used to derive the equations and to illustrate the interrelationship is the concept of the "fixed point."

In the "Introduction," Mr. Weiss states:

> "Usually such points [points of zero bending moment] are thought of in connection with beams continuous over three or more supports; but two such 'fixed points' exist in every member of any frame. They are called 'fixed' because their position on the elastic curve is stationary."

The position of the "fixed point" is actually stationary in only one direction since it is free to deflect transversely. The choice of the term "nodal" further implies that this condition is not true. The number of "fixed points" occurring at any time depends upon the moments acting on the member. Either none, or one, will actively occur in each of the unloaded spans (Fig. 11). When distributing a single fixed-end moment to a frame, all the unloaded members will have one and only one fixed point, which will occur either at N_A or N_B. The distance measured along the span to this point always will be the same regardless of the magnitude or sense of the moment.

(a) NO FIXED POINT (b) ONE FIXED POINT (c) ONE FIXED POINT

Fig. 11

The solution of Eq. 9 for n_{AB} in the frame of Fig. 1 requires the use of n_{BC} which is unknown since it depends on the restraining properties of joint C. Similarly, the restraining properties of joint C depend upon those of joint D, etc. Presumably it is mathematically necessary to start the solution at some joint where the restraining properties at the far ends of all of the concurrent members, except one, are known. Having solved for n at such a joint, it is possible to solve the equations at the other joints progressively. If no such joint exists the equations must be written for each joint and solved simultaneously. This is merely a solution of the slope-deflection equations for the entire structure with an applied moment at A in terms of the parameter n and the amount of computation involved is about the same as if the conventional equations had been used.

---

[32] Melbourne Beach, Fla.

The solution of n may be made directly from the geometry of flexure by using an elastic curve traverse.[33] For example, in Fig. 12, relative stiffness factors have been assigned to a part of the frame of Fig. 1 and joints F and L are assumed to be fully restrained. To find n_{CD}, assume that a bending moment induced from joint C acts to rotate joint D. Draw the traverse. Since the traverse angles marked 19/3 and 56/3 are a measure of the moments existing at joints D and C, respectively, $n_{cD} = \dfrac{\frac{56}{3}}{\frac{19}{3} + \frac{56}{3}} = \dfrac{56}{75}$. The traverse may be continued for the entire frame and the fixed points for each member can be found as easily, if desired.

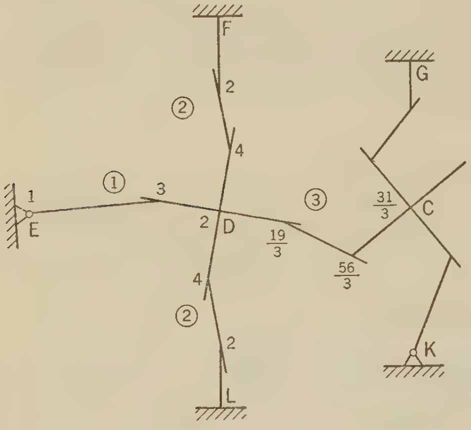

FIG. 12

However, moments might just as well have been determined in the first place. As an example, suppose the moment to be carried over from end C is 100; then all of the moments in the members about joint D may be computed immediately since they are proportional to the traverse angle and the relative stiffness: $M_{DC} = \dfrac{100}{\frac{56}{3}} \times \dfrac{19}{3} = 34.0$; and $M_{DF} = \dfrac{100}{\frac{56}{3}} \times 4 \times \dfrac{2}{3} = 14.3$. Similarly: $M_{FD} = 7.2$; $M_{DE} = 5.4$; $M_{DL} = 14.3$; and $M_{LD} = 7.2$. The traverse could easily be extended through the frame to point A and all moments due to the moment at A computed.

In the "Introduction" Mr. Weiss states:

> "The method of moment distribution introduced by Hardy Cross,[2] M. Am. Soc. C. E., offers a relatively rapid and precise means of computation and, in the writer's opinion, is as good a method as can be devised. It permits the analysis of a framework from a unique point of view. Whereas the method of least work is based on the concepts of work and energy; the slope-deflection method on relations governing deformations comprising the geometry of flexure; the Cross method may be considered as based on a complex of concepts that can be summed up under the term 'restraint.'"

It is the writer's desire to point out that the concepts summed up under the term "restraint" are basically associated with the relations comprising the geometry of flexure. The solution for n, Fig. 12, is based on an extension of these relationships. It is further noted that the slope-deflection equations (Eqs. 2) are the basic equations of the author's mathematical development.

---

[33] "Relative Flexure Factors for Analyzing Continuous Structures," by Ralph W. Stewart, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 521.

From a consideration of Eqs. 9, 10, 11, and 12, it may be stated that the "restraint" imposed by any joint, not fully fixed or hinged, in a continuous structure is dependent upon every member and upon every other joint in the frame. Prior to the introduction of the Cross method this complete interdependency was stated in the form of a set of simultaneous equations involving, as unknowns, rotations or moments at each joint. In order to avoid the usually arduous task of solving these equations, Professor Cross developed a means of "distributing" unbalanced moments to the concurrent members of a joint assuming the far ends of the members to be fixed. By successively releasing each joint the effects of the "restraint" of remote joints and members were added as increments to the moment at the original joint. In this method the conceptions of "stiffness factor," "carry-over factor," and "distribution factor" are based on the assumption that the remote ends of the members are fully fixed. In Mr. Weiss' paper these factors are based on the true "restraint" of the joints at the far ends. Therefore, in the general case, none of them can be evaluated except after, or in connection with, some kind of a complete analysis for a moment imposed at some joint on the frame. Since such an analysis will also determine the resulting moments (which is the information that interests the designer), the various concepts set forth by this paper, although interesting from an academic point of view, appear to be of secondary importance in practice. For example, while, from the solution of the frame of Fig. 12, it is possible to determine n_{CD}, the moments resulting from the loading were also determined by the same analysis. This would generally be true regardless of the method of analysis. The use of the terms "stiffness factor," "carry-over factor," and "distribution factor" to describe physical conceptions somewhat different than those which they describe in the method of moment distribution may lead to some confusion.

A. A. EREMIN,[34] ASSOC. M. AM. SOC. C. E.—It is true, as Mr. Weiss has stated, that a uniform mathematical language, composed of commonly recognized terms, simplifies the presentation and development of computation methods. This is true regardless of how often such "standard" symbols may need to be revised. As knowledge of a subject increases and new symbols are introduced, the alphabet is often insufficient to cover the required terms. Furthermore, normal progress will require new interpretations of the physical properties of a structure. For instance, the term, "fixed point," is not defined conclusively at present. This term may be applied to three pairs of fixed points—central points, inflection points, and elastic points, as explained by the writer elsewhere.[35] The position of all these characteristic points is controlled by the physical and geometric properties of structures. With doubtful justification, Mr. Weiss introduces the term "node point" to denote an inflection point. The term "inflection point" is more directly associated with the characteristic variations in the shape of a member, its neutral axis, and moment diagram. Less effort is required to memorize the various steps in the moment-distribution method when thought of in terms of inflection points.

[35] *Transactions*, Am. Soc. C. E., Vol. 110 (1945), p. 1542.

By a simple change in the notation the authors' algebraic expressions for the restraining factors may be converted to those derived by the writer in 1943.[36] These restraining factors also may be obtained by simple graphical methods, resulting in a saving of time and effort. The member AB in Fig. 13 has a constant section, its basic stiffness being $K_{AB} = I/L$. The stiffness factor of AB at B, with end A fixed, may be determined as follows: Draw line A′B′ through the third point of the span and through the ordinate 2 K_{AB} at the third point of the span near end B. The ordinate BB′ is equivalent to the stiffness factor r_{AB}. If the restraint at end A is reduced to zero by introducing a hinge the stiffness line will be revolved about the ordinate 2 K_{AB} to the hinge at end A. The ordinate BB″ is equivalent to the stiffness factor of AB with the opposite end hinged. If the restraint at end A is reduced to one half of the full restraint, the inflection point in this case will occur midway between end A and the third point of the span, and the stiffness line will be revolved about the ordinate 2 K_{AB} to the inflection point. The ordinate BB‴ is equivalent to the stiffness factor of AB with the opposite end 50% restrained. The dashed parallel lines near end A in Fig. 13 illustrate the graphical construction of the inflection-point location according to the given degree of restraint.

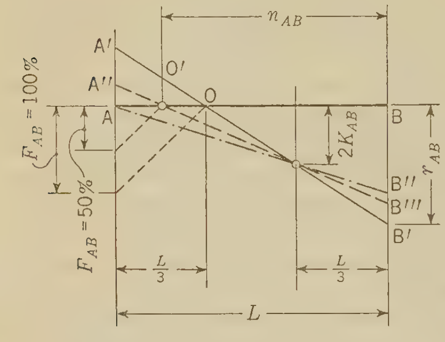

FIG. 13

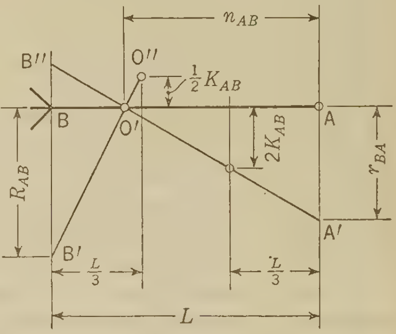

FIG. 14

The graphic construction for locating the inflection point in a rigid frame is shown in Fig. 14. Member BA in Fig. 14 is the same as that shown in Fig. 3. The inflection point O′ is determined by intersecting the member axis BA with line BO″ drawn through the ordinate of the restraint R_{AB} at end B and the ordinate 1/2 K_{AB} at the third point of the span. The stiffness factor r_{BA} is determined as shown in Fig. 13.

The inflection points are used with a considerable advantage in the graphical distribution of moments. Therefore, it is gratifying that Mr. Weiss has adopted the inflection points also in his algebraic formulas. Obviously the author's restraining factors will facilitate development of various semigraphical methods of moment distribution.

[36] "Analysis of Continuous Frames by Graphical Distribution of Moments," by A. A. Eremin, published by the author, Sacramento, Calif., 1943.

Camillo Weiss,[37] M. Am. Soc. C. E.—Discussion of the interrelation of certain structural concepts elicited interesting comment and instructive criticism. It also revealed a certain amount of disagreement among the discussers with respect to the relative merits of the concepts presented. Several new and additional concepts were proposed and methods of analysis compared.

The concepts treated in the paper were not selected with a view to advocating their use, but were included as they appeared in natural sequence during the course of the study. Carried further, Mr. Stewart's interesting and useful angle traverse relations might well have been added. Equally intriguing is Mr. Eremin's graphical representation of restraining factors.

Several of the discussers brought up the question of methods. Although outside the scope of the paper, some of the problems presented illustrate how the algebraic interrelations can be used. Mr. Stewart's problem serves particularly well and shows his complete familiarity with the various concepts and their interrelation.

Professor Hickerson is right in stating that the "correct" interrelations do not constitute an integral part of the Cross method. They belong rather to the various methods of "direct moment distribution." On the other hand, Hardy Cross, M. Am. Soc. C. E., must be credited with conceiving and introducing such terms as "carry-over factor"—thus giving structural analysis an entirely new angle of approach. Practical use of the relations in combination with the Cross method would be limited, in the writer's opinion, to cases in which part of the frame was to be isolated for investigation. For such purposes it is often customary to make assumptions of a "degree of restraint"—the usefulness of which concept has been questioned by several writers.

In Professor Brumfield's opinion the distribution factor as defined and derived holds only for the Cross method, but this is not the case. The sharp distinction which he makes between the moment applied to a joint by some external means, such as a crank, and the moment delivered to the joint by one of its members (carry-over moment) may be helpful but is not required. The carry-over moment may be considered as an external moment applied to the joint. By considering the joint as consisting of the restraining members only, the formulas give the correct distribution factors for a carry-over moment as well.

Professor Brumfield states that the terms "stiffness factor" and "restraint factor" were used interchangeably. Under the given definitions the two concepts are identical. The writer agrees with Professor Brumfield that "restraint factor" is preferable. Unfortunately, "stiffness factor" is in common usage whereas "restraint factor" is not. The terms "stiffness index" and "restraint index" were introduced by Professor Brumfield but have not been interpreted as concepts that can be visualized.

Mr. Strauss presents a general equation for the carry-over factor and also demonstrates a direct method of solution by the use of moment splits. Mr. Strauss takes issue with the statement that the Cross method is based on a concept of restraint. He considers it equivalent to solving the simultaneous slope-deflection equations by successive approximations. This is quite a legitimate view to take; but, on the other hand, Professor Cross himself presented his method as a dramatic sequence of alternately locking and unlocking the joints of a framework—quite obviously a systematic control of restraints rather than a solution of equations.

---

[37] Designer, Bethlehem Steel Co., Fabricated Steel Constr., Eng. Dept., Bethlehem, Pa.

Mr. Beskin, in tracing some of the concepts back to their origin, emphasizes their importance and calls attention to their close relationship. In his opinion it is improbable that any new physical interpretation is given to structural terms in this paper. He challenges the statement that "fixed points" are usually thought of in connection with beams and makes the counterclaim that the analysis of frameworks by determining the locations of the fixed points is a common practice. In support of this contention he refers to papers by Yves Nubar,[17] M. Am. Soc. C. E., and Professor Brumfield [12] and to lectures of Professor Campus of Liége University, in Liége, Belgium. In his paper Mr. Nubar does not state or imply that a generalized theory of fixed points is common practice, but he indicates that such a theory could be based on a geometric interpretation of one of his findings. Mr. Nubar refers to the paper by L. H. Nishkian and D. B. Steinman,[38] Members, Am. Soc. C. E., on the conjugate points of the continuous beam. Professor Brumfield, far from lending support to Mr. Beskin's contention, does not mention fixed points at all in his paper.[12] Indeed, in his discussion of structural concepts, Professor Brumfield states that he would eliminate the idea of fixed points from consideration entirely. Thus, only the lectures of Professor Campus remain, of which unfortunately there are no records available. However, even if there were occasional instances of a more general application, the statement that fixed points are usually thought of in connection with continuous beams would not be refuted.

In Mr. Beskin's opinion the "so-called" Cross method does not permit the analysis of framework from a different or novel point of view. However, when the method was first proposed it was greeted with such expressions as "ingenious," "an outstanding contribution to the field of structural analysis," "a refreshingly new and eminently useful avenue of approach," "quite unique," "the most convenient and expeditious method yet brought forward," "the most powerful and versatile tool presented in many years," and "the greatest single contribution to the theory of stress analysis in a generation."

With reference to Mr. Beskin's Eqs. 41, it should be stated that they apply to a moment acting at joint B. Eqs. 42 correspond to those given by Professor Hickerson in Table 5 except Eq. 42*a* which is in error as comparison with Table 5 will show.

The statement made in the paper (see "Introduction") that "The method of moment distribution * * * is as good a method as can be devised" was rather irrelevant to the main theme of interrelations, but Mr. Beskin challenges the statement and for this purpose presents a very scholarly comparison of various methods. Although distantly related to the topic of the paper, the subject of methods does not come within its modest scope.

Mr. Dodge has contributed instructive comment and made valuable suggestions. His statements concerning symbols are well taken, and his remarks concerning the introduction of the proper subscripts for the general case of varying moments of inertia are pertinent. His adaptation of the interrelations to more general application is a welcome contribution.

[38] "Moments in Restrained and Continuous Beams by the Method of Conjugate Points," by L. H. Nishkian and D. B. Steinman. *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 1–206.

To Mr. Spiker the interrelations suggest a possible method, but he believes that the formulas of the paper are unnecessarily abstruse and that Table 1 is not clear. The writer is in sympathy with Mr. Spiker and wishes he could have expressed himself more clearly. Mr. Spiker's discussion shows, however, that he is quite familiar with the subject of interrelations. He favors the use of the "point of inflection" and tables and charts for this and other concepts. He objects to certain symbols used in the paper because of conflict with others. This conflict does exist and is admittedly confusing to both reader and writer. Appendix II was added in the hope of stimulating discussion for the remedy of just such conflicts.

In Table 5 Professor Hickerson presents a welcome supplement to Table 1 and contributes some valuable interrelations of his own including some which modify advantageously certain relations presented by Mr. Strauss. Since Professor Hickerson was a pioneer in the study of restraint, his comments carry special weight.

Mr. Peterson is correct in stating that, when a single moment is applied to a joint of a frame, only one "fixed point" in each member will be a point of inflection: It will be the left-hand point for unloaded members to the left of the joint and the right-hand point for unloaded members to the right of the joint. In general, it will always be the far point. One of the fixed points may be a hinged end in which case it may not appear to be a point of inflection. These are well-known characteristics of the fixed points. Mr. Peterson states that it is mathematically necessary to start the solution of the nodal intercept at some joint where the restraining properties of the far ends of all the concurrent members, except one, are known. This is theoretically quite correct. In practice, however, it is not necessary. The restraining properties of members several panels removed from the joint under investigation may be arbitrarily assumed. In most cases their influence will be found negligible.

Special attention is called to Mr. Eremin's interesting graphical representation of restraining factors.

Among the various terms used, the term "node" has drawn the heaviest fire. Professor Brumfield holds that there is no movement at a "node" although the "fixed point" does move laterally. Mr. Beskin correctly states that the amplitude of displacement of a node is different from zero; and, characteristically, a node is a point of inflection. Mr. Peterson believes that the "fixed point" is stationary in only one direction since it is free to deflect transversely.

Actually, the "fixed point" may move in any direction. It is "fixed" only longitudinally relative to the restrained end of the unloaded member and moves with it in any direction, but it remains stationary on the elastic curve, or neutral axis, of the unloaded member. The term "node" is admittedly not an ideal choice. It was used primarily for brevity and for want of a better or more descriptive term. The term "characteristic point" is cumbersome without being descriptive. "Fixed point" is better, except that the point is not really fixed and "point of inflection" is a general mathematical term. "Grove's Dictionary of Music and Musicians" [39] defines "node" essentially as follows:

> "When a string is plucked it does not vibrate in any one of the simple forms, but in several of them at once. There the node is no longer a point of complete rest, but a point where the amplitude of vibration is least."

In general, adverse criticism of the paper appears to have been directed chiefly against terminology, definitions, and method of derivation. Constructive comment has been offered to supplement and generalize the interrelations presented. Therefore the conclusion is justified that the substance of the study, the stated algebraic interrelations of the various concepts, has been accepted as being essentially correct.

STRESSES IN THE LININGS OF SHIELD-DRIVEN TUNNELS

By Anders Bull,[1] M. Am. Soc. C. E.

With Discussion by Messrs. J. A. Van den Broek, Nathan D. Brodkin, M. A. Drucker, Sigvald Johannesson, Jacob Feld, Leon Beskin, D. P. Krynine, A. A. Eremin, G. N. Alexander, Louis Balog, and Anders Bull.

Synopsis

A rational method for determining the amounts and distribution of the soil reactions (passive pressures) developed around a shield-driven tunnel lining is presented in this paper.

Considering the lining supported by a hypothetical diaphragm, the thrust, shear, and moment produced at the support are first determined. From the values obtained, formulas are next derived, and tables prepared, permitting the deflections produced at various points of the lining under the combined influence of active loads and soil reactions to be expressed as simple product sums. However, the deflections may also be expressed in a different way, as functions of the soil reactions and the settlement. By equating the two sets of expressions a number of simultaneous equations are obtained from which the soil reactions are determined.

Applying the method to an actual case, the values obtained for the dimensions of the lining are compared with those obtained by the customary method of analysis, and the economic aspects thus raised are discussed, as are the comparative merits of steel as a lining material.

Present State of Art

1. *Introductory Remarks.*—With few exceptions, shield-driven tunnels are of circular cross section. The shell or "lining" resisting the pressure of the surrounding ground is usually made of a succession of rings of iron, steel, or concrete, each of which is built up inside the shield from a number of segments. For purposes of design, the axial cross section through a ring at a joint is considered equivalent to one taken between joints as the latter is supposed to have the same strength as the segments proper. Although a tunnel lining is thus one

Note.—Published in November, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Civ. Engr., Board of Transportation, New York, N. Y.

of the simplest structures imaginable, its rational design is complicated by the highly indeterminate character of the pressure distribution.

Among the pressures acting on a lining may first be mentioned those due to the weight of the surrounding ground. They are referred to as "active pressures" and are determined with sufficient accuracy by means of certain broad rules roughly fitting the average soil condition anticipated within a given length of tunnel, it being obviously impracticable to make provision for minor variations. The accepted rule in the typical case of a sandy soil is to take the vertical pressure at a given point as the unit weight of the soil times the depth of the point below the surface, and the corresponding horizontal pressure as one third of that amount, additional allowance being made for the weight of the lining and the hydrostatic pressure of any water present.

Wherever the lining, as a result of these active pressures, is displaced in a direction away from the center of the tunnel, it causes the abutting ground to be compressed, and secondary pressures are developed which tend to resist the displacement. In sandy soils the latter pressures, according to the rules, are proportional to the amount of displacement, regardless of the depth of the point considered. They are generally referred to as "passive pressures." The word "passive" is misleading in this connection, however, because in a more widely used sense it denotes the maximum pressure that a soil is capable of exerting without being ruptured, a pressure which increases with the depth; so in order to preclude any confusion on this score, the term "soil reactions" will be used for pressures and forces due to displacement.

To narrow the scope of the paper, it will be assumed that the soil considered is of a type to which the foregoing rules may be applied.

2. Original Theory.—As stated, the active pressures exerted against a tunnel lining vary from point to point, depending on the depth below ground surface and water table, respectively. If the vertical pressures are plotted along a horizontal diameter, and vice versa, the pressure distribution is somewhat as indicated by the outlines of the unshaded diagrams in Fig. 1.

The thrust, shear, and moment which these pressures produce in the lining at some principal points along the periphery are found by treating the lining as an arch spanning a complete circle. In order to facilitate the mathematical work involved, the diagrams are divided into elementary shapes 1 to 11, Fig. 1, the effects due to each shape being determined separately, after which the combined effects are found by algebraic summation. The active pressures are: The downward pressure due to weight of soil (areas 1 and 2) and water (areas 3 and 4) above the horizontal diameter of the tunnel; the downward pressure due to weight of lining (area 5); the upward pressure due to hydrostatic action (areas 6 and 7); and the horizontal pressure due to soil (areas 8 and 9) and water (areas 10 and 11).

The horizontal pressures are usually symmetrical with respect to the vertical diameter of the lining, the corresponding forces being, therefore, in static equilibrium. Such is generally not the case with the active vertical pressures, the corresponding downward force being either larger or smaller than the upward one. If the downward force predominates (as assumed in this paper) the lining will settle, compressing the ground below until soil reactions in the amount required for static equilibrium have been developed.

By the original theory,[2] the vertical soil reactions are assumed to be uniformly distributed over the horizontal diameter of the lining, as indicated by the shaded rectangle 12 in Fig. 1. By adding their effects to those produced by the active pressures 1 to 11, the total thrust, shear, and moment at each principal point are obtained, from which the required strength of the lining is determined.

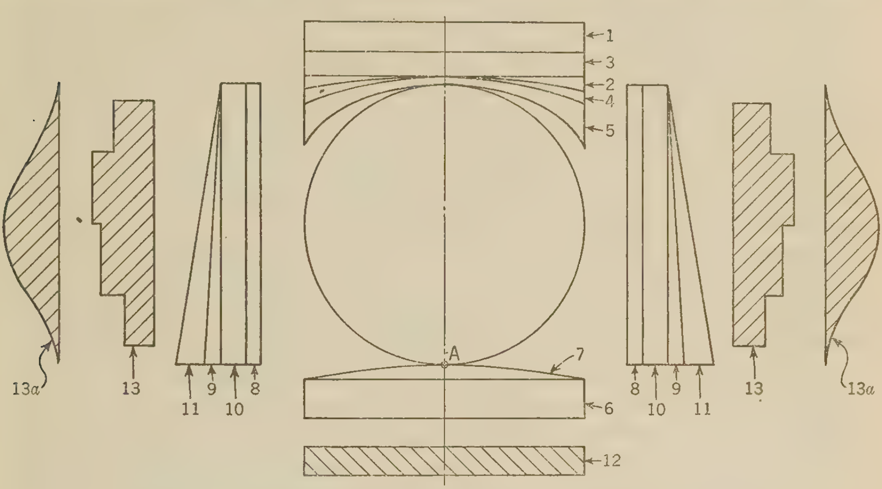

FIG. 1.—ASSUMED SOIL PRESSURE DISTRIBUTION AROUND A LINING

It is clear at once that the theory disregards a most important feature—the deflection of the lining—since only for a perfectly rigid lining could the soil reactions be distributed in the manner claimed. Although the deflection may amount to only a few hundredths of an inch, the change it causes in the pressure distribution has a profound effect on the moments that to a large extent govern the stresses in the lining. This is due to the sensitive state of moment balance prevailing in a ring-shaped structure. As will be shown, the resultant moment at any point is the outcome of positive and negative moments whose magnitude may each be several hundred times that of the former, so that even a slight error in determining the component moments may upset the final result completely.

The failure to take the deflection into consideration leads to excessive values for the moments computed and thereby to designs which are very uneconomical. It seems unlikely, in fact, that a tunnel was ever built in strict compliance with the original theory, as a comparison with other tunnels, already long in service, would immediately have revealed that something must be radically wrong.

3. Customary Method of Analysis.—Not until the middle 1920's was serious attention paid to the relieving influence which the deflection has upon the moments in the lining. As a result of these investigations a theory was developed which may be considered the foundation of present-day tunnel design.

---

[2] "Shield and Compressed Air Tunneling," by B. H. M. Hewett and S. Johannesson, 1st Ed., McGraw-Hill Book Co., Inc., New York, N. Y., 1922, p. 74.

The problem was not fully grasped at the outset, however, and the erroneous conception of a uniform distribution of the vertical soil reactions was thus inherited by the newer theory. As a novel feature, horizontal soil reactions were introduced which are subject to the following considerations:

Under the pressures 1 to 12, Fig. 1, the lining deflects, the horizontal components of the deflection being directed outward, compressing the ground horizontally. Due to the restraining influence of the resulting soil reactions the deflection is reduced; this, in turn, causes the soil reactions to be also reduced, until a balance is established. The problem is simplified by assuming a step-by-step variation of the horizontal soil reactions, as indicated by diagrams 13. The values required for a balance may be determined mathematically, but the further details are not open to discussion as no account of the procedure seems as yet to have been published.

A simple method for attaining the same end has been described by M. A. Drucker,[3] who determines the horizontal soil reactions as continuous functions of the depth, the resulting pressure distribution being shown by diagrams 13a. The procedure would be an improvement except for the fact that also in this case the vertical soil reactions are assumed to be uniformly distributed.

Because of the restraint exerted by the horizontal soil reactions, the modified methods will yield lower values for the moments than does the original theory; but the obvious inconsistency of treating the lining as if it were, at the same time, both flexible and perfectly rigid makes it a foregone conclusion that the results obtained on such premises cannot be correct. The error incurred is found to increase with the flexibility of the lining.

In this paper the problem is approached from a different angle, permitting a method to be developed by which the complete pressure distribution due to a given loading condition may be determined in accordance with accepted mechanical laws and engineering practice. The important bearing which the flexibility of the lining has upon the economy of design—a feature which, so far, has been obscured because of the assumed fixed distribution of the vertical soil reactions—is thereby revealed.

Notation.—The letter symbols in this paper are defined where they first appear, either in the text or by diagram, and those used in solving specific problems are assembled for convenience of reference in the Appendix, where the adopted sign convention is also defined.

Reactions in a Tunnel Lining

4. Basic Principle.—The thrust, shear, and moment produced at any point of a tunnel lining may be found by the same principle as the one on which the method of structural model analysis introduced by the late George E. Beggs,[4] M. Am. Soc. C. E., is based, and which may be briefly stated as follows: In an elastic structure, if a support is displaced by an infinitesimal amount in a given direction the resulting deflection line is identical with the influence line for the similarly directed reaction at that support.

---

[3] "Determination of Lateral Passive Soil Pressure and Its Effect on Tunnel Stresses," by M. A. Drucker, *Journal of the Franklin Institute*, May, 1943, p. 499.

[4] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208.

For a proof of the truth of the foregoing statement it is customary to refer to Maxwell's theorem, from which it was originally deduced. However, the same conclusion is reached more directly by considering that the work performed, respectively, by a load and the corresponding reaction during an infinitesimal displacement of the support must be of equal amount and opposite sign, since the work spent on the elastic deformation of the structure, being a function of the square of the displacement, becomes negligible. The latter method, which has the advantage of greater clarity, will be followed.

A circular tunnel ring lends itself particularly well to this type of analysis because of its assumedly uniform cross section and perfectly regular shape, as the result of which the deflection lines due to given displacements are of fixed shapes, comparable to the deflection lines for simple beams.

The ring in Fig. 2 is a 1-ft slice cut from a tunnel lining, the neutral circle of which is marked c. The ring is assumed to be cut at the invert point A and to be supported by a thin, inflexible diaphragm D, made up of two interlocking and detachable halves of which the upper half is rigidly connected to the left-hand end of the ring, while the lower half is rigidly connected to the right-hand end.

The reactions to be determined are those exerted by the diaphragm as a whole upon the right-hand end when a single force P is applied to the ring at a point p, located on the neutral circle at an angular distance α from point A.

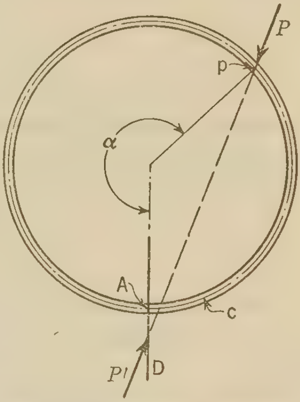

FIG. 2.—HYPOTHETICAL SUPPORT OF A TUNNEL RING

5. *Reactions at the Support.*—Referring to Fig. 3, the curved dashed lines represent the neutral circle of the ring, whereas the solid curves indicate the shapes assumed when the right-hand end is displaced in the various ways shown.

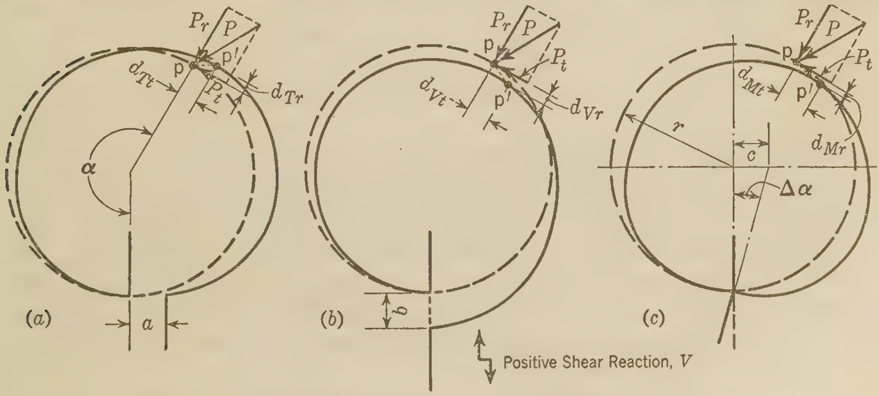

FIG. 3.—INFLUENCE LINES OBTAINED BY DISPLACING THE SUPPORT

For finding the thrust reaction T, the right-hand end is assumed to be displaced by an infinitesimal amount a in the direction of positive thrust reaction (see Fig. 3(a)). The point p will then move to the new position p′. Resolving the deflection pp′ into its radial and tangential components d_{Tr} and d_{Tt}, respectively, and the force P, similarly, into the components P_r and P_t, one may write the work equation:

$$T\,a = P_r\,d_{Tr} + P_t\,d_{Tt} \qquad \text{(1)}$$

a deflection component being considered positive when its direction is opposite to that of the force component by which it is multiplied (work negative). From Eq. 1 it follows that

$$T = P_r\frac{d_{Tr}}{a} + P_t\frac{d_{Tt}}{a} \qquad \text{(2)}$$

For the shear reaction V, the right-hand end of the ring is assumed to be displaced downward by an amount b in the direction of positive shear reaction. Resolving the deflection pp′ into its components d_{Vr} and d_{Vt}, the work is expressed by: $V\,b = P_r\,d_{Vr} + P_t\,d_{Vt}$ or

$$V = P_r\frac{d_{Vr}}{b} + P_t\frac{d_{Vt}}{b} \qquad \text{(3)}$$

For the moment reaction M, the right-hand end of the ring is rotated in the direction of positive moment reaction (so as to stretch the outer fibers in the right-hand end). This is done by tilting the lower half of the diaphragm clockwise by an angle $\Delta\alpha$ about the invert point. The deflection pp′ is resolved into the components d_{Mr} and d_{Mt}, and the work equation becomes:

$$M\,\Delta\alpha = P_r\,d_{Mr} + P_t\,d_{Mt} \qquad \text{(4a)}$$

The infinitesimal angle $\Delta\alpha$ is equal to c/r, in which c is the intercept made by the produced lower half of the diaphragm on the horizontal diameter of the ring, and r is the radius of its neutral fibers. Substituting this value gives:

$$M = r\left(P_r\frac{d_{Mr}}{c} + P_t\frac{d_{Mt}}{c}\right) \qquad \text{(4b)}$$

Eqs. 2, 3, and 4 show that the three reactions T, V, and M, due to a given force P, are obtained, simply, by multiplying the radial and tangential force components P_r and P_t by the quotients formed in dividing the respective deflection components d_r and d_t by the displacements to which they are due. For the small displacements considered, the numerator, in each case, is proportional to the denominator, which means that the six quotients obtained for any given point p are fixed in value. Denoting the quotients by the letter A, Eqs. 2 to 4 take the forms, respectively:

$$T = P_r\,A_{Tr} + P_t\,A_{Tt} \qquad \text{(5a)}$$

$$V = P_r\,A_{Vr} + P_t\,A_{Vt} \qquad \text{(5b)}$$

$$M = r\,(P_r\,A_{Mr} + P_t\,A_{Mt}) \qquad \text{(5c)}$$

the subscripts being self-explanatory. As the deflection pp′ changes from point to point along the periphery, both in amount and direction, the six factors A (to be referred to henceforth as A-constants) will assume different values, each of them typical of the point considered.

When the ring is subjected to several forces, acting at different points, the thrust, shear, and moment reactions are determined separately for each force, and commensurable reactions are added up. The total reactions produced at the right-hand side of the support are, accordingly, expressed by the following general equations:

$$T = \sum(P_r A_{Tr}) + \sum(P_t A_{Tt}) \ldots\ldots (6a)$$

$$V = \sum(P_r A_{Vr}) + \sum(P_t A_{Vt}) \ldots\ldots (6b)$$

$$M = r\,[\sum(P_r A_{Mr}) + \sum(P_t A_{Mt})] \ldots\ldots (6c)$$

6. Evaluating the A-Constants.—In the case of a circular ring, formulas for the six A-constants at any point p may be derived once for all, the operation involving the following steps: (1) Determine the forces and moments required at the right-hand end of the ring to reproduce the displacements a, b, and c ($\Delta\alpha$) in Fig. 3; (2) determine the radial and tangential deflections d_r and d_t simultaneously produced at any point by such forces and moments; and (3) divide the deflections by the corresponding displacements in accordance with Eqs. 2 to 4.

For the computations, which are omitted for the sake of brevity, the following standard deflection equations are used:

$$\Delta x = + \int \frac{M_o}{E\,I}(Y - y)\,ds \ldots\ldots (7a)$$

$$\Delta y = - \int \frac{M_o}{E\,I}(X - x)\,ds \ldots\ldots (7b)$$

$$\Delta\alpha = + \int \frac{M_o}{E\,I}\,ds \ldots\ldots (7c)$$

in which X and Y are the rectangular coordinates of point p, as referred to the vertical diameter of the ring and a tangent to the neutral circle at point A (positive to the right and upward, respectively); x and y are the coordinates of a moving point; M_o = moment at point x, y; s = length of arc along the neutral circle from point A to point x, y; E = modulus of elasticity; and I = moment of inertia of lining per foot of tunnel. The details of these computations are contained in the original complete manuscript, filed for reference in Engineering Societies Library.

The formulas thus derived are:

$$\left.\begin{aligned} A_{Tr} &= -\frac{\alpha \sin\alpha}{2\,\pi}; & A_{Tt} &= \mp\frac{\sin\alpha - \alpha\cos\alpha}{2\,\pi} \\ A_{Vr} &= -\frac{\sin\alpha - \alpha\cos\alpha}{2\,\pi}; & A_{Vt} &= \mp\frac{2\,(1 - \cos\alpha) - \alpha\sin\alpha}{2\,\pi} \\ A_{Mr} &= -\frac{\alpha\sin\alpha + 1 - \cos\alpha}{2\,\pi}; & A_{Mt} &= \mp\frac{\alpha\,(1 - \cos\alpha)}{2\,\pi} \end{aligned}\right\}\ldots (8)$$

In the right-hand column of Eqs. 8, the upper sign is used with angles α between 0 and π, the lower sign with angles between π and $2\,\pi$.

7. Load Concentrations.—The loads on tunnel rings are usually distributed loads, as indicated in Fig. 1. By replacing these loads with equivalent load concentrations, acting at points spaced a uniform distance apart, any desired approximation to the true loading condition may be obtained by making the spacing close enough. A spacing equal to one sixteenth of the periphery will be suitable for present purposes.

Accordingly, the ring is considered composed of sixteen rigidly joined segments of equal size, with the respective load concentrations acting at the middle point of each segment. (These segments should not be confused with the segments into which a ring is divided for construction purposes.) For identifying the various segments, joints, middle points, forces, etc., the markings shown in Fig. 4 are used. Subscripts are used when necessary for specifying the location or character with which a quantity is identified. Thus, A_{Mt5} would denote the A-constant by which the tangential component of a force at point 5 is multiplied in determining its share of the moment reaction at the support, whereas A_5 would denote any or all of the six A-constants typical of point 5.

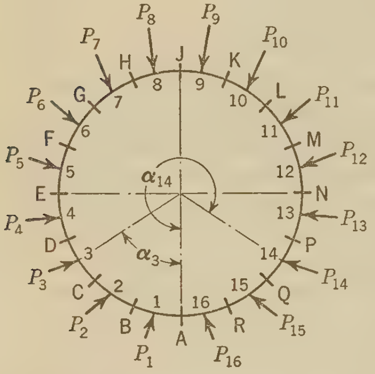

FIG. 4.—IDENTIFICATION MARKINGS

The location of the points to be considered having thus been fixed, the numerical values of the corresponding A-constants are next computed from Eqs. 8, and arranged, as shown in Table 1.

TABLE 1.—A-CONSTANTS FOR THRUST, SHEAR, AND MOMENT REACTIONS AT THE INVERT JOINT

Force	A_{Tr}	A_{Vr}	A_{Mr}	Force	A_{Tt}	A_{Vt}	A_{Mt}
P_{r1}	−0.00610	−0.00040	−0.00915 −0.00822	P_{t1}	−0.00040	−0.00002	−0.00060 ....

8. Adjusting for Polygonal Effect.—Because of the delicate balance of positive and negative moments in a tunnel ring, the substitution of forces for distributed loads may give rise to an appreciable error in the value obtained for the moment reaction M in Eqs. 6, making an adjustment necessary. For an illustration, assume that a ring is subjected to a radial pressure of a uniform intensity along its entire periphery. The pressure line then takes the shape of a circle coinciding with the neutral fibers, as indicated in Fig. 5. However, if the uniform pressure is replaced by sixteen equivalent forces P_r, acting at the middle points of the segments, the pressure line changes into a polygon, a moment being produced at each of the sixteen joints, amounting to

$$M = +0.01644\,P_r\,r \ldots\ldots (9)$$

in which r is the radius of the neutral circle. To compensate for this moment, which is essentially a local effect due to the two forces P'_r and P''_r straddling the joint, a negative moment of equal amount must be added. For the invert joint, P'_r and P''_r become P_{r1} and P_{r16}, respectively; therefore the moment to be added to the product sum $\sum(P_r\,A_{Mr})$ in Eqs. 6 is:

$$-M = -0.01644\,\frac{P'_r + P''_r}{2} = -0.00822\,(P_{r1} + P_{r16}) \ldots\ldots (10)$$

as indicated in Table 1. The adjustment does not pretend to be accurate when a load distribution is not uniform, but it meets all practical requirements and is easy to apply. No great error results from the concentration of tangential pressures; nor is any adjustment required in the thrust or shear reaction.

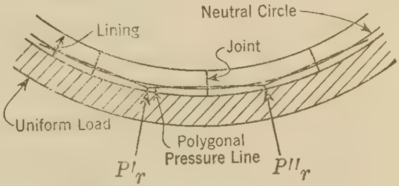

FIG. 5.—PRESSURE LINE AS AFFECTED BY TYPE OF LOADING

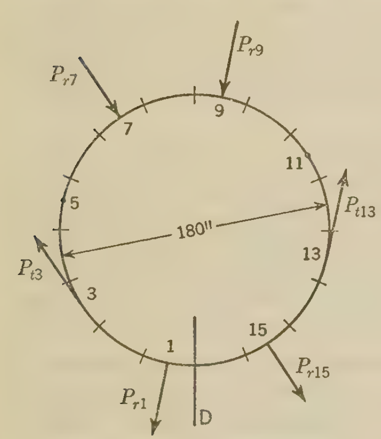

FIG. 6.—LOADING OF THE RING

9. Example.—A 180-in. ring (Fig. 6) is supported by the diaphragm D and subjected to forces P_1 to P_{15}, Table 2. The radial forces are concentrations of distributed loads on the respective segments. The problem is to determine the resulting reactions at the right-hand side of the support. The forces, multiplied by the corresponding A-constants in Table 1, yield the products entered under the respective headings. The products are added algebraically, as in Eqs. 6, and the moment product sum is multiplied by the radius: $T = -1.08317 - 1.77015 = -2.85332$ kips; $V = -4.01595 + 5.05450 = +1.03855$ kips; and $M = \frac{180}{2}(-3.14551 + 2.79700) = -31.3659$ in-kips.

10. Forces in Static Equilibrium.—Along with the reactions T, V, and M, conjugate reactions T', V', and M' are set up simultaneously at the left-hand side of the diaphragm D. With only a single force P applied to the ring, the sum of each pair of conjugate reactions represents, respectively, the total thrust, shear, and moment that must be exerted on the ring by the support as a whole in order that static equilibrium be maintained. In order to be able to exert those reactions, the support must be restrained by subjecting it to an outside force P', equal and opposite to the force P, as shown in Fig. 2.

TABLE 2.—DETERMINING THE REACTIONS FOR A SPECIFIED LOADING

Force		Reactions Caused by Radial Forces			Reactions Caused by Tangential Forces		
Fig. 6	Kips	$P_r A_{T_r}$	$P_r A_{V_r}$	$P_r A_{M_r}$	$P_t A_{T_t}$	$P_t A_{V_t}$	$P_t A_{M_t}$
P_{r1}	−2	+0.01220	+0.00080	+0.01830 +0.01644	....	....	....
P_{t3}	+5	....	....	....	−0.22760	−0.05775	−0.34720
P_{r7}	+4	−0.90280	−1.70484	−2.06876	....	....	....
P_{r9}	+3	+0.31092	−1.46997	−0.63483	....	....	....
P_{t13}	+5	....	....	....	−1.54255	+5.11225	+3.14420
P_{r15}	−1	−0.50349	−0.84194	−0.47666	....	....	....
Total	....	−1.08317	−4.01595	−3.14551	−1.77015	+5.05450	+2.79700

However, if the ring is subjected to a system of forces which are by themselves in static equilibrium, it is obvious that there can be no reaction left for the support to exert, in which case the support can have no influence on the stresses in the ring.

The forces acting on a tunnel ring must always be in static equilibrium as the ring would otherwise be subject to accelerating motion. The three reactions found from Eqs. 6 are then simply the reactions exerted by the ring portion to the left of the invert point upon the portion immediately to the right of it, being numerically equal to the thrust, shear, and moment produced in the ring at that point.

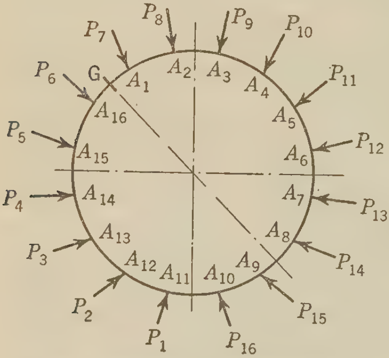

FIG. 7.—SHIFTING OF A-CONSTANTS

11. Reactions at Other Joints.—When the reactions at the invert joint, as well as all the forces acting on the ring, are known, the reactions at any other joint may be determined by treating the ring as a simple beam; but the procedure involves a lot of arithmetical work. An easier method will be explained by an example. In Fig. 7, the ring is assumed to be cut and supported at joint G instead of at the invert joint. Turning the diagram until joint G is at the bottom, one may imagine that the ring end to the right is displaced in the same manner and by the same amounts as was the right-hand end in Fig. 3.

It is evident that the resulting deflection lines will be identical with those obtained in the former case, yielding the same values for the A-constants, except that the latter are now referred to joint G. The effect of this procedure is that the constants are shifted with respect to the forces, as shown in Fig. 7. However, since the tangential components of the forces are considered positive when directed upward—that is, away from the invert joint—the trend of the components P_{t1} to P_{t6} and P_{t9} to P_{t14} with respect to joint G is reversed. This has the same effect on the products $P_t\,A_t$ as if the signs of the constants A_t for points 1 to 6, and 9 to 14, were reversed. Thus, for the moment reaction at joint G,

$$\begin{aligned} M_G = r\,[&P_{r1}\,0.29808 + P_{r2}\,0.51473 \cdots - P_{r15}\,0.21161 + P_{r16}\,0.03838 \\ &- (P_{r6} + P_{r7})\,0.00822 - P_{t1}\,1.02084 - P_{t2}\,0.85897 \cdots \\ &- P_{t6}\,0.01861 - P_{t7}\,0.00060 - P_{t8}\,0.01580 + P_{t9}\,0.06944 \\ &+ P_{t10}\,0.17607 \cdots + P_{t14}\,0.92849 + P_{t15}\,1.05229 + P_{t16}\,1.08744] \quad (11) \end{aligned}$$

The reactions found are those exerted by the support on the ring portion extending counterclockwise from joint G. When the forces are in static equilibrium, the reactions are numerically equal to the thrust, shear, and moment in the ring at that joint, for the reason explained in Section 10.

12. Special Case of Symmetrical Loading.—The loading on tunnel linings is mostly symmetrical with respect to the vertical diameter, which means that $P_1 = P_{16}$; $P_2 = P_{15}$; $\cdots$ $P_8 = P_9$. For use in such cases, Table 1 may be put into a more convenient form by combining the A-constants, by which the radial and tangential components of any two equal forces would have to be multiplied, into a single constant, thereby reducing the number of multiplications. The factor $-\,0.00822$ in Eq. 10 is likewise included in the new constants, which will be referred to as B-constants and identified by the letter B. The B_M-constants for the invert joint, for example, are computed as shown in Table 3.

TABLE 3.—COMPUTATION OF B_M-CONSTANTS FOR INVERT JOINT A

Constant	For radial forces	For tangential forces
B_{M1}	$-0.00915 + 0.18594 - 2 \times 0.00822 = +0.16035$	$-0.00060 + 0.01861 = +0.01801$
B_{M2}	$-0.07891 + 0.47666 = +0.39775$	$-0.01580 + 0.15273 = +0.13693$
....	....	....
....	....	....
....	....	....
B_{M8}	$-0.40670 - 0.21161 = -0.61831$	$-0.92849 + 1.05229 = +0.12380$

The B-constants for any other joint are obtained by the same process of shifting as was described in Section 11, due attention being paid to the signs of tangential components. Again taking joint G for an example (see Fig. 7), the combination of the A_M-constants for equal forces is demonstrated by Table 4.

TABLE 4.—COMPUTATION OF B_M-CONSTANTS FOR JOINT G

Constant	Radial constants, B_r	Tangential constants, B_t
B_{M1}	$+A_{Mr11} + A_{Mr10} = +0.29808 + 0.03838 = +0.33646$	$-A_{Mt11} + A_{Mt10} = -1.02084 + 1.08744 = +0.06660$
....	....	....
....	....	....
....	....	....
B_{M6}	$+0.18594 - 0.46605 - 0.00822 = -0.28833$	$-0.01861 + 0.33612 = +0.31751$
B_{M7}	$-0.00915 - 0.34265 - 0.00822 = -0.36002$	$-0.00060 + 0.17607 = +0.17547$
B_{M8}	$-0.07891 - 0.20065 = -0.27956$	$-0.01580 + 0.06944 = +0.05364$

The B-constants for moment and thrust reactions at the joints A to J are arranged in Table 5, permitting the reactions at any joint to be determined with equal ease, it being noted that the reactions are alike at symmetrical joints, such as B and R in Fig. 4. No B-constants are given for shear reactions; in the rare cases where they are of interest, the loading is usually asymmetrical, and Table 1 must be used.

Table 5 is used in the same way as Table 1: Each force component acting on the left half of the ring is multiplied by the B-constant given in the same line under the proper heading, and the products are added. The moment reaction at any joint may thus be expressed symbolically by the formula:

$$M_N = r\left[\sum(P_r B_N) + \sum(P_t B_N)\right] \dots\dots\dots\dots\dots (12)$$

in which the subscript N stands for any of the letters A to J, identifying the joint, and B_N stands for the corresponding sixteen B-constants in Tables 5(a) and 5(b).

DEFLECTION OF A TUNNEL LINING

13. The next step involves the evaluation of the radial deflection d (Fig. 8) produced at any point q of a ring by a single force P applied at a point p and having the radial and tangential components P_r and P_t, respectively. This deflection is in no way related to the deflections d_{Tr} to d_{Mt} referred to in discussing Fig. 3, which are due to the displacement of one end of the cut ring at the support and which are independent of the stiffness of the ring.

Formulas for d may be derived by means of Eqs. 7, expressions being first obtained for the rectangular deflections Δx and Δy. The calculations (on file in Engineering Societies Library) yield the following equations:

$$\begin{aligned} d = \frac{r^3}{EI}\Bigg\{ & T\left(1 - \cos\beta - \frac{\beta\sin\beta}{2}\right) + V\left(\frac{\beta\cos\beta}{2} - \frac{\sin\beta}{2}\right) \\ & + \frac{M}{r}(\cos\beta - 1) + P_r\left[\frac{\cos\alpha\sin\beta}{2} - \frac{\beta\cos(\alpha-\beta)}{2}\right] \\ & \pm P_t\left[\frac{\sin\alpha\sin\beta}{2} - \frac{\beta\sin(\alpha-\beta)}{2} + \cos\beta - 1\right]\Bigg\} \quad \ldots\ldots(13a) \end{aligned}$$

and

$$\begin{aligned} d = \frac{r^3}{EI}\Bigg\{ & T\left(1 - \cos\beta - \frac{\beta\sin\beta}{2}\right) + V\left(\frac{\beta\cos\beta}{2} - \frac{\sin\beta}{2}\right) \\ & + \frac{M}{r}(\cos\beta - 1) + P_r\left[\frac{\sin\alpha\cos\beta}{2} - \frac{\alpha\cos(\beta-\alpha)}{2}\right] \\ & \pm P_t\left[\cos\beta - \cos(\beta-\alpha) + \frac{\sin\alpha\sin\beta}{2} + \frac{\alpha\sin(\beta-\alpha)}{2}\right]\Bigg\} \quad ..(13b) \end{aligned}$$

The upper sign is used with P_t for values of α between 0 and π, the lower sign for values between π and $2\,\pi$. Eq. 13a covers the ring portion extending clockwise from the invert joint to point p, and Eq. 13b covers the remainder of the ring. In order not to make the formulas too bulky, the deflection is expressed as a function of the reactions at the invert joint.

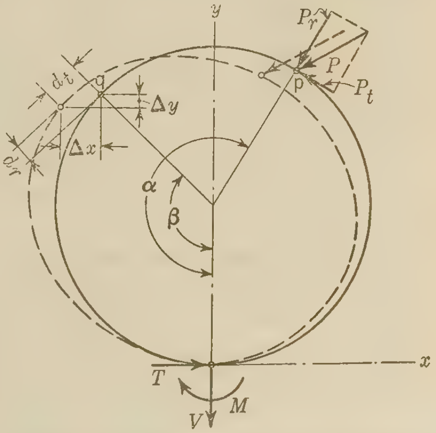

FIG. 8.—RING DEFLECTED BY A SINGLE FORCE

14. C-Constants.—With the aid of tables, the deflection d may be determined with the same ease as are the reactions T, V, and M, by multiplying the components P_r and P_t by a set of constants, which are, in this case, functions of two angles—α, which locates point p at which the force is applied; and β, which locates point q for which the deflection is sought. The new constants will be named C-constants. Their numerical values for all possible combinations of the sixteen values of α and of β identified with points 1 to 16 are given in Table 6. Because of symmetry, the deflections produced at points 9 to 16 by a unit radial or tangential force applied, say, at point 3, must equal those produced at points 8 to 1, respectively, by a unit radial or tangential force applied at point 14. It therefore suffices to register the C-constants for the first eight points, the forces being simply used in reversed order with the constants C_9 to C_{16} (see Fig. 4).

TABLE 6.—C-CONSTANTS FOR RADIAL DEFLECTIONS

(Use Forces in Parentheses for Determining Deflection at Points (9) to (16))

For finding the deflection d produced at any of the sixteen points by a system of forces applied at some or all of the same sixteen points, the respective force components are multiplied by the C-constants in the corresponding column and lines, after which the products are added and their sum is multiplied by the factor $\frac{r^3}{EI}$. It should be noted that the deflection thus found is the one produced in a ring supported as shown in Fig. 2. Only when the forces are in static equilibrium is the restraining influence of the support eliminated, as was explained in Section 10.

15. Example. To Determine the Amount by Which the Length of a Diameter Through Points 3 and 11 on the Ring in Fig. 6 Has Been Changed as a Result of Radial Deflections Due to the Forces Shown.—Assuming $E = 30{,}000$ kips per sq in. and $I = 4$ in.^{4}, then $\frac{r^3}{E\,I} = \frac{729{,}000}{120{,}000} = 6.075$. The computations, given in Table 7, show that the deflections at points 3 and 11 are both positive. Therefore, the diameter is lengthened by the amount $+\,0.376 + 1.957 = 2.333$ in. The lengthening would be the same if the ring were not supported, the forces in the example being in static equilibrium.

16. D-Constants.—In the most common case of a symmetrically loaded tunnel lining, Table 6 may be simplified by combining, in each column, the two constants used with symmetrical and equal forces, just as was done in deriving the *B*-constants. The constants thus obtained will be referred to as *D*-constants. Their numerical values are given in Table 8, which is used in the same manner as Table 6. For symmetrical loading, the radial deflection d at any of the eight points in the left half of the ring may be expressed by the formula:

$$d_n = \frac{r^3}{E\,I}\left[\sum(P_r\,D_n) + \sum(P_t\,D_n)\right] \dots\dots\dots\dots\dots (14)$$

in which the subscript n refers to any of the numbers 1 to 8 designating the point, and D_n stands for the sixteen *D*-constants given for that point in Table 8.

SOIL REACTIONS

17. Effects of Displacement.—When a plane surface of area A' square feet, abutting on soil, is displaced in a normal direction by an amount ρ inches, the soil will resist the displacement with a force F which, on the assumptions made in Section 1 is determined by the formula:

$$F = \rho\,K\,A' \dots\dots\dots\dots\dots\dots\dots\dots (15)$$

in which K stands for the "soil compression constant"; that is, the resisting force in kips exerted by the soil on a surface of 1 sq ft which is displaced normally by an amount of 1 in. The resistance offered by the soil to a lateral displacement of the surface must be presumed to increase, at first, in accordance with a similar formula, the soil being stressed elastically in shear. There is the difference, however, that when the shearing stress at any point reaches a certain limit a slip takes place between the surface and the soil particles, or between the soil particles themselves, causing the stress at that point to be relieved suddenly. Instead of an elastic reaction the result is what is known as friction, representing the integrated value of the resistance offered at all the points of the surface. The shearing stress between soil and surface, therefore, cannot exceed a certain limit determined by the physical characteristics and the normal force pressing them together. The critical value at which the individual slips set in may drop almost to zero, in sandy soils, when the soil is vibrated, the hold of the particles being thereby relaxed momentarily.

18. Tangential Forces.—Lateral shear between a tunnel lining and the abutting soil would evidently give rise to tangential forces. However, in tunneling by the shield method, some special features must be considered in connection with shearing stresses. As the shield is being shoved ahead for the erection of another ring, an annular void is formed around the lining, and the soil, which before the shove surrounded the upper tail end of the shield, is thereby left without a support; but this does not necessarily lead to collapse, as arch action and cohesion combine to keep the bulk of the soil in place until the void has been filled with gravel which is injected from the working chamber by air pressure. As an additional precaution, grout is next forced into the gravel. The mixture of gravel and grout is in a more or less plastic state for a day or two and is thus incapable of resisting shearing forces. For some distance back of the shield the tunnel rings, therefore, are subjected to the major onset of the soil pressure at a time when only radial pressures can be transmitted through the gravel and grout filling. Moreover, any tangential forces developed later eventually spend themselves because of their distribution around the lining, being directed clockwise as well as counterclockwise. During the slips induced by earth tremors and vibrations from the numerous small cave-ins taking place in the surrounding ground as it gradually settles, the forces will thus impel the soil particles in opposite directions. Through these tiny movements the soil particles are crowded together on some parts of the periphery, the pressure between them increasing until it balances the impelling force, at which point the movements come to a stop. The final outcome is that the shearing forces between the soil and the ring surface are replaced by tangential compressive forces in the adjacent ground, the lining at this stage performing a function similar to that of the scaffolding or "centering" used in erecting a masonry arch.

On the basis of the foregoing reasoning, one is justified in disregarding the tangential components of forces due to soil pressure, the only tangential components to be considered being those due to the weight of the lining.

19. Soil Reactions Due to Settlement and Deflection.—Loading a lining embedded in homogeneous soil has the effect of displacing it in the direction of the resultant of the active forces. With the assumed preponderance of downward forces, a symmetrically loaded lining is thus displaced vertically downward, the underlying soil being thereby compressed until soil reactions in sufficient amount to balance the downward forces have been developed.

The soil reactions are not determined by the settlement alone, however. Under the influence of all the forces, active as well as reactive, the lining deflects. The radial deflection at any point will either increase or reduce the compression of the soil at that point, and thus add to or detract from the soil reaction due to settlement.

In Fig. 9, let the solid circle c represent the position of a ring before it is loaded, and the line d its position and shape upon completion of the downward movement. Wherever line d is on the outside of circle c the soil is being compressed; at all other points voids are created which are presently filled as the soil closes in upon the ring under the push of active forces.

Settlement is defined in this paper as the distance δ by which the invert joint A has been displaced. In the imaginary case of a perfectly rigid ring there could be no deflection; the soil reactions would here be due to settlement only and would be confined to the lower half of the ring (see dashed circle in Fig. 9), the middle point of each of the lower segments being displaced radially by an amount $\delta \cos \alpha$. As the flexibility increases, however, deflection becomes more and more of a contributing factor,

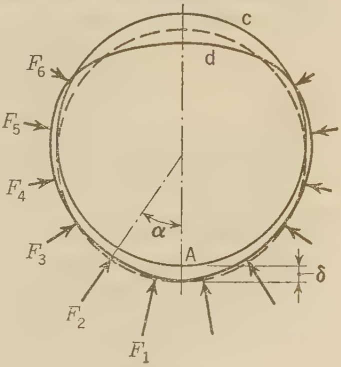

FIG. 9.—DISTRIBUTION OF SOIL REACTIONS

and the range within which the soil is being compressed gradually extends over the upper half of the ring, giving rise to soil reactions of a downward trend, such as F_5 and F_6 in Fig. 9. Far from resisting the active force resultant, such forces add to its intensity, thereby increasing the settlement.

Referring to the left-hand half of a symmetrically loaded ring, let u be the number of segments in which soil reactions are developed (that is, those whose middle points are outside of the circle c in Fig. 9). In most practical cases these segments will be consecutive from the invert point up. For a very stiff ring $u = 4$, whereas for a perfectly flexible one it would be 8. For the rings used in tunnels it is usually 5 or 6; the value is not known definitely beforehand but is tentatively assumed, the result of the computations being relied on to show whether the choice made was a correct one.

Like the active pressures (see Section 7), the soil reactions are replaced by forces F applied at the middle points of the u segments, the forces being considered proportional to the radial displacement at those points. Since the displacement at point n is equal to the amount due to settlement, $\delta \cos \alpha_n$, plus the radial deflection d_n, Eq. 15 yields, for the soil reaction developed in any of the u segments:

$$F_n = (\delta \cos \alpha_n + d_n)\, K\, A' \dots\dots\dots\dots\dots\dots (16)$$

in which A' is the area of the segment as projected on its chordal plane, the width of the segment being, as before, 1 ft.

20. Evaluation of Soil Reactions.—Solving for d_n in Eq. 16 gives, for each of the u segments:

$$d_n = \frac{F_n}{K\, A'} - \delta \cos \alpha_n \dots\dots\dots\dots\dots\dots (17a)$$

Taking into account both active forecs and soil reactions, the same deflection d_n, according to Eq. 14, may be expressed as:

$$d_n = \frac{r^3}{E\, I}\left[\sum_1^8 (P_r\, D_n) + \sum_1^8 (P_t\, D_n) + \sum_1^u (F\, D_n)\right] \dots\dots (17b)$$

If the amounts of the u forces F were known, their substitution in Eqs. 17a and 17b would yield identical values for the deflection d_n. Conversely, by equating the right-hand side of the two equations for each one of the deflections d_n and solving the u simultaneous equations thus obtained, the particular values of the forces F may be determined by which such equality is brought about.[5]

Assuming soil reactions to be developed in segments 1 to 5 only (that is, $u = 5$), the equation for point 2, say, is: $\frac{F_2}{K\, A'} - \delta \cos \alpha_2 = \frac{r^3}{E\, I}[\sum (P_r\, D_2) + \sum (P_t\, D_2) - 0.00657\, F_1 - 0.03747\, F_2 \cdots - 0.01252\, F_5]$; or, by rearranging the terms:

$$- 0.00657\, F_1 - \left(0.03747 + \frac{E\, I}{r^3\, K\, A'}\right) F_2 \cdots - 0.01252\, F_5$$
$$= - \frac{E\, I}{r^3} \cos \alpha_2\, \delta - \sum (P_r\, D_2) - \sum (P_t\, D_2) \dots\dots\dots\dots (18)$$

---

[5] Compare: "Soil Pressure Distribution Along Flexible Foundations," by Anders Bull, *Journal of the Franklin Institute*, June, 1942, p. 562.

Denoting by Q the quantity $\frac{E\,I}{r^3\,K\,A'}$, and by $-\sum(P\,D_n)$ the terms $-\sum(P_r\,D_n) - \sum(P_t\,D_n)$, for brevity, one may write for the complete set of five simultaneous equations:

$$\left.\begin{aligned}
&-(0.00215+Q)\,F_1 - 0.00657\,F_2 - 0.00753\,F_3\\
&-0.00540\,F_4 - 0.00115\,F_5 = -\frac{E\,I}{r^3}\cos\alpha_1\,\delta - \sum(P\,D_1)\ldots\ldots\\
&-0.00657\,F_1 - (0.03747+Q)\,F_2 - 0.05142\,F_3\\
&-0.04068\,F_4 - 0.01252\,F_5 = -\frac{E\,I}{r^3}\cos\alpha_2\,\delta - \sum(P\,D_2)\ldots\ldots\\
&-0.00753\,F_1 - 0.05142\,F_2 - (0.09098+Q)\,F_3\\
&-0.08340\,F_4 - 0.03397\,F_5 = -\frac{E\,I}{r^3}\cos\alpha_3\,\delta - \sum(P\,D_3)\ldots\ldots\\
&-0.00540\,F_1 - 0.04068\,F_2 - 0.08340\,F_3\\
&-(0.09611+Q)\,F_4 - 0.05254\,F_5 = -\frac{E\,I}{r^3}\cos\alpha_4\,\delta - \sum(P\,D_4)\ldots\\
&-0.00115\,F_1 - 0.01252\,F_2 - 0.03397\,F_3 - 0.05254\,F_4\\
&-(0.04653+Q)\,F_5 = -\frac{E\,I}{r^3}\cos\alpha_5\,\delta - \sum(P\,D_5)\ldots\ldots\ldots
\end{aligned}\right\}\ldots(19)$$

On the left-hand side of the equality signs the coefficients for the unknown forces F are simply the D-constants given in the first five lines and columns of Table 8(a), except that the quantity $-Q$ has been added to the D-constants forming the diagonal row (underscored in Table 8(a)).

On the right-hand side all the quantities, except the settlement δ, are fixed by the dimensions and other data given in the specific case. Hence, in solving for the forces F expressions are obtained having the form:

$$F_n = C'_n\,\delta + C''_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(20)$$

in which C'_n and C''_n are numerical quantities. From these expressions the unknown δ is determined by the conditions of equilibrium requiring that the sum of the vertical components of the soil reactions, $\sum_1^u(F\cos\alpha)$, must balance the sum of the vertical components of the active forces, or: $\sum_1^u(C'\,\delta\cos\alpha) + \sum_1^u(C''\cos\alpha) = -\sum_1^8(P_r\cos\alpha) - \sum_1^8(P_t\sin\alpha)$; from which:

$$\delta = \frac{-\sum_1^u(C''\cos\alpha) - \sum_1^8(P_r\cos\alpha) - \sum_1^8(P_t\sin\alpha)}{\sum_1^u(C'\cos\alpha)}\ldots\ldots\ldots(21)$$

Substituting this value for δ in Eq. 20, the forces F are determined. The active forces P being known, the moments and thrusts in the lining are found by means of Table 5, and from the values thus obtained the stresses are computed.

PRACTICAL APPLICATION

21. Specified Conditions.—The proposed method will now be applied to an actual case. A tunnel lining will be designed for the identical conditions prevailing for a short stretch of tunnel, forming part of the Sixth Avenue line of the Independent Subway System of New York, N. Y. As the latter was designed by the customary method the results obtained by the two methods may be compared.

The crown of the lining is 36 ft below the ground surface and 27 ft below the ground-water level, as shown in Fig. 10. The governing data are:

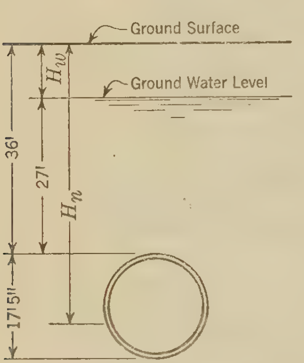

FIG. 10.—CROSS SECTION OF TUNNEL

Radius r_e of the outer surface, in feet.	8.71
Radius r of the neutral circle, in inches	102.1
Assumed Weight W, in Kips per Cubic Foot of—	
Soil above ground-water level	0.100
Soil below ground-water level	0.125
Water	0.063

Denoting by H_w and H_n, respectively, the depth below ground surface of the water table and any of the points 1 to 16 in Fig. 4, the vertical and horizontal pressures p, in kips per square foot at points 1 to 8 (or 16 to 9), are determined by the following formulas, pressures directed upward being considered positive:

Vertical pressure at points 1 to 4—

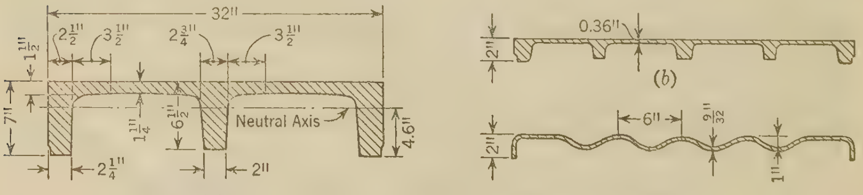
$$p_V = +0.063\,(H_n - H_w) \qquad (22a)$$

vertical pressure at points 5 to 8—

$$p_V = -0.100\,H_w - 0.125\,(H_n - H_w) \qquad (22b)$$

and horizontal pressure at points 1 to 8—

$$p_H = +\frac{0.100\,H_n}{3} + 0.063\,(H_n - H_w) \qquad (22c)$$



(a) (c)

FIG. 11.—AXIAL CROSS SECTION OF TUNNEL SEGMENTS

The lining is of cast iron for which a modulus E of 12,000 kips per sq in. is assumed. It has an inner covering of concrete which, however, is disregarded as to strength. Fig. 11(*a*) shows an axial cross section of the segments used whose physical properties per foot of tunnel are:

Area A, deducting area of holes (square inches)	27.6
Gross moment of inertia I (in.^{4})	136
Net Section Modulus S (in.^{3})—	
Intrados	23.4
Extrados	55.0
Weight W, including concrete (kips per square foot of lining surface)	0.22
Soil compression constant K (assumed)	12

22. Active Forces.—By means of Eqs. 22, the vertical and horizontal pressures at points 1 to 8 of the lining (Fig. 4) are determined as in Cols. 3 and 4, Table 9. The pressures are multiplied by the projected area of each segment (1 ft wide) in a horizontal and vertical plane, respectively, and the amount $-\frac{2\pi \times 8.71 \times 0.22}{16} = -0.752$ kip is added to each vertical force for the weight of the lining, yielding the values given in Cols. 7 and 8, Table 9. The forces P_r (Col. 9) are the sums of the radial components of each force pair, P (vertical) $\cos\alpha + P$ (horizontal) $\sin\alpha$, whereas the forces P_t, as stated in Section 18, are the tangential components of the weight of the lining only, $-0.752 \sin\alpha$. Points 1 to 8 being located as in Fig. 4, the respective values of $\cos\alpha$ and $\sin\alpha$ are:

TABLE 9.—COMPUTATIONS FOR DETERMINING RADIAL AND TANGENTIAL FORCES

Point	Depth H_n, in ft	Pressure, in Kips per Sq Ft		Projected Area, in Sq Ft		Forces, in Kips			
		Vertical	Horizontal	Horizontal	Vertical	Vertical	Horizontal	P_r	P_t

$$\cos\alpha_1 = -\cos\alpha_8 = \sin\alpha_4 = \sin\alpha_5 = 0.98079$$
$$\cos\alpha_2 = -\cos\alpha_7 = \sin\alpha_3 = \sin\alpha_6 = 0.83147$$
$$\cos\alpha_3 = -\cos\alpha_6 = \sin\alpha_2 = \sin\alpha_7 = 0.55557\ .$$
$$\cos\alpha_4 = -\cos\alpha_5 = \sin\alpha_1 = \sin\alpha_8 = 0.19509$$

23. Simultaneous Equations.—The values found are substituted for P_{r1} to P_{t8} in the first column of Table 8, and each force is multiplied by the eight D-constants in the same line, the products being entered, in Table 10, in the same order as the D-constants. The products are next added up vertically, the sums representing the terms $\sum(P\,D_n)$ on the right-hand side of Eqs. 19.

The coefficients for δ are found by multiplying the quantity $\dfrac{E\,I}{r^3} = \dfrac{12{,}000 \times 136}{1{,}064{,}331} = 1.533$ by the successive values, $\cos\alpha_1$, $\cos\alpha_2$, $\cdots$.

Since each of the sixteen segments is spanning an angle of 22° 30′, its chordal projection has an area of: $A' = 2\,r_o \sin\dfrac{22.5°}{2} = 3.40$ sq ft, from which $K\,A' = 12 \times 3.40 = 40.80$; and $Q = \dfrac{E\,I}{r^3\,K\,A'} = \dfrac{1.533}{40.80} = 0.03758$.

The lining shown in Fig. 11(a) is considered relatively stiff and, therefore, the low value of 5 is assumed tentatively for u. Consequently there are five simultaneous equations for determining the soil reactions F, the equations, according to the foregoing, taking the form:

$$\left.\begin{array}{l}
-\,0.03973\,F_1 - 0.00657\,F_2 - 0.00753\,F_3 - 0.00540\,F_4 - 0.00115\,F_5 \\
\qquad = -\,1.50390\,\delta - 0.08900 \ldots\ldots\ldots\ldots \\
-\,0.00657\,F_1 - 0.07505\,F_2 - 0.05142\,F_3 - 0.04068\,F_4 - 0.01252\,F_5 \\
\qquad = -\,1.27500\,\delta - 0.55320 \ldots\ldots\ldots\ldots \\
-\,0.00753\,F_1 - 0.05142\,F_2 - 0.12856\,F_3 - 0.08340\,F_4 - 0.03397\,F_5 \\
\qquad = -\,0.85190\,\delta - 0.94340 \ldots\ldots\ldots\ldots \\
-\,0.00540\,F_1 - 0.04068\,F_2 - 0.08340\,F_3 - 0.13369\,F_4 - 0.05254\,F_5 \\
\qquad = -\,0.29920\,\delta - 0.94630 \ldots\ldots\ldots\ldots \\
-\,0.00115\,F_1 - 0.01252\,F_2 - 0.03397\,F_3 - 0.05254\,F_4 - 0.08411\,F_5 \\
\qquad = +\,0.29920\,\delta - 0.49090 \ldots\ldots\ldots\ldots
\end{array}\right\}\ldots(23)$$

24. Soil Reactions.—The F-values satisfying Eqs. 23 are listed in Cols. 4 and 5, Table 11, which also shows the steps by which they are reduced to numerical terms. Proceeding in accordance with Eq. 21 and selecting proper values from

Table 11, δ is computed as: $\delta = \frac{-5.156 + 9.769 + 3.010}{+48.857} = +0.156$ in.; and finally, by substitution for δ in Col. 6, the soil reactions are determined as given in Col. 10, Table 11. The sum of their vertical components $F \cos \alpha$ (Col. 11, Table 11) is $+12.778$, which tallies with $-\sum(P_r \cos \alpha) - \sum(P_t \sin \alpha) = +9.769 + 3.010$, as required for equilibrium (see derivation of Eq. 21).

It remains to be ascertained whether the tentative assumption, $u = 5$, is correct. For that purpose the D-products of the soil reactions are determined in Table 12, the F-values being substituted for the forces P in Table 8. To the sums of these products in line 6, Table 12, are added the amounts obtained for $\sum(P\,D)$ in Table 10, and the totals (line 8) are multiplied by the factor $\frac{r^3}{E\,I} = \frac{1{,}064{,}331}{12{,}000 \times 136} = 0.6522$, yielding the deflections, in inches, at points 1 to 8 (line 9, Table 12). Adding to each deflection the radial displacement due to settlement, $\delta \cos \alpha_n$, the amounts are found (line 10) by which the points have moved out from their neutral position on circle c in Fig. 9. Only at points

where this amount is positive are soil reactions developed. Table 12 shows that the displacement (line 11) is positive at points 1 to 5 only, proving that the tentative assumption, $u = 5$, is correct. This table provides a rigorous check on the correctness of the arithmetical work since, according to Eq. 16, the radial displacement at any of the points 1 to 5, multiplied by the factor $K A' = 40.8$, should give the soil reaction at that point. As shown in line 12, Table 12, this is the case within the limits of unavoidable error.

25. Bending Moments and Thrusts.—The bending moments and thrusts produced in the ring may now be determined, as shown in Table 13, active forces and soil reactions having been treated separately. The procedure is the same as in finding the deflections: Each force is multiplied by the nine B_M-constants appearing in the same line in Table 5(a), and the products, entered in the order of the constants, are added. The product sums $\sum(P\ B)$ due to the active forces are then added to those due to soil reactions $\sum(F\ B)$ (Table 13(b)), and the sums are multiplied by the radius $r = 102.1$ in. Thus, for the moment at the various joints, the amounts given in the last line of Table 13(b) are obtained.

The thrusts are determined only for joints F and J, where the stresses reach critical values. The last two columns of Table 13 are used for that purpose, the products being those of the forces in the B_T-constants of Tables 5(*c*) and 5(*d*).

Table 13 illustrates what was stated in Section 2 in regard to the sensitive state of moment balance in a ring. At joint B (Fig. 4), for example, the B_M-products due to forces P_{r3} and P_{r8} are 6.791 and $-$ 14.005, respectively, as compared to the total of 0.044.

26. Critical Stresses.—The design of a lining is governed by the maximum stresses caused by bending and thrust combined, the negative thrust due to the increased air pressure in the working chamber during construction being also considered. With a cross section like the one in Fig. 11(*a*), the greater part of the maximum stresses are due to bending, the fibers most highly stressed being those in the ribs at the intrados.

According to Table 13(*b*), the moment in the present case reaches a positive maximum at joint F, and a negative maximum at joint J. For the properties given in Section 21, therefore, the respective bending stresses σ_b, expressed in kips per square inch, are: $\sigma_{bF} = \frac{51.2}{23.4} = -2.19$; and $\sigma_{bJ} = \frac{58.2}{23.4} = +2.49$—a positive sign indicating tension and a negative sign compression.

The thrusts at joints F and J are shown in Table 13(*b*) to be 37.7 kips and 35.5 kips, respectively, which yield, for the corresponding stresses σ_t: $\sigma_{tF} = \frac{37.7}{27.6} = -1.37$; and $\sigma_{tJ} = \frac{35.5}{27.6} = -1.29$.

The internal air pressure is usually made equal to the hydrostatic pressure of the ground water at the level of the tunnel axis. For a pressure head of 35.7 ft and an effective radius of 8.5 ft, the tensile force produced in the lining is $35.7 \times 0.063 \times 8.5 = 19.1$ kips, resulting in a stress of $\sigma_a = \frac{19.1}{27.6} = +0.69$.

Accordingly, the maximum tensile stress, occurring at joint J, is $\sigma_J = +2.49 - 1.29 + 0.69 = +1.89$ kips per sq in. The compressive stress at joint F does not reach its maximum until the internal air pressure is removed, when $\sigma_F = -2.19 - 1.37 = -3.56$ kips per sq in.

As the usual working stresses for cast iron are 4.0 kips per sq in. in tension and 20.0 kips per sq in. in compression, the stress at joint J is only 47% and that at joint F only 18% of the respective allowable values.

The obvious conclusion is that the lining, as designed, is too heavy; but to what extent its cross section should be reduced in order to meet the requirements of economy is not immediately apparent. A reduction in area also involves the moment of inertia, and as the latter enters into Eqs. 19 by which the soil reactions are determined, the pressure distribution will not remain the same as before. This affects the moments in particular because of their extreme sensitiveness to changes in the pressure distribution.

27. Economic Cross Section.—For investigating the question raised in the preceding section assume the moment of inertia of the lining, per foot of tunnel, to be reduced in a geometric progression to 1/4, 1/16, 1/64, etc., of its original value of 136 in.^{4}, the reduction being effected by shrinking the radial dimensions of the cross section, Fig. 11(*a*). Such shrinking causes the section modulus and area to be reduced correspondingly to $(1/4)^{2/3}$, $(1/16)^{2/3}$, $(1/64)^{2/3} \cdots$ and $(1/4)^{1/3}$, $(1/16)^{1/3}$, $(1/64)^{1/3} \cdots$ of the original amounts of 23.4 in.^{3} and 27.6 in.^{2}, respectively. The soil reactions, moments, thrusts, and critical stresses are then determined for each of the reduced sections by means of the method explained.

TABLE 14.—EFFECTS OF VARIATIONS IN THE MOMENT OF INERTIA OF THE TUNNEL LINING

Omitting the arithmetical work for the sake of brevity, the results are tabulated for ready comparison in Table 14. The substantial change in the moments attending a relatively slight variation in the soil reactions should be noted.

The effects of a successive reduction in cross section are more strikingly revealed in Fig. 12, where the moments obtained for the several cross sections have been plotted against the developed periphery of the left half of the lining, each graph being marked with the corresponding value of *I*. The thrusts, which vary but slightly, have been plotted for the largest and smallest cross section only.

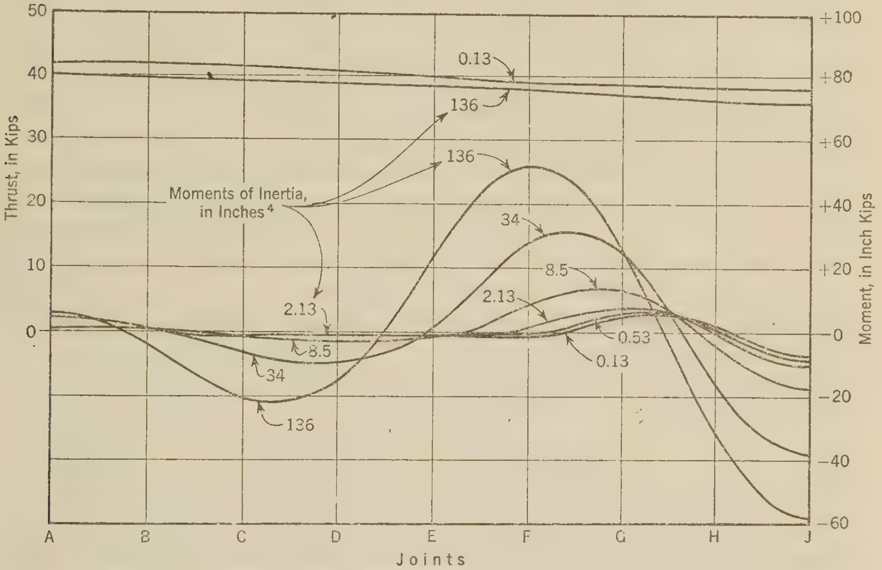

FIG. 12.—MOMENTS AND THRUSTS RELATED TO THE MOMENT OF INERTIA OF A TUNNEL LINING

Fig. 12 shows that, when the cross section is reduced beyond a certain point, the moments in the lower portion of the lining practically disappear, the only moments remaining being those produced in the arch formed by the top portion, where there are no soil reactions. In this respect the results differ sharply from those obtained by the customary method of analysis, according to which the moment at the invert joint is only slightly smaller than that at the crown.

When the reduction is accomplished, as in this case, through radial shrinking of a cross section of a given shape the relatively most economic section is evidently that at which one of the critical stresses reaches its allowable limit, although this does not necessarily mean that it is the most economic section attainable. For determining the relatively most economic section, the critical stresses, section moduli, and cross section areas in the last four columns of Table 14 have been plotted against the corresponding moments of inertia, as shown in Fig. 13, a logarithmic scale being used.

Referring to the curves drawn in solid lines, representing the case of a cast-iron lining, in order to bring the tensile stress at joint J up to the allowable 4 kips per sq in. the moment of inertia must be reduced to 3.3 in.^{4}, corresponding to an area of 8.0 sq in. This would indicate that with a lining as actually designed more than 70% of the cast iron is wasted.

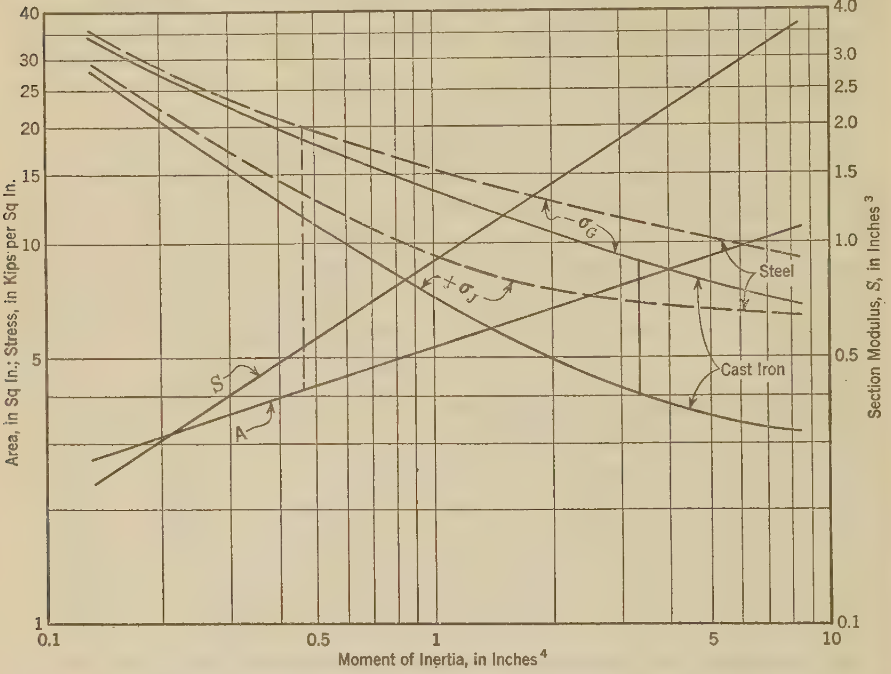

FIG. 13.—ECONOMIC SECTION DETERMINED BY A GRAPHIC INTERPOLATION

Theoretically, the cross section shown in Fig. 11(*b*) would meet requirements as regards strength. Practically, however, the casting of large segments of such a slender shape is apt to present difficulties, the cylindrical portion or "skin" being less than 3/8 in. thick.

28. Steel Versus Cast Iron.—By making the lining of steel, not only is the fabrication of the segments simplified, but a still further reduction of the cross section is made possible because of the greater tensile strength of that material. The consequent lighter weight of the segments will make them easier to handle. They may be made to span wider angles, so that the number of joints per ring may be reduced and erection facilitated. Because of the high ductility of steel, cracking of segments, always a source of serious trouble, is eliminated. Although cast iron is less apt to rust, a number of inexpensive treatments are now available by which steel surfaces are rendered inert toward oxygen. Steel has proved entirely satisfactory as a lining material in many instances, both in the United States and elsewhere, so one may rather wonder at the continued use of cast iron for shield-driven tunnels, when for most other structures it has long ago been replaced by steel.

On account of the higher modulus of elasticity of steel (30,000 kips per sq in., as compared to 12,000 for cast iron), a steel lining will be stiffer than a cast-iron one of the same dimensions, the effect being the same as if its moment of inertia were increased to 30,000/12,000 = 5/2 times its actual value, resulting in higher bending moments and slightly lower thrusts, as shown in Fig. 12. The stresses produced are easily determined from the data in Table 14, observing that the actual moment of inertia corresponding to the moments and thrusts in any column is thus only 2/5 = 0.4 times the value given for I in that column and that, therefore, the section modulus S is to be multiplied by $0.4^{2/3} = 0.542$, and the area A by $0.4^{1/3} = 0.737$ when computing the stresses.

The critical stresses thus obtained for a steel lining are represented by the two curves drawn in dashed lines in Fig. 13. If working stresses of ± 20 kips per sq in. are allowed, the strength of the lining is no longer governed by the tensile stress at joint J, but by the compressive stress at joint G, the value − 20 corresponding to a moment of inertia of 0.47 in.^{4}, a section modulus of 0.53 in.^{3}, and an area of 4.1 sq in. per foot of tunnel.

The cross section shown in Fig. 11(*c*) approximately meets these requirements. It has a moment of inertia of 0.58 in.^{4}, a section modulus of 0.79 in.^{3}, and an area of 3.8 sq in. per ft. The maximum stresses produced under the loading conditions assumed will be − 18.0 kips per sq in. at joint G, and + 7.6 kips per sq in. at joint J. The higher economy attained as compared to the section derived from Fig. 13 is due to a more favorable distribution of the material about the neutral axis.

The foregoing results are in good agreement with the sections used in large corrugated steel culverts under comparable loading conditions, details of which have been published. A culvert of 15-ft diameter was thus installed in 1939 under an embankment of the Denver and Salt Lake Railway.[6] It has served satisfactorily under a 42-ft cover of dry fill and superimposed train load. The embankment is 20 ft wide at the top, with slopes 1 on 1.5. According to data furnished by M. G. Spangler,[7] M. Am. Soc. C. E., the corrugations have a depth of 2 in. and a spacing of 6 in., the thickness of the plates varying from 3/16 in. at the intake and outlet to 9/32 in. at the center of the embankment. The latter thickness gives a moment of inertia of 2.3 in.^{4}, a section modulus of 2.0 in.^{3}, and an area of 4.3 sq in. per ft.

Other corrugated steel culverts of 13.75-ft and 15-ft diameters with covers of 57 ft and 27 ft, respectively, were built in connection with the Lake Mead Road project.[8] For the smaller diameter the same type of plates was used as for the aforementioned railroad culvert; for the larger diameters, plates of somewhat lighter size were used.

A paper by Karl Terzaghi, M. Am. Soc. C. E., "Liner-Plate Tunnels on the Chicago Subway,"[9] may also be referred to in this connection. Discussing cases in which the soil conditions as well as the shape of the tunnel are different from those considered in the present paper, Professor Terzaghi, on empirical premises, arrives at the same conclusion in regard to the excessive strength of the linings required by the customary method of design because of its failure to make proper allowance for the soil reactions.

---

[7] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Eng. Experiment Station, Iowa State College, Ames, 1941.

[8] "Drainage Problems on New Lake Mead Road," by George D. Whittle, *Civil Engineering*, April, 1942, p. 196.

[9] *Transactions*, Am. Soc. C. E., Vol. 108 (1943), p 970.

Lieutenant-Commander Spangler[10] calls attention to what he terms "deferred deflection," representing the slow, additional deflection observed in culverts after the loading has reached its maximum. The writer considers this phenomenon as being in accord with the views expressed in Section 18 regarding the gradual transfer of the tangential soil pressures from the lining to the surrounding ground. As the pressures are directed outward, both in the upper and lower half of the lining, such transfer would naturally cause an outward yielding of the soil at either end of the horizontal diameter and a sagging at the crown, without a corresponding increase in radial loads, the flexible lining adjusting itself to these movements.

29. Construction Features.—In view of the light cross section required when a lining is made of steel, segments of the rolled or pressed type would be the most suitable ones. The skin and the curved ribs are here formed from a single plate, the straight, axial ribs being subsequently welded on in the shop. Bolts (which are now used for joining the segments to one another) may conceivably be dispensed with, as the small thickness of the flanges makes them particularly well adapted to resistance welding. With the welding transformer mounted at the end of the erector arm a series of "shot welds" may be produced through the flanges in a fraction of the time needed for bolting them together. By overlapping the welds, the flanges may be joined by a continuous seam of fused metal insuring a waterproof joint requiring no calking, except at corners. As no arc or flame is used with this kind of welding, no fire hazard is involved.

One objection that may be raised to reducing the weight of the lining is that a large cross section is necessary for resisting the pressure of the shoving jacks. There seems to be no good reason, however, for making material that is needed only during the erection of a tunnel an integral part of it, something that is being done in no other type of structure. A more satisfactory solution would be to use scaffolding, as it could be reclaimed after having served its purpose. The scaffolding should be tied in with the lining so as to effect a gradual transfer of the jack pressure to the surrounding ground; some distance back of the shield it would then no longer be stressed during a shove, so that it could be detached and used over again. Furthermore, it should leave the joints in the ring to be welded free and easily accessible.

Although it is true that such a type of scaffolding has yet to be developed, it may also be stated that, thus far, there has been no demand for it, as a heavy lining has been considered essential on account of the soil pressures. Once the fallacy of this contention is recognized, a solution of the problem presented by the scaffolding may be confidently expected.

Conclusions

In designing the linings of shield-driven tunnels, the erroneous assumption is currently made that the vertical soil reactions are uniformly distributed over the horizontal diameter of the lining. When, instead, their distribution is determined by rational methods it is found that the stresses in the lining are much lower than heretofore presumed, permitting the cross section to be substantially reduced. Such reduction, because of the consequent increase in the flexibility of the lining, has the effect of still further reducing the stresses. By successive reductions and interpolation of the values obtained for the stresses, an economic cross section may be determined.

---

[10] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Eng. Experiment Station, Iowa State College, Ames, 1941, p. 61.

Steel is more economical than cast iron as a lining material because of its higher tensile strength. Steel segments are simpler to manufacture and may be joined to one another by means of resistance welding, thus facilitating erection and waterproofing of the tunnel.

In order that the prospective savings in material and labor may be realized, however, a suitable form of scaffolding must first be developed.

APPENDIX

NOTATION

The letter symbols, used in this paper, conform essentially to American Standard Symbols for Mechanics, Structural Engineering and Testing Materials[11] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932. Symbols for soil characteristics conform to "Soil Mechanics Nomenclature."[12] Subscript n, standing for any number from 1 to 16, is used for identifying any one of the sixteen imaginary segments of a tunnel ring; and subscript N, standing for any letter from A to R, serves to identify the joint between any two such segments (see Fig. 4). Subscripts T, V, and M signify "thrust," "shear," and "moment," respectively; and r and t signify "radial component" and "tangential component," respectively. Symbols are defined where they first appear; only those entering the formulas used in solving specific problems are listed in this Appendix.

A_N = a constant used in determining reactions at the invert joint A;

A = axial cross section of lining per foot of tunnel, in square inches;

A' = area of a segment as projected on its chordal plane, in square feet;

B_N = a constant used with symmetrical loading in determining reactions at any of the joints A to J;

C_n = a constant used in determining radial deflection at any of the points 1 to 16;

D_n = a constant used with symmetrical loading in determining radial deflection at any of the points 1 to 8;

d, d_r = radial deflection, in inches; positive when directed away from center of tunnel;

E = modulus of elasticity, in kips per square inch;

---

[11] ASA—Z10a—1932.

[12] *Manual of Engineering Practice No. 22*, Am. Soc. C. E., 1941.

F = soil reaction, in kips; positive when directed toward center of tunnel;
H_n = depth of any point n below ground surface, in feet;
H_w = depth of water table below ground surface, in feet; considered negative when ground surface is submerged;
I = average moment of inertia of lining per foot of tunnel, in inches^4;
K = soil compression constant, in kips per square foot per inch;
M = moment reaction, in inch-kips; positive when stretching outer fibers of lining;
P = active load, in kips; the radial component P_r is positive when directed toward center of tunnel; the tangential component P_t is positive when directed upward;
Q = a constant = $\frac{E\,I}{r^3\,K\,A'}$;
r = radius of neutral circle of lining, in inches;
r_o = radius of outer surface of lining, in feet;
S = section modulus of lining per foot of tunnel, in inches^3;
s = arc measured on neutral circle from point A to point x,y (see Eqs. 7);
T = thrust reaction, in kips; positive when due to compression;
u = number of segments in which soil reactions are developed;
V = shear reaction, in kips; positive when it tends to produce clockwise rotation;
X,Y = rectangular coordinates of a given point; X is positive to the right of the vertical diameter of the lining; Y is positive above a tangent to the neutral circle in point A;
x,y = rectangular coordinates of a moving point;
α, β = angles measured from point A to points p and q on neutral circle;
δ = settlement, or vertical displacement of invert point A due to loading, in inches; positive when directed downward.

DISCUSSION

J. A. VAN DEN BROEK,[13] M. AM. SOC. C. E.—Mr. Bull's impressive paper deals with different subjects, three, to be exact—soil mechanics, elasticity, and theory of strength—all in relation to his main topic, that of lining stresses in shield-driven tunnels. The writer wishes to confine his comments to only one of these subjects, that of theory of strength, in Sections 4 to 12, inclusive.

For some fifty years or more designers have been familiar with the fact that an elastic curve, suitably interpreted, is an influence line. Much depends, however, on the "suitable interpretation." The use of elastic curves as influence lines for closed rings is new, at least to the writer, and in itself constitutes a worthy contribution to the theory of strength. In addition to presenting a difficult subject simply, lucidly, and in very readable language, Mr. Bull has done a vast amount of work, very little of which appears on the surface. All his computations, which must be voluminous, are on file in the Engineering Societies Library. This is eminently proper. Had they been published few would have checked them, and even then few would have been absolutely sure of the results. Mr. Bull offers tables which are of the greatest value. They are classic in the sense that they seem to provide the last word in regard to the analyses of circular rings of uniform cross section.

Mr. Bull has apparently neglected one thing, inclusion of which some of his readers would have appreciated. He has failed to call attention to some obvious partial checks of his tables which appear readily at hand. This may be understandable. Apparently Mr. Bull set himself the task of condensing enough material for a book within the space of only thirty pages. No doubt he applied numerous checks as he progressed. Possibly he regards some of them as self-evident.

The writer has applied Mr. Bull's tables to the solution of certain problems, the answers for which were known in advance. This, to him, serves to inspire confidence both in Mr. Bull's logic and in the correctness of the values given in the tables. Not that Mr. Bull's logic needs confirmation. On the contrary, it is as clear as a crystal and rings true. Especially, Section 10 seems a master stroke. If Mr. Bull will realize that the writer has full faith in his own logic, yet questions all his own computations, he will pardon him, he trusts, when he refuses to accept any tabular data on faith. Typographical errors sometimes occur, and, if tables are to stand the test of time, a great deal of independent checking appears justified.

Below are offered a few such simple checks:

1. The formula for the bending moment in a ring subject to a number of equal and evenly spaced radial forces P is

$$M_A = \frac{P\,r}{2}\left(\frac{1}{\sin\phi} - \frac{1}{\phi}\right) \quad \ldots\ldots\ldots\ldots (24)$$

---

[13] Prof., Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

in which ϕ is one half the angle between the forces. If this formula is applied to Fig. 4, with $\phi = 11° 15'$, $M_A = 0.0164\,P\,r$. Adding Col. A_{Mr}, Table 1 (without including the two terms $-$ 0.00822—apparently Mr. Bull's solution for the same problem), the result is also $M = 0.0164\,P\,r$. To the writer, this constitutes one partial check. Mr. Bull's correction factor of 0.00822 seems sound and is very ingenious indeed.

2. The addition of all the entries in Col. A_{Mr}, Table 1, including the two correction factors $-$ 0.00822, gives zero for an answer. This was explained in the text and is somewhat of a check. When it is considered, however, that Table 5 was obtained from Table 1, that it involves a regrouping of the constants in Table 1 nine separate times, and that each time the columns for moment reactions caused by radial loading add up to zero, then it is hard to conceive how any typographical or other error may be hidden without being detected.

3. As a third independent check that the values in the tables are numerically correct, apply them to the evaluation of the moment at the bottom of a circular pipe of constants E and I, flowing full with water and supported radially by two reactions, each 33° 45′ removed from the vertical diameter and therefore corresponding to P_2 and P_{15} in Fig. 4. The so-called exact solution may be obtained by superimposing Case V and Case VIII[14] in the writer's book, "Elastic Energy Theory." This solution involves the assumptions of elasticity, constants E and I, and constant circular shape which are the same assumptions as those involved in Mr. Bull's theory.

Substituting $\phi = \pi$ in Case V, $M_A = +\,0.23873\,W\,r$, in which W is the weight of the water.

Substituting $\phi = \pi$ and $\phi_1 = \frac{3}{16}\pi = 0.58905$ radians in Case VIII,

$M = -\,0.23919\,W\,r$. Superposing these two values, $M_A = -\,0.00046\,W\,r$. This value checks the value shown[15] in the right half of Fig. 14, in which M_A is shown as substantially zero for the case of $\phi_1 = 33° 35'$.

In evaluating, by means of the tables, the moment at the bottom point of a ring (point A, Fig. 4) loaded with hydrostatic pressure and concentrated radial reactions R applied in the middle of Sections 2 and 15, Fig. 4, the value of the P-forces was computed as follows: The hydrostatic pressure, say, at the midpoint of segment 6, is $w\,r\,(1 + \cos\phi_6) = w\,r\,(1 + \cos 123° 45') = 0.44443\,w\,r$ (the relation between the unit weight of water, w, and the total weight of water, W, is $W = \pi\,r^2\,w$). Considering this pressure to act uniformly over segment 6, $P = 0.44443\,w\,r \times \frac{\pi\,r}{8} = \frac{0.44443\,W}{8}$. At segment 2 the reaction R is of opposite sense to that of the P-forces and equals $\frac{W}{2\cos 33° 45'} = \frac{W}{1.66294}$. The hydrostatic force P_2 acting on segment 2 would be $w\,r\,(1 + \cos 33° 45')$

---

[14] "Elastic Energy Theory," by J. A. Van den Broek, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1942, pp. 128–129.

[15] "Elastic Energy Theory," by J. A. Van den Broek, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1942, p. 136, Fig. 57.

$\times \frac{\pi r}{8} = \frac{1.83147\ W}{8}$. The resultant force acting on segment 2 would be $R - P_2 = 0.372410\ W$. The other P-forces are computed similarly. Multiplying these values for P-forces, thus obtained, by their corresponding values listed in Col. A, Table 5, for moment reactions caused by radial components, and adding this entire column, with due regard for signs, $M_A = 0.000446\ W\,r$. This is in substantial agreement with the value of $0.00046\ W\,r$ obtained by the so-called exact analysis.

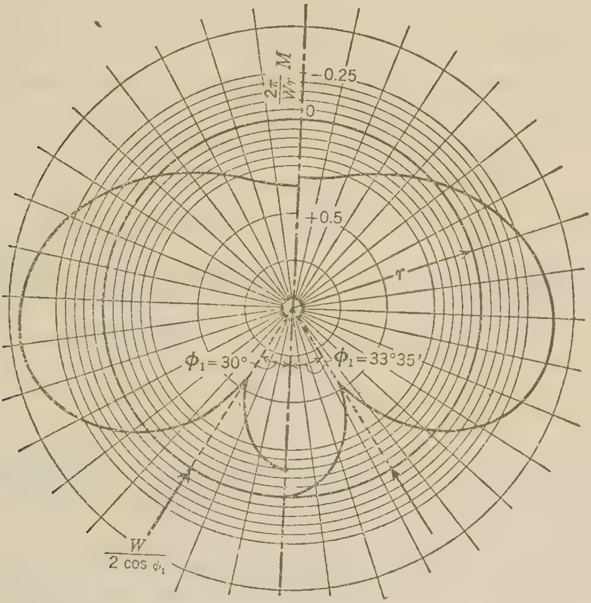

FIG. 14.—MOMENT DIAGRAMS, SYMMETRICAL ABOUT CENTER LINES, FOR CYLINDRICAL SHELLS FLOWING FULL WITH RADIAL SUPPORTS

4. If a circular pipe full of water, supported at its bottom, point A, is considered, force P_2 is included in the tabulation and the reaction R is disregarded. Table 5 then yields $M_A = 0.23877\ W\,r$, which compares with the value of $M_A = 0.23870\ W\,r$ obtained by the so-called exact analysis developed previously.

5. Fig. 15 represents a ring subject to sixteen uniformly distributed tangential forces P. The equation for the moment in this ring, at any point, is

$$M = \frac{T}{2\pi}(\phi - 2\sin\phi) \qquad \text{.....................(25)}$$

Thus, at point A the moment is

$$M_A = \frac{16\ P\,r}{2} = 8\ P\,r \qquad \text{.....................(26)}$$

Adding all the coefficients in Col. A_{Mt}, Table 1, provided they all are given the same sign, and multiplying by $P\,r$, the moment M_A is 7.99999 $P\,r$, which again is a beautiful check. As to signs, the writer knows no rule in regard to elastic curves interpreted as influence lines other than the one which states that, when force and deflection are of the same direction and sense, their product is positive. When they are of the same direction but opposite sense, their product is negative. It would seem that Mr. Bull followed some other rule which does not appear to be explained in the paper. Some more light on this very crucial matter would be much appreciated.

6. The shear stresses in an aeroplane fuselage act tangential to the surface (see Fig. 16) and are given by the expression $\frac{W \sin \phi}{\pi\, r\, t}$, in which t is the thickness of the ring. The equation for the bending moment at any point [16] is

$$M = \frac{W\,r}{2\,\pi}\left(1 - \phi \sin \phi - \frac{\cos \phi}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots (27)$$

Therefore,

$$M_A = \frac{3\,W\,r}{4\,\pi} = 0.2387\,W\,r \quad \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

The shear stress at the midpoint of segment 6, for example, is $\frac{W \sin}{\pi\, r\, t}$ (56° 15′) $= \frac{0.83147\,W}{\pi\, r\, t}$. Assuming this stress to act uniformly over the entire segment,

$$P_{6t} = \frac{0.83147\,W}{\pi\, r\, t} \times \frac{\pi\, r\, t}{8} = \frac{0.83147\,W}{8} \quad \ldots\ldots\ldots\ldots (29)$$

Computing the other P_t forces in similar manner, multiplying them by the coefficients for A in Table 5(*b*), and adding the resulting numbers, $M_A = 0.2387\,W\,r$.

These few checks have greatly increased the writer's confidence in the accuracy of Mr. Bull's tables. Possibly they may serve the same purposes for others.

Mr. Bull nominally crowds enough material for a book into a limited number of pages, dealing strictly with but one issue—tunnel stresses. To the writer he has done a great deal more than that. He has offered a sound bit of engineering philosophy. Section 8 is clever, and Section 10 is a stroke of genius. He has offered a very simple method which has applications far beyond tunnel analyses. Aeroplane fuselages, dirigible airships, submarines, large pipes, and various kinds of tanks are all closed rings. Last but not least, there is the large size sewer. The analysis of a sewer on the assumption that it may be regarded either as a fixed arch or as a hinged arch is so palpably beside the truth as to be worthless. Mr. Bull, it seems to the writer, offers a method which lends itself to any degree of precision. Mr. Bull has chosen to compute the mathematical values found in his tables to an accuracy of five significant places. All this was natural and necessary. The accuracy of five significant places is fictitious, of course. It was necessary, however, if Mr. Bull wanted to apply checks such as the foregoing and, furthermore, if he wanted some of his columns to add up exactly to zero. The procedure is also well justified in view of the fact that Mr. Bull's tables may be used several generations hence in their present form. However, to apply Mr. Bull's method of analysis to a sewer section with a variable moment of inertia, and other than perfect circular outline, would require about double the amount of work represented by Mr. Bull's complete paper in the Engineering Societies Library. Thus, although possible and accurate, it may not be feasible. Furthermore, such work could probably not be generalized as Mr. Bull has done for the circular ring of constants E and I and would have to be repeated for each new section considered in any one design problem. One way out of this dilemma, it seems to the writer, would be to obtain the elastic curve experimentally instead of mathematically. This would not result in an accuracy such as is implied in numbers of five significant places. The writer has already called such an accuracy fictitious, as probably Mr. Bull will agree. However, provided the technique in obtaining elastic curves is properly under control, the results would be more reliable—that is, philosophically more sound—than results obtained by conventional mathematical analyses such as Mr. Bull and the writer have used.

[16] "Elastic Energy Theory," by J. A. Van den Broek, 2d Ed., John Wiley & Sons, Inc., New York, N. Y., 1942, Appendix II, p. 271, and Example 31, p. 123.

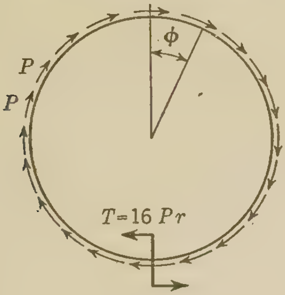

FIG. 15

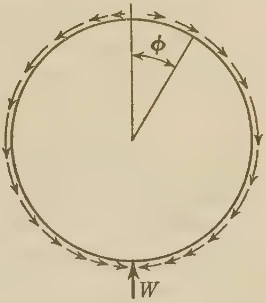

FIG. 16

The so-called exact analyses used in checks Nos. 1 to 6 were based on the conventional assumption that the principle of superposition applies; namely, that the rings maintain their original shape even in an analysis made for the purpose of obtaining changes in shape. Consider that the model from which the elastic curve is obtained is not perfectly elastic and thus violates elastic theory. How about applying an elastic theory to a structure as imperfectly elastic as reinforced concrete? In such a case, is the structure wrong or is the theory wrong? The philosophy of elastic curves as influence lines is sounder than any other mathematical theory of elasticity known to the writer because it is not restricted by assumptions of superposition and perfect elasticity as other theories of elasticity commonly are. Even the extremely small deformations, which often are stipulated, are philosophically not essential.

To some engineers who are not overly familiar with the science of soil mechanics, it may appear difficult to realize how tangential forces may be transmitted from earth to a smooth steel shell. However, in the shells of the aeroplane fuselages the shear forces are very real and are all directed tangentially. This leads the writer to surmise that Mr. Bull's carefully composed tables may well find wider application in other fields than merely the field of tunnel stresses for which they were originally computed.

The writer takes pleasure in expressing his admiration for, and his sense of indebtedness to, Mr. Bull's contribution. He expects to see Mr. Bull's theory and methods applied to a variety of problems, some of them possibly of greater importance, economically, than linings of shield-driven tunnels.

NATHAN D. BRODKIN,[17] ASSOC. M. AM. SOC. C. E.—The primary value of this paper is that it presents a rational method of determining the soil reactions for shield-driven tunnels and dispels much of the "fog" hitherto surrounding an analytical treatment of the subject. The high cost of modern, shield-driven, vehicular and rapid transit tunnels makes it of prime importance to attain the utmost economy of design consistent with reasonably assumed loading conditions. The author's proposal for reducing the weight of metal in the linings of such tunnels deserves the careful thought of tunnel builders.

An elastic tunnel ring subjected to a system of active loads will deform at all points in a definite manner; and, consistent with these deformations, soil reactions of definite magnitude and direction will appear in the surrounding material, dependent only on the elastic properties of the soil and the flexibility of the tunnel lining. The customary practice of assuming arbitrarily that the vertical soil reactions are of uniform intensity is basically erroneous and may lead (as indicated by the author) to uneconomical designs.

Selecting the invert joint as a point of reference, the author has derived expressions for A-constants (Eqs. 8), which, when multiplied by the external radial or tangential forces, yield the moment, thrust, and shear at that joint, provided the system is in static equilibrium. When referred to the developed periphery of the ring, the A-constants represent the ordinates to the influence lines for moment, thrust, and shear at the invert joint due to a unit load acting radially or tangentially at sixteen points on the circumference of a ring of unit radius.

For example, the constants A_{Mr} and A_{Mt}, when so plotted, yield the influence diagrams shown in Fig. 17. To locate the maxima and minima of the influence curves, first derivatives of the expressions in Eqs. 8 are equated to zero, yielding the angular values of these points. The influence ordinates corresponding to these values may then be found by resubstitution in Eqs. 8.

In Table 1 the A-constants have been determined for intervals of 22° 30′. Where force concentrations are applied anywhere between the sixteen tabulated points, a linear interpolation of the A-values might lead to inaccurate results. Influence diagrams plotted to a large scale give a truer indication of point-to-point variation, permit the intermediate values to be determined more accurately, and furnish a means for determining graphically the reactions for any system of loads in static equilibrium. Since any joint may be assumed as a point of origin similar to the invert joint, the same influence diagrams may be used for any joint by shifting the joint and force notation—in a manner similar to the analytical procedure described by the author in Section 11.

---

[17] Civ. Engr., Board of Transportation, City of New York, New York, N. Y.

Eqs. 8 are basic for any ring-shaped structure, greatly simplifying the mathematical work of deriving equations for moment, thrust, and shear in tunnel rings due to any given loading, as an example will serve to illustrate.[18]

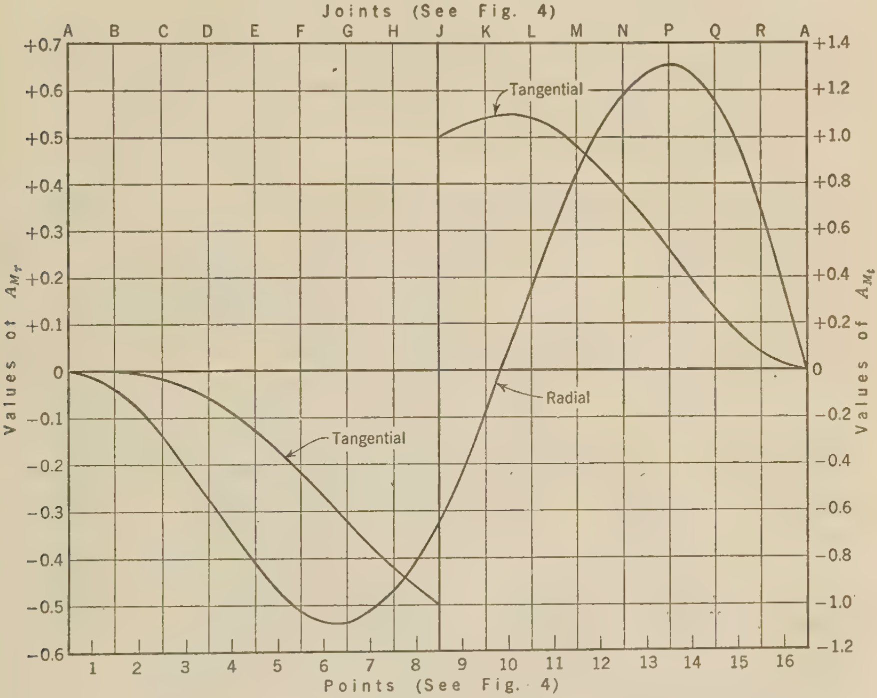

FIG. 17.—MOMENT INFLUENCE LINE FOR RADIAL FORCES AND TANGENTIAL FORCES

The ring, shown in Fig. 18, is subjected to two equal and opposite horizontal forces P concentrated at θ and $2\pi - \theta$. An equation must be written for moment at point A.

In Fig. 18, the horizontal forces P have been replaced by their radial and tangential components, $P \sin\theta$ and $P \cos\theta$, respectively. Substituting in Eq. 6c for A_{Mr} and A_{Mt} from Eqs. 8 and replacing α by θ and $2\pi - \theta$, respectively, the separate effects of radial and tangential forces may be written as follows: Moment produced by radial forces—

$$M'_A = -\frac{P r}{2\pi}\sin\theta\,(\theta\sin\theta + 1 - \cos\theta) - \frac{P r}{2\pi}\sin\theta\,[-(2\pi - \theta)\sin\theta + 1 - \cos\theta] = -\frac{P r}{\pi}[-(\pi - \theta)\sin^2\theta + \sin\theta - \sin\theta\cos\theta] \;..(30a)$$

---

[18] "Stress Coefficients for Large Horizontal Pipes," by James M. Paris, *Engineering News-Record*, November 10, 1921, p. 768.

and moments produced by tangential forces—

$$M''_A = +\frac{P\,r}{2\,\pi}\cos\theta \times \theta\,(1 - \cos\theta) - \frac{P\,r}{2\,\pi}\cos\theta\,(2\,\pi - \theta)\,(1 - \cos\theta)$$

$$= -\frac{P\,r}{\pi}\left[(\pi - \theta)\cos\theta - (\pi - \theta)\cos^2\theta\right] \ldots\ldots\ldots\ldots (30b)$$

Adding the separate effects:

$$M_A = M'_A + M''_A = -\frac{P\,r}{\pi}\left[-(\pi - \theta)(\sin^2\theta + \cos^2\theta) + (\pi - \theta)\cos\theta\right.$$

$$\left. + \sin\theta - \sin\theta\cos\theta\right] = +\frac{P\,r}{\pi}(\pi - \theta - \sin\theta)(1 - \cos\theta) \ldots . (31)$$

The writer would like to call attention to the effect caused by a change in the value of the soil compression constant K. For this purpose the moments produced in the tunnel lining shown in Fig. 11(*a*) for successive values of K from $K = 3$ to $K = 15$ were computed using the author's method of analysis. The results are summarized in Table 15, and moment diagrams corresponding to the various values of K have been plotted against the developed ring circumference in Fig. 19. Values for $K = 12$ in Fig. 19 are taken from Table 14.

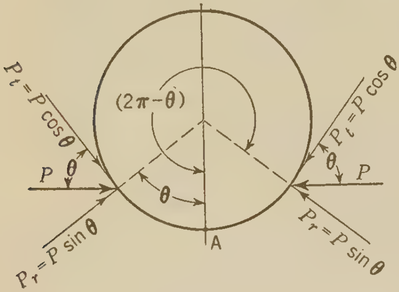

Fig. 18

Fig. 19 shows the progressive reduction in crown moment with an increase in the value of K. If this moment is plotted against the soil compression constant as in Fig. 20, it is seen that the variation in this reduction is nonlinear. Mr. Drucker,[3] although treating the problem of soil reactions from a different standpoint, obtains a curve of similar nature.

Assuming, as a basis, a sandy soil having a K-value of 12 to which the example given by the author applies, it is seen from Table 15 that, for decreases in K to 9, 6, and 3, the crown moment increases 9.5%, 23.7%, and 48.5%, respectively. Similarly, the increase in crown tensile fiber stress is 12.7%, 32.3%, and 65% for the respective values of K. When it is considered that a soil having a K-value as low as 3 might be somewhat plastic, and would exert a greater active lateral pressure than that assumed herein, the percentages for $K = 3$ are perhaps too high. Unless conclusive evidence is at hand as to the nature of the soil, it would appear prudent to assume a conservative value for K.

From the foregoing, it is evident that increasing the soil compression constant has the same effect as increasing the flexibility of the lining. The simple relationship existing between I and K may be shown in the following manner: Eq. 18 may be written in the form,

$$\Sigma(F\,D_1) - \Sigma(P\,D_1) = +\frac{E\,I}{r^3}\cos\alpha_1\,\delta - \frac{E\,I}{r^3\,K\,A'}F_1 \ldots\ldots (32a)$$

or

$$\frac{[\Sigma(F\,D_1) - \Sigma(P\,D_1)]\,r^3}{E} = I \cos \alpha_1\, \delta - \frac{I\,F_1}{K\,A'} \quad \text{.........} (32b)$$

Denoting by F_A the soil reaction on a segment extending from point 1 to point 16, Eq. 15 takes the form $F_A = \delta\,K\,A'$ or $\delta = \dfrac{F_A}{K\,A'}$. Substituting,

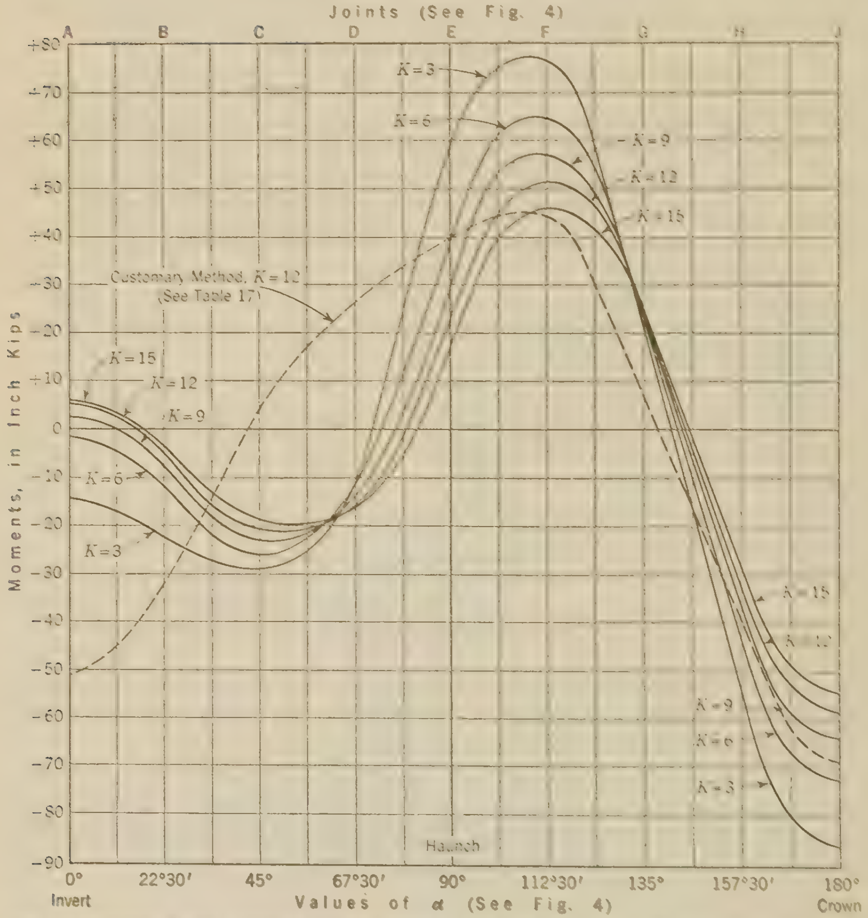

FIG. 19.—MOMENTS IN THE TUNNEL LINING RELATED TO THE SOIL COMPRESSSION CONSTANT (I = 136 IN.^{4})

Since there is a definite relationship between the soil reactions F_1, F_2, $\cdots$, F_5 for any given loading, F_A must likewise bear a fixed relationship to F_1.

From Eq. 33*b*, it is seen that, if the value of K is multiplied by a certain factor, it has the same effect as if the value of I were divided by the same factor.

Stated in other words, if the soil compression constant is increased, it has the same effect as a corresponding increase in the flexibility of the lining.

It is interesting to note in Table 15 that, for the various values of K for which analyses were made, the reactive forces F vary only slightly at similar points on the ring for different values of K. These small variations, however, are sufficient to cause large changes in the moments.

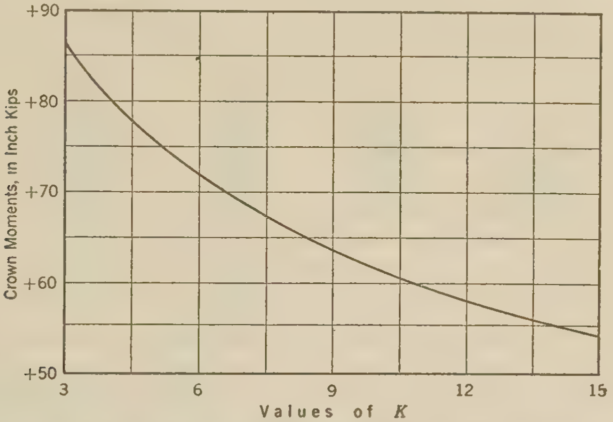

Fig. 20.—Crown Moment in the Tunnel Lining Related to the Soil Compression Constant (I = 136 In.^{4})

It is further noted in Table 15 that, as the soil compression constant is decreased, the effects of soil reaction diminish on the upper parts of the tunnel. For low values of K and a moment of inertia of 136 in.^{4}, the reactive forces are confined to the lower half of the tunnel periphery.

Contrary to the usual conception of a flattening at the invert of the ring with a predominance of downward loads, the results obtained using the author's method of analysis indicate that it is quite possible for the curvature to sharpen at the invert. The computed radial deformations of the lining due to combined active loads and soil reactions, corresponding to the assumed values of K, have been listed in Table 16. The final displacements are due to three factors—active loads, soil reactions, and the settlement. Actual deformation of the ring is a function of the first two factors only. A negative radial deformation means that the point has moved inward and a positive value indicates an outward movement with respect to the position of the ring before it is loaded. Table 16 shows quite clearly that, for high values of K, points 1 and 2 move inward with respect to joint A. As the soil compression constant is decreased, the soil, becoming more yielding, allows the lining to flatten at points near the invert under the effects of active loads, until a value of K is reached where all points from 1 to 6, inclusive, move outward. This is the case for an assumed value of K = 3. Thus, for high values of K it is possible to obtain moments at the invert causing tension on the outer fibers.

With an increase in the soil compression constant, the soil reactions tend to reduce the moments in the lower half of the lining, and, with a simultaneous reduction in the amount of the displacement at the horizontal diameter as shown in Table 16, they cause this part of the ring to act somewhat as an abutment for the upper half. The upper part of the ring then behaves much as an arch subject mainly to the effects of active loads.

[a] See line 9, Table 12.

For purposes of comparison, the writer has analyzed the tunnel chosen by the author as an example in Section 21 (for which I = 136 in.^{4}) by the customary method of analysis described in Section 3, assuming (1) the vertical soil reactions to be distributed uniformly over the horizontal diameter (Fig. 1, loading 12); and (2) an induced lateral passive pressure of an intensity dependent on the increase in the horizontal diameter under active loads. The effects of lateral passive pressure are in accordance with the pressure diagram shown in Fig. 1, loading 13a, and are based on the theory developed by Mr. Drucker,[3] using a value of K = 12. A lateral displacement of 0.51 in. at joint E (Fig. 4) due to active loads was applied to Mr. Drucker's formulas for the passive pressure and the resulting moments were determined utilizing the author's B-constants from Table 5. The results are shown in Table 17 and the corresponding moment diagram has been plotted in Fig. 19. The moments as determined by the author are also given in Table 17 for purposes of comparison. Comparing the two sets of values, the difference in results is apparent at once, especially in the lower parts of the lining. The customary analysis yields a crown moment 18% greater than that obtained by the author. The invert

moment is about 74% of the crown moment obtained by the customary method, whereas the author's analysis shows a very small moment at this point amounting to about 9% of that at the crown. From the foregoing, it is evident that the customary assumptions relative to soil reactions result in moments in the lining varying considerably from those obtained by a more rational method.

M. A. Drucker,[19] Esq.—A fundamental method of complete stress analysis for tunnels is presented in this paper including the effects of both the active loading and the passive soil resistance, or, as the author designates the latter, "soil reactions." It should be of interest to ascertain the effects of the active loading separately in order to study the effect, on the final stresses, of considering the passive pressures. This would also show to what extent reliance is placed on the capability of the passive pressures to keep the stresses in the tunnel from exceeding the maximum permissible stress. In the author's analysis, however, the two sets of stresses are inseparably combined. Therefore, to form a clear idea of the effect of the proposed method, as compared with what may be termed the ordinary method, it would be necessary first to obtain the stresses due to the active loading according to general practice in tunnel design.

For the purpose of comparison, of course, the active loading and pressures used by the author will have to be followed. However, attention may be called to what appear to be several discrepancies. In considering the effect of the weight of the tunnel ring, 220 lb per sq ft is used. This weight consists of 110 lb for the weight of the cast-iron ring having a sectional area of 27.6 sq in. and of 110 lb for the weight of the concrete lining; but, as the concrete lining is poured in normal air, a considerable time after the cast-iron ring is erected, the weight of the cast iron alone should have been considered in conjunction with the effect of the internal air pressure used to keep out the water while erecting the cast-iron lining. In obtaining the moment of inertia and section modulus of the tunnel ring, the author correctly disregards the concrete lining.

Another point that may be noted is that the author apparently neglects the buoyant effect of the water on the soil when obtaining the lateral active pressures against the tunnel. Using Eq. 22*c* he takes a unit active horizontal pressure equal to one third the weight of overlying soil—100 lb per cu ft. This corresponds to an active pressure due to a dry soil having an angle of repose of 30°. If the buoyant effect of the water were considered, the unit active lateral earth pressure, of course, would be less than 33.3 lb. The variation in stress resulting from this difference in pressure will be considered subsequently.

Tunnel design analysis, for active loading, based on the ordinary method, resulted in a simplification by employing coefficients for bending moments and thrusts for the component parts of the total loading and pressures. These coefficients, for the stresses at point J, are given in Table 18, Cols. 2 and 4. In the problem considered by the author (see Section 21), the outside diameter of the tunnel is 17 ft 5 in. and the radius at the neutral axis is 8.5 ft. Loaded on the tunnel section are an earth cover of 36 ft and 27 ft of water. The net sectional area of the ring is 27.6 sq in., its gross moment of inertia is 136 in.^{4}, and the intrados section modulus is 23.4 in.^{3}, all per foot of tunnel length. Applying the coefficients of Table 18 to this case, the stress at point J is $20.57 \times \frac{12}{23.4} - \frac{28.36}{27.6} = 10.53 - 1.03 = 9.50$ kips per sq in. The author finds the final stress at this point to be + 1.89 kips per sq in., including + 0.69 kip per sq in. due to the air pressure, which is independent of the effect of the external loading. Therefore, the remaining stress, without air pressure, would be + 1.2 kips per sq in., so that, in accordance with the method presented in the paper, the tensile stress reduction due to the passive pressures may be said to be 9.5 − 1.2 or 8.3 kips per sq in.

[a] The loading numbers correspond to those shown in Fig. 1; loading 6 is omitted because its effect is included in loadings 1 to 5.

On the loading diagram, Fig. 1, the author represents by loading 13*a* the distribution of passive pressures as considered by the writer.[3] He states (see Section 3) that these pressures are "continuous functions of the depth." It would be more correct to describe this method as one in which the horizontal passive pressures are assumed proportional to the lateral deflections caused by the active loading. In conjunction with this method, the excess of the downward vertical loading over the upward water pressure is assumed to be uniformly distributed below the horizontal diameter in accordance with general practice. The author states several times that such assumed vertical pressure distribution is the cause of high calculated stresses. From the following computations it should become clear that such pressure distribution does not result in large computed stresses.

To determine the stress reduction due to the passive pressures in accordance with the writer's method, the horizontal deflection at the horizontal tunnel axis due to all the active loading and pressures will first be found from the resulting bending moment at point J—the assumption being that the deflections due to all the active loadings will be the same as the deflection due to a uniform vertical loading causing the same moment at this point.

For a uniform vertical loading of w lb per sq ft, $M_J = 0.25\, w\, r^2$. Table 18 gives M_J as 20,570 ft-lb. Therefore, $0.25\, w\, r^2 = 20{,}570$ and $w = \dfrac{20{,}570}{0.25\,(8.5)^2}$ $= 1{,}140$ lb per sq ft. For such uniform load the deflection d_1 at the horizontal diameter is

$$d_1 = \frac{144\, w\, r^4}{E\, I} \quad \text{(34)}$$

For the problem under consideration, $d_1 = \dfrac{144 \times 1{,}140 \times (8.5)^4}{12{,}000{,}000 \times 136} = 0.526$ in.

The effect of the passive pressures may be found in the following manner: $p = 1.28\, w = 1.28 \times 1{,}140 = 1{,}460$ lb. In this computation p is the maximum intensity of a pressure, varying as $\sin^3 \alpha_J$ (see Fig. 21), that would be capable of deflecting the tunnel back to its original position. This is an extreme pressure and is obtained only as a necessary intermediate step.

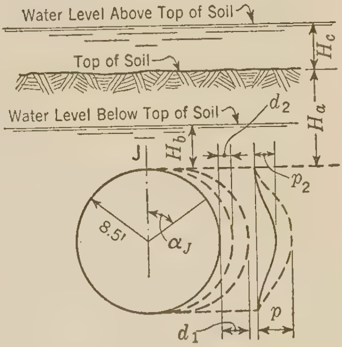

FIG. 21

With the foregoing information and the given value of 12,000 lb for the soil constant, K, the reduction in stress, σ_x, at point J, due to the passive pressures may be found from the following formula derived by the writer:

$$\sigma_x = \frac{12 \times 0.182\, K\, r^2\, p\, d_1}{\dfrac{I}{c}\,(K\, d_1 + p)} + \frac{0.59\, K\, r\, p\, d_1}{A\,(K\, d_1 + p)} \quad \text{(35)}$$

Substituting the proper values in Eq. 35,

$$\sigma_x = \frac{2.18 \times 12{,}000 \times (8.5)^2 \times 1{,}460 \times 0.526}{23.4\,(12{,}000 \times 0.526 + 1{,}460)}$$

$$+ \frac{0.59 \times 12{,}000 \times 8.5 \times 1{,}460 \times 0.526}{27.6\,(12{,}000 \times 0.526 + 1{,}460)} = 8.22 \text{ kips per sq in.}$$

As previously indicated, the author's method gives a stress at point J of 8.3 kips per sq in. less than that obtained by the ordinary method for active loading only. Comparing this value with the foregoing stress reduction of 8.22 kips per sq in. due to the passive pressures, the difference in the results obtained by the two methods is found to be only about 1%. It is gratifying, indeed, to find that the writer's method, which includes approximations for the sake of simplicity and which requires only simple slide-rule computations, gives results in such close agreement with the author's more extensive analysis.

With the reduction in stress of 8.22 kips per sq in., due to the developed passive pressures, the stress at point J would become 9.5 − 8.22 = 1.28 kips per sq in. without considering the stress due to air pressure, and 1.28 + 0.69 = 1.97 kips per sq in. considering the stress due to air pressure, as against the author's 1.2 kips per sq in. and 1.89 kips per sq in., respectively.

At times it may be more desirable to determine the value of the soil constant, K, necessary to keep the stress from exceeding the maximum allowable value, than to begin with an assumed value for this constant to find the resulting stress. In the present stage of knowledge of soil mechanics, it would be rather difficult to defend any definite K-value even if it were based on the best possible available information as to the nature of the soil through which the tunnel is to be constructed. Surely, one could not contend for a value of $K = 12$ while another argued for a value of, say, 10 or 8.

Knowing the stress at point J due to the active loading, computed as indicated in Table 18, and the maximum permissible tensile stress, the necessary value of the soil constant may be obtained from the following formula derived by the writer:

$$K = \frac{\sigma_x}{d_1 \left[\frac{2.18\, r^2}{\frac{I}{c}} + \frac{0.59\, r}{A} - \frac{\sigma_x}{p} \right]} \qquad \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

in which, as before, σ_x is the necessary stress reduction to be provided by the passive pressures.

For a maximum allowable tensile stress of 4 kips per sq in. for cast iron and taking into account the stress due to air pressure, σ_x, for the problem under discussion, would have to be $9.50 + 0.69 - 4.00 = 6.19$ kips per sq in. Substituting this and other known values in Eq. 36,

$$K = \frac{6.19}{0.526 \left(\frac{2.18\,(8.5)^2}{23.4} + \frac{0.59 \times 8.5}{27.6} - \frac{6{,}190}{1{,}460} \right)} = 4.37.$$

This result shows that, for the tunnel section considered, there would be no reason for urging a soil constant of $K = 12$ in checking as to whether the tunnel ring is of sufficient strength for a certain location, when one of only $K = 4.4$ would keep the stress from exceeding 4 kips per sq in.

In this discussion, reference has been made to the stresses at point J only, because it is the point of greatest tensile stress and, therefore, governs for cast iron. Theoretical computations, including those by the author, as well as tests on rings used for the London tubes,[20] show this to be the case. The loading during these tests (which were conducted under conditions approximating those affecting a tunnel after construction) was increased until cracks appeared in the rings—at the crown of the tunnel. Also, if the stress is known at one point, the stress at any other point can be determined readily, if for any unusual reason it should be desired to do so, by considering the bending and thrust at the point of known stress in conjunction with the known or assumed loading, including the passive pressures.

As previously noted, the author assumed the weight of the tunnel ring as 220 lb per sq ft whereas he should have used only 110 lb for the ring having a sectional area of 27.6 sq in. He also neglected to consider the buoyant effect of the water on the surrounding soil. Making the correction for the weight of the tunnel ring, the final stress at J for this ring was found to be 1.71 kips per sq in. as indicated in Table 19 for condition C. Correcting for the effect of buoyancy, assuming 40% voids, and taking the angle of repose of the soil as 30° gave the effective weight of the soil below water as 100 − 0.60 × 63 = 62.2 lb per cu ft and the unit active earth pressure as $62.2 \times \frac{1 - \sin 30°}{1 + \sin 30°} = 62.2 \times \frac{1 - 0.5}{1 + 0.5} = 20.7$ lb. For this reduced active earth pressure below water the stress at J was found to be 2.71 kips per sq in. for condition D.

[20] "Tunnel Linings with Special Reference to a New Form of Reinforced Concrete Lining," by G. L. Groves, *Journal*, Institution of Civ. Engrs., London, England, March, 1943, p. 29.

TABLE 19.—COMPARISON OF STRESSES AT POINT J

Condition	Description	Stress[a] σ_J	
		$A = 27.6$	$A = 11.0$
A	Author's specified conditions (see Section 21) and method	1.89	3.18
B	Conditions A, with passive pressures based on the writer's method	1.97	3.70
C	Conditions B, with corrected tunnel weights[b]	1.71	2.95
D	Conditions C, taking buoyant effect of water into account, with angle of repose = 30°	2.71	4.90
E	Conditions D, with angle of repose = 45°	3.87	7.50
F	Conditions C, except that all active side earth pressure is disregarded	5.10	9.40

[a] Stresses are in kips per square inch, for section areas of 27.6 sq in. and 11.0 sq in., respectively. [b] For $A = 27.6$ sq in., the weight was corrected to 110 lb; and, for $A = 11.0$ sq in., the weight was corrected to 50 lb.

The angle of repose was taken to be 30° as assumed by the author. It may not be out of place, however, to give this assumption a little thought. An angle of repose of 30° is considered a reasonable basis for obtaining side pressures on structures, whose safety requires that the highest possible active pressure be assumed to provide sufficient resistance against it. In the case of tunnels, however, as the active side earth pressures reduce the tensile stress at the governing point, or at the crown of the tunnel, it becomes necessary to decide on an angle of repose that would give active earth pressures which may be counted on to exist at all times. This may be a rather difficult question to decide; but the angle of repose for maximum active earth pressure should not be used when the minimum pressure is desired. In this connection, it may be noted that Lieutenant-Commander Spangler[7] assumes no active side earth pressure whatever although he analyzes fills at culverts. Therefore, for such a soil as that to which the author assigns a value of $K = 12$ for the soil constant, which is compact and undisturbed, an angle of repose of 45° would not be too large. For such angle of repose, and taking buoyancy into account, the unit active earth pressure would be $62.2 \times \frac{1 - \sin 45°}{1 + \sin 45°} = 10.7$ lb. Based on this active earth pressure the stress at J was found to be 3.87 kips per sq in. for the heavier tunnel section as indicated for condition E, Table 19. Neglecting all active side earth pressure, σ_J was found to be + 5.10 kips per sq in. for condition F. As the angle of repose of the undisturbed soil would very likely be greater than 45°, the final stress, even for so large a soil constant as $K = 12$, would be between + 3.87 and + 5.10 kips per sq in.

The low stresses determined by Mr. Bull prompted him to state (see Section 27) "* * * that with a lining as actually designed more than 70% of the cast iron is wasted." That these low stresses are not inherent in Mr. Bull's method of analysis is demonstrated in Table 19 which shows that, for the same tunnel ring, the same low stresses were obtained by the writer's method under the conditions assumed by the author. The low stresses were due to two factors: (1) The author neglected the buoyant effect of the water on the soil when computing the active horizontal soil pressures; and (2) he assumed a high value for the soil constant without assuming a correspondingly large angle of repose. A more correct basis is that represented by condition E which includes the effects of buoyancy and assumes an angle of repose of 45°. For this condition σ_J was found to be 3.87 kips per sq in. which is close enough, for all practical purposes, to the limiting design stress of 4 kips per sq in. for cast iron.

To compare the writer's method with that of the author for lighter ring sections, a ring having a moment of inertia of 8.5 in.^4, or one sixteenth of that so far considered, was analyzed. For condition B, Table 19, the stress at J was found to be 3.70 kips per sq in. as against 3.18 kips per sq in. given by the author. The difference between the two stresses should not be surprising in view of the fact that, due to the active loading, the stress for this light ring was found to be 66.0 kips per sq in. so that the stress of 3.70 kips per sq in. represents a reduction in stress of 62.3 kips per sq in. due to the passive pressures. For the other conditions, after making corrections for the weight of the ring, the stresses increase somewhat more than for the heavier section (see Table 19).

For the tunnel ring having an area of 27.6 sq in. the stress at J, computed by the writer's method, was found to be 0.08 kip higher than that given by the author. For the ring having an area of 11.0 sq in. the stress obtained by the writer is about 0.5 kip higher than that given by the author. However, for the area of 17.4 sq in. the writer's value for the stress was found to be 0.9 kip less than that given by the author. In an effort to interpret these varying and irregular differences both sets of stresses were plotted in Fig. 22. As may be seen the stresses computed by the writer (identified by the letter D in Fig. 22) could be joined by a fairly smooth curve marked L_D whereas the author's stress points, due to the stress of 3.14 kips for the area of 17.4 sq in., cannot be so joined except for the stress points for 11.0 sq in. and less, through which a curve L_B could be passed. The irregularity of the other points may be explained by the fact that, as indicated in Table 14, for areas of 11.0 sq in. and less the stresses were obtained on the basis of having six ring segments in contact with the soil whereas for heavier sections only five segments on each side of the tunnel were considered pressing against the soil.

Assuming that all stress values given by the author are correct, in accordance with his method, the question arises as to what the stress might be for areas between 11.0 and 17.4 sq in. Between these areas there should be one for which, if six segments be assumed in contact with the soil, the pressure on the sixth segment would prove to be zero or nearly so. For such sectional area, which may occur about halfway between those for which the stresses are given, and which may be represented by line A–A in Fig. 22, five segments in contact with the soil could then be assumed. It would seem reasonable that by extending line L_B toward the right the stress for this area would be at point a or not far from it. Similarly, by extending line F toward the left, the stress for this area of ring would be represented by point b or b_1 if the stress line be assumed to curve upward as suggested by the other stress curves. Although the computed stress values for the area at section A–A may be somewhat different from those indicated in Fig. 22, it would appear that for the same sectional area and loading a consideration of six segments and then five segments would give stresses differing by more than a kip for an average of two stresses of about 3.0 kips. A break in stress values such as at line A–A suggests that the accuracy of computed stress values, by the author's method, for areas on either side of this line would also be questionable. If this be so it would indicate that an accurate method of tunnel design, including the effects of passive pressures, has yet to be developed.

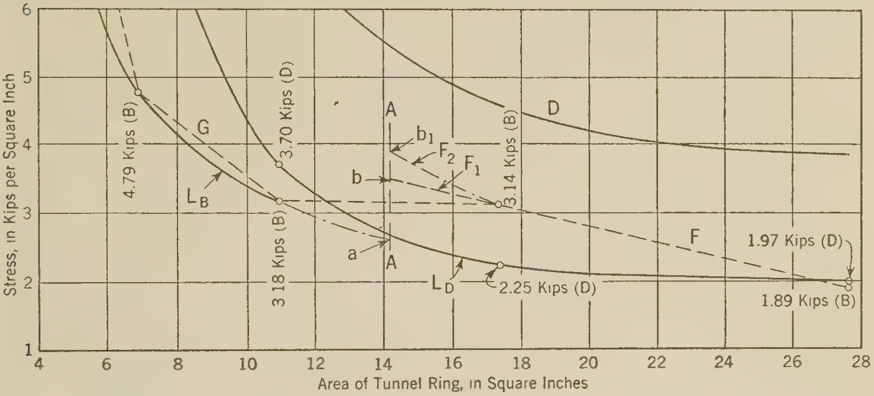

FIG. 22

It should also be noted that the stresses represented by lines L_B, L_D, and F are based on the author's loading assumptions; line D shows the stresses that could be expected based on the writer's method, as obtained for condition E, Table 19, for the assumed loading and active soil pressures which, in his opinion, should have been used.

Mr. Bull asserts that the large critical moments obtained by methods other than his occur because (see "Conclusions") "* * * the erroneous assumption is currently made that the vertical soil reactions are uniformly distributed over the horizontal diameter * * *." That this is not the cause of large moments may be noted from the close agreement between the stresses for the same conditions based on the writer's analysis (which assumes uniform pressure distribution below the horizontal diameter) and those obtained by the author. In fact, from the vertical components of reactions in Col. 11, Table 11, the pressure distribution obtained on the horizontal projections of the corresponding segments is greatest at the vertical axis of the tunnel and less toward the sides. Such pressure distribution causes greater moments at J than does uniform upward pressure for the same total load. Therefore, the relatively small stresses, obtained by either the author's method or the writer's method, are due to the horizontal passive pressures involved in both methods.

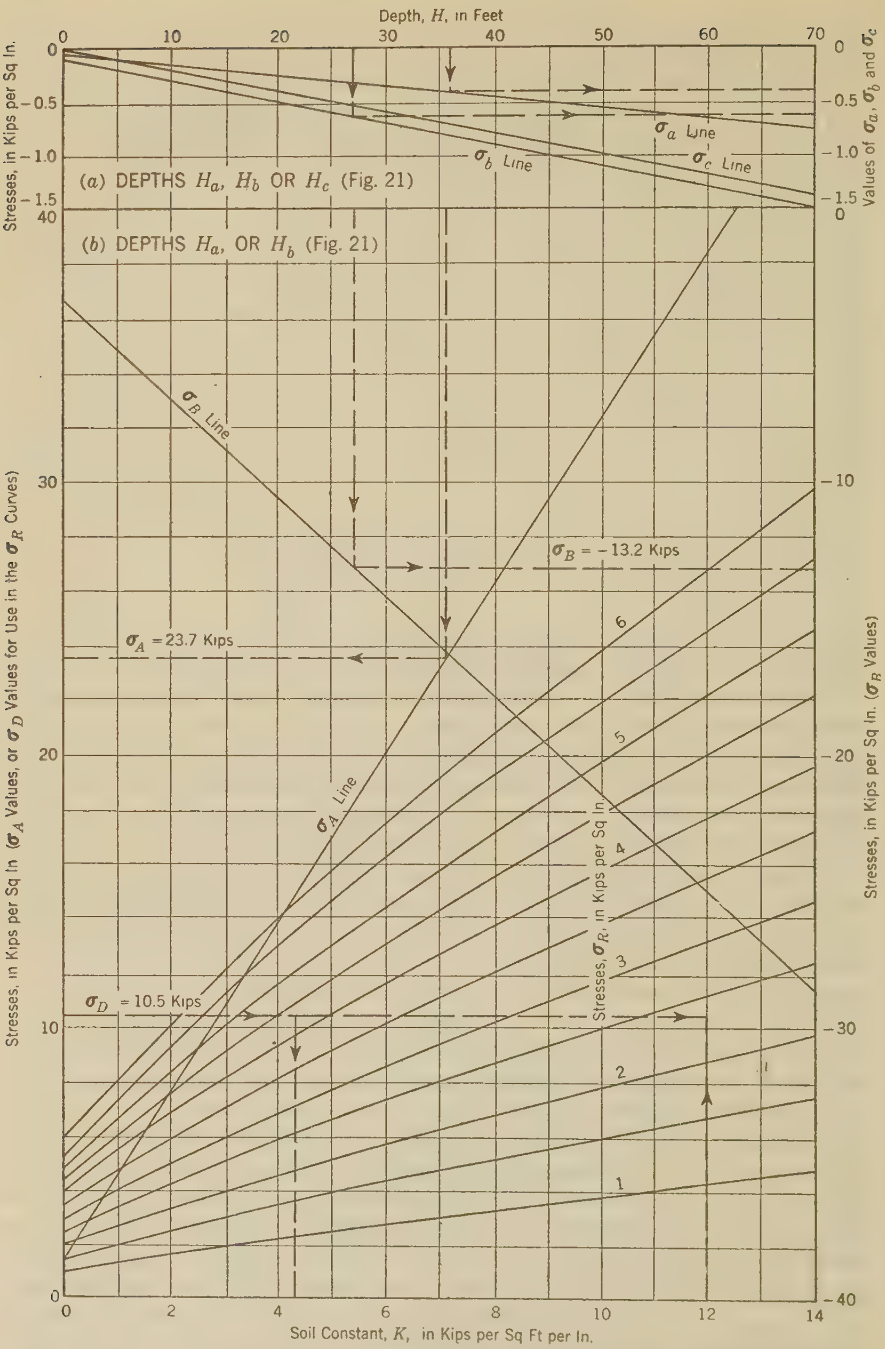

FIG. 23.—COMPREHENSIVE CHART FOR DETERMINING THE STRESS AT JOINT J FOR A TUNNEL RING HAVING AN AREA OF 27.6 SQ IN.

When a tunnel section is considered or finally decided upon for a project, it may be necessary to obtain the stresses for various conditions of head of water, height of earth cover, and nature of soil, for which different soil constant values may have to be assigned. To further simplify the process of obtaining the stress at point J for various conditions, a chart similar to Fig. 23 would be useful. This chart was prepared for the ring having a sectional area of 27.6 sq in. and, on the basis of the author's loading assumptions, without corrections.

The notation is defined as follows: σ_A = bending stress for active loading, including side earth pressure, cover = H_a (see Fig. 21); σ_B = bending stress caused by the water load, without considering buoyancy (to conform with the author's assumption), head of water = H_b; σ_D = bending stress due to all active loading ($\sigma_D = \sigma_A - \sigma_B$); σ_a = compressive stress due to the thrust caused by active earth pressure only; σ_b = compressive stress in addition to σ_a, due to the thrust caused by water, head of water = H_b; and σ_c = compressive stress in addition to σ_a, due to the thrust caused by water, head of water = H_c.

The σ_R-lines, based on Eq. 36, are used to obtain the final bending stresses after taking account of the bending stresses due to the passive pressures corresponding to the indicated soil constants. The other lines in Fig. 23 were obtained by selecting the proper moment and thrust coefficients from Table 18. From Fig. 23 the final stress can be obtained readily after assuming a soil constant, or the soil constant necessary to limit the stress to a certain amount may be determined.

Problem 1.—Under the conditions stipulated by Mr. Bull in Section 21 (see conditions B, Table 19), let H_a (Fig. 21) = 36 ft and H_b = 27 ft. Entering Fig. 23 at H = 36 ft, the vertical dropped to the σ_a-line in Fig. 23(*a*) intersects at $\sigma_a = -0.4$ kip per sq in.; and, extended vertically to the σ_A-line in Fig. 23(*b*), intersects at $\sigma_A = 23.7$ kips per sq in. Again entering Fig. 23 at H = 27 ft, the vertical dropped to the σ_b-line in Fig. 23(*a*) intersects at $\sigma_b = -0.6$ kip per sq in.; and, extended vertically to the σ_B-line in Fig. 23(*b*), intersects at $\sigma_B = -13.2$ kips per sq in. The bending stress σ_D due to all active loading is $23.7 - 13.2 = 10.5$ kips per sq in. In Fig. 23(*b*), the intersection of a horizontal from $\sigma_D = 10.5$ and a vertical from $K = 12$ gives $\sigma_R = 2.3$ kips per sq in. The total of $\sigma_a + \sigma_b = -0.4 + -0.6 = -1.0$ kip per sq in., and σ_J, without considering air pressure, is $2.3 - 1.0 = 1.3$ kips per sq in. Adding the air-pressure effect, + 0.69 kip per sq in., the final value of $\sigma_J = +1.3 + 0.69 = 1.99$ kips per sq in., which checks the stress given in Table 19. For a total stress σ_J limited to 4.0 kips per sq in., σ_R could be as great as $4.0 + 1.0 - 0.69 = 4.31$ kips per sq in. Entering Fig. 23(*b*) at $\sigma_D = 10.5$ kips per sq in. and drawing a line horizontally to $\sigma_R = 4.31$ yields (vertically) $K = 4.4$, which demonstrates how the necessary soil constant may be obtained so that the stress shall not exceed a certain value.

SIGVALD JOHANNESSON,[21] M. AM. SOC. C. E.—The use of cast iron for tunnel linings was conceived by Marc Isambard Brunel in 1818, but it was not until the Tower Subway under the Thames River in London, England, was built in 1869 that a tunnel was constructed with cast iron as lining material.

---

[21] Chf., Highway Planning Bureau, State Highway Dept., Trenton, N. J.

Since then cast-iron tunnel lining has been used extensively for shield-driven tunnels, particularly in Great Britain and the United States.

Until comparatively recently cast-iron linings have been proportioned almost entirely by judgment, checked perhaps by static stress analysis. Since about 1920, however, various attempts have been made to develop a rational method for determining the stresses in tunnel linings, and the author is to be congratulated for having made a most important step in this development.

Based on his formulas the author finds that an excessive volume of metal is used in the present cast-iron linings. Although this may be true theoretically, it is still questionable whether cast-iron linings could be materially decreased in weight. The author gives two reasons why this may not be done: The first is the difficulty of casting large segments of slender shape; and the second is the need for a large cross section to resist the pressure of the shoving jacks. Also, cast-iron linings are cast in segments bolted together at the horizontal flanges, the deflections of which, under circumferential tension, confound the theoretical conclusion; and forces originating in the interior of the tunnels, such as an explosion or a collision, might cause the tunnel to collapse if the cast-iron lining were as thin as the theoretical stress computations would indicate to be safe. These conditions have been, and must be, considered in proportioning the lining as long as the present type of cast-iron lining is used.

However, with the development of the art of making, shaping, and fabricating steel, the present type of cast-iron lining should, and will, become obsolete, and it will be superseded by linings of steel (as suggested by the writer in 1922),[22] provided that the natural hesitancy of tunnel designers to break with precedent may be overcome. One of the greatest obstacles to change has been the uncertain knowledge of the stresses to which a tunnel lining may be subjected. The author's contribution to the determination of these stresses will greatly facilitate the solution of this problem.

JACOB FELD,[23] M. AM. SOC. C. E.—A complete mathematical analysis of stresses in tunnel sections, based upon assumed loadings and resulting deformations of a circular ring, has been developed in this paper. The method of attack and the resulting tabular data provide useful tools for a rigid solution of the design problem. However, the value of the results is dependent upon the validity of the assumptions as to the soil materials and as to the relationship between acting loads or resisting reactions and deformations of the ring.

All the forces acting on a shield-driven tunnel can be divided into two classes: (*a*) Those acting in planes normal to the axis of the tunnel in the form of radial forces and tangential forces; and (*b*) those acting parallel to the longitudinal axis. It must be kept in mind that the problem is a space, or three-dimensional, problem and that the longitudinal forces will affect the radial forces and vice versa.

The science of tunnel design is dependent upon the art of tunnel construction. It is a serious mistake to design a tunnel without considering the feasibility of construction and also the conditions under which construction can proceed safely.

---

[22] "Shield and Compressed Air Tunneling," by B. H. M. Hewett and S. Johannesson, 1st Ed., McGraw-Hill Book Co., Inc., New York, N. Y., 1922.

[23] Cons. Engr., New York, N. Y.

In an indeterminate structure of the type described in this paper, the distribution of stresses is dependent on the strain or shape of the ring. If the construction of the ring is progressing in a perfectly fluid or liquid medium, the reactions are determinate. Even in this medium, the shape of the ring does not remain circular, although the balancing effect of the air pressure tends to eliminate the required vertical resultants acting outside the ring. If it were possible to vary the amount of air pressure at various heights within the ring, a perfect balance could be obtained and the only deformation would be a radial squeezing of the ring.

If the tunnel is being constructed in a solid material, of sufficient internal resistance strength to permit immediate transfer of loads beyond the limits of the excavation, there is no reaction on the ring, and, of course, in this case no ring is necessary. It should be remembered that, in some solid materials, tunnels bored without shields and without rings do encounter trouble from the lateral, and sometimes also from the upward, squeeze of the rock or earth into the previously excavated tunnel section.

The case considered by the author is that of a tunnel in a saturated soil material. In this case the author makes the basic assumptions that the active pressure acting at any point in the ring is independent of the amount of ring deformation, but that the magnitude of the soil reaction at any point in the ring is directly proportional to the amount of the outward deformation from the theoretical circular shape. Information on soil reactions does not warrant such an assumption. There is no doubt that there can be no soil reaction without a strain. The value of the active pressure at any point is dependent upon the deflection at that point. This phenomenon was described a number of times by the late James C. Meem, M. Am. Soc. C. E., and termed by him "arching action over the tunnel." Mr. Meem stressed that the effects of the compressed air would be (1) to dry the soil locally above the shield, and (2) to form localized arches of rigid soil which would relieve the vertical pressure. The distribution of active pressure depends upon the change in shape of the upper portion of the circular ring. In general, those portions which deflect least will carry the greater part of the total load; and, conversely, those portions which deflect most will carry less than their share of the total load.

The amount of soil reaction at any point depends upon the amount of displacement into the soil at that point. It is questionable whether the relationship is linear. Of course, even if the relationship is linear for small deflections, the materials encountered in shield-driven tunnels are usually quite plastic, and a redistribution of soil reactions will occur in time. Just what the actual conditions will be at any one time and just how long the conditions will remain static are items of necessary information, which are lacking.

However, it seems necessary to design a ring for the worst condition of each series in the various stages of construction. When the shield is shoved forward, there must be an annular ring of soil mixed with water and air surrounding the entire perimeter which is substantially fluid. Just how long the material will remain fluid depends upon the nature of the soil in which the tunnel is built. The less clay the material contains, the sooner the liquid state will disappear. However, if the soil has a sufficient clay content to form a colloidal gel as a result of the shield compression and movement, a liquid contact ring may exist for a considerable length of time. The tunnel design must take such a possible state into account.

Farther back from the shield, the soil will be in more intimate contact with the ring. If the soil has sufficient solid characteristics, the change in the shape of the top portion may relieve the center section of the expected load and will then transfer practically all the active pressures to the sides of the tunnel ring, and possibly a large portion also to the adjacent soil. This is the condition termed "arching" by Mr. Meem.

As the shield is pushed forward, with partial removal of the soil in the front of the shield, the shear strength of the material penetrated is overcome by compression against the compressed rings. If these rings are in intimate contact with the outside soil, a portion of such force is transformed into the soil in the form of a longitudinal compressive strain. Such a strain will disappear into the soil farther away from the ring. This action shows as a relative tendency of the ring sections to separate, as if the longitudinal length increased or expanded. The result is the formation of hair cracks or separations in the tunnel lining, having the appearance usually resulting from the shrinkage of the lining.

When some methods are developed for measuring the distribution of radial forces and tangential forces during the various stages of construction, as well as for measuring the actual values of such acting forces, the necessary data will be available for a proper use of the author's design procedure. Until such information is available, it seems very doubtful to the writer that a radical decrease in tunnel lining weight and thickness can be, or should be, proposed.

Leon Beskin,[24] Assoc. M. Am. Soc. C. E.—The "basic principle" on which this paper is based has been used since the beginning of the twentieth century and is probably due to H. F. B. Müller-Breslau. It was taught by Bertrand de Fontviolant for at least twenty years before publication of his book on strength of materials.[25] The author has expended considerable energy on the redevelopment of conventional formulas for rings, which can be found in textbooks on stress analysis. These equations appear in various forms, such as the charts devised by Joseph A. Wise,[26] M. Am. Soc. C. E., and reproduced by Alfred S. Niles, Assoc. M. Am. Soc. C. E., and Joseph S. Newell.[27] Lieutenant-Commander Wise's formulas are more convenient than the author's expressions, which can be derived from them. Whereas Commander Wise uses a supporting fictitious shell, which has shearing reactions defined by a conventional beam distribution, the author deals with diaphragm reactions, in such a manner that the shell reactions vanish if the loads applied to the ring are in equilibrium. Influence factors are obtained in both methods.

A great advantage of the fictitious shell over the diaphragm is that the shell does not introduce any dissymmetry with respect to the load. Thus, the tables need be computed only for one half of a ring. It is a simple matter to transform Commander Wise's formulas into those of the paper. For instance, the function A_{Mr} is obtained by the superposition of the following loads on the ring shown in Fig. 2; thus, for a load P_r at any point p:

[27] "Airplane Structures," by Alfred S. Niles and Joseph S. Newell, John Wiley & Sons, Inc., New York, N. Y., 3d Ed., Vol. II, 1943, p. 272 et seq.

$$P'_r = P_r \cos \alpha \qquad (37a)$$

and

$$P'_t = P_r \sin \alpha \qquad (37b)$$

At the invert joint A,

$$M = P_r\, r \sin \alpha \qquad (38)$$

Defining W_1, W_4, and W_7 as the three coefficients of moment due to unit radial and tangential forces and unit moments—

$$A_{Mr} = -W_1(\alpha) + W_1(0) \cos \alpha + W_7(0) \sin \alpha - W_4(0) \sin \alpha \qquad (39)$$

The values found by Commander Wise are:

$$\left.\begin{aligned} 2\,\pi\, W_1(\alpha) &= 0.5 \cos \alpha - (\pi - \alpha) \sin \alpha + 1 \\ 2\,\pi\, W_4(\alpha) &= 1.5 \sin \alpha - (\pi - \alpha)(\cos \alpha - 1) \\ 2\,\pi\, W_7(\alpha) &= 2 \sin \alpha + \alpha - \pi \end{aligned}\right\} \qquad (40)$$

which, substituted into Eq. 39, yields the expression for A_{Mr} given by the author in Eqs. 8. The A-functions in this paper are no more informative than the charts presented by Commander Wise. In addition, the author's method is extremely sensitive to small computational inaccuracies, because the fictitious reaction is concentrated, instead of being distributed, as in the case of the Wise formulas. For instance, if applied forces are not balanced by a small couple, the total unbalance appears at the diaphragm location, so that the total error is repeated at each station, successively. When a shell is used as a fictitious support, the couple is absorbed by a constant shear flow and the error is distributed on the entire ring, instead of being concentrated at each section.

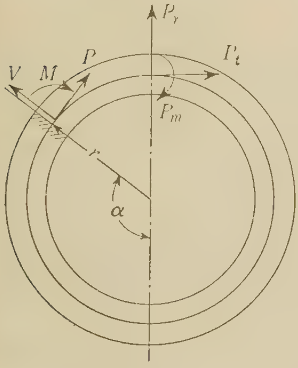

Fig. 24

The coefficients of moment can be established in a straightforward manner. The equations of equilibrium of a ring are:

$$\frac{dM}{d\alpha} = r\, V_p \qquad (41a)$$

$$\frac{dV_p}{d\alpha} = P \qquad (41b)$$

and

$$\frac{dP}{d\alpha} = -r\, V_s - V_p \qquad (41c)$$

in which M, P, and V_p represent the moment and the axial and shearing forces at a section p; and V_s represents the shear from the fictitious shell. This shear is defined by the conventional beam formulas applied to the shell:

$$V_s = -\left(\frac{P_m}{2\,\pi\,r^2} + \frac{P_t}{2\,\pi\,r}\right) + \frac{P_t}{\pi\,r}\cos\alpha - \frac{P_r}{\pi\,r}\sin\alpha \quad \text{........} (42)$$

in which P_t, P_r, and P_m are the concentrated tangential and radial loads and the concentrated moment applied at the point $\alpha = \pm\,\pi$ in the shell (Fig. 24). Elimination of P and V_p in Eqs. 41 leads to:

$$\frac{dM}{d\alpha} + \frac{d^3M}{d\alpha^3} + r^2\,V_s = 0 \quad \text{....................} (43)$$

Considering a tangential load P_t, the solution for M is the general antisymmetrical solution of Eq. 43, in which V_s has the value defined by Eq. 42, in which $P_r = P_m = 0$. For $\alpha > 0$:

$$M = r\,P_t\left[\,k\sin\alpha + \frac{\alpha}{2\,\pi}(1 + \cos\alpha)\,\right] \quad \text{.............} (44)$$

The constant k is defined by the condition of minimum strain energy which gives:

$$k = -\frac{\displaystyle\int_0^\pi \alpha\,(1 + \cos\alpha)\sin\alpha\,d\alpha}{\displaystyle 2\,\pi\int_0^\pi \sin^2\alpha\,d\alpha} = -\frac{3}{4\,\pi} \quad \text{............} (45)$$

Thus, the expression for M is:

$$M = r\,P_t\,\phi(\alpha) \quad \text{........................} (46a)$$

in which

$$\phi(\alpha) = \frac{1}{2\,\pi}\left[\,\alpha\,(1 + \cos\alpha) - \frac{3}{2}\sin\alpha\,\right] \quad \text{............} (46b)$$

Applying Eqs. 41, V_p and P are obtained by differentiation:

$$V_p = P_t\,\phi'(\alpha) \qquad \text{with} \qquad \phi'(\alpha) = \frac{1}{2\,\pi}\left(1 - \alpha\sin\alpha - \frac{\cos\alpha}{2}\right) \quad \text{..} (47a)$$

and

$$P = P_t\,\phi''(\alpha) \qquad \text{with} \qquad \phi''(\alpha) = -\frac{1}{2\,\pi}\left(\frac{\sin\alpha}{2} + \alpha\cos\alpha\right) \quad \text{..} (47b)$$

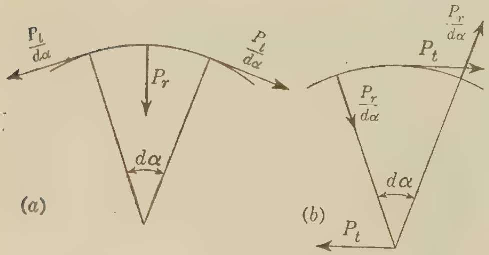

FIG. 25

Considering two loads $P_t = \pm\,P_r/d\alpha$, placed at a distance $r\,d\alpha$ from one another (Fig. 25(a)), which are equivalent to a load P_r, it appears that the coefficients for a unit load P_r are obtained by differentiating the coefficients corresponding to P_t; thus:

$$M = r\,P_r\,\phi'(\alpha) \quad \text{........................} (48a)$$

$$V_p = P_r\,\phi''(\alpha) \quad \text{........................} (48b)$$

and

$$P = P_r \phi'''(\alpha) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48c)$$

Applied couples may be considered as the limit of two loads $\pm P_r/d\alpha$ and a load $P_t = P_r$ (Fig. 25(*b*)), since this combination of loads is equivalent to a couple, $P_m = P_r r$. Thus, combining Eqs. 46, 47, and 48:

$$M = P_m (\phi + \phi'') = P_m \psi \ldots\ldots\ldots\ldots\ldots\ldots (49a)$$

$$V_p = \frac{P_m \psi'}{r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (49b)$$

and

$$P = \frac{P_m \psi''}{r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (49c)$$

The *A*-constants in Table 1 are computed for very large increments (22° 30′); and the curves presented by Commander Wise do not always yield values of sufficient accuracy for practical use. Using the latter, the writer prepared[28] a table of ϕ-functions and ψ-functions for 5° increments of α, in which four ϕ-functions replace the author's six *A*-functions.

Adjusting for Polygonal Effect.—The adjustment proposed by the author in Section 8 can be avoided if the concentrated loads are replaced by uniformly distributed loads on an arc $2\,\epsilon$ defined by the angles $\alpha - \epsilon$, $\alpha + \epsilon$. For instance, the coefficient A_{M_r} would be (the angle ω varying between $\alpha - \epsilon$, $\alpha + \epsilon$):

$$A_{M_r} = -\frac{1}{2\,\pi \times 2\,\epsilon} \int_{\alpha-\epsilon}^{\alpha+\epsilon} (\omega \sin \omega + 1 - \cos \omega)\, d\omega$$

$$= -\frac{1}{2\,\pi} \left(\alpha \sin \alpha \frac{\sin \epsilon}{\epsilon} + 1 - \cos \alpha \cos \epsilon \right) \ldots\ldots\ldots\ldots (50)$$

which yields values that differ but slightly from the values given by the formulas in Eqs. 8.

Symmetrical Loading.—The *B*-constants (see Section 12) require an extremely extended table if the functions are to be computed by small increments. The time saved by these coefficients is of relatively minor importance in any case.

Deflections of a Tunnel Lining.—The expressions given by the author contain two angles, α and β, and their computation by sufficiently small increments is a laborious operation. When a shell is used instead of a diaphragm, the method is greatly simplified. Coefficients of deflection can be defined by expressions of the type:

$$k_{(ti)(rj)} = \int_0^{2\pi} m_{ti}\, m_{rj}\, d\alpha \ldots\ldots\ldots\ldots\ldots\ldots (51)$$

in which the subscripts denote values caused, respectively, by a unit load P_t at point I and by a unit load of P_r at point J—that is, the first of two subscripts shows the location of the load and the second shows the nature of the load. Replacing coefficients *m* by the functions computed by Eqs. 46 to 49 and integrating, coefficients *k* are obtained. The deflections can be computed by means of unit dummy loads. Using radial and tangential dummy loads, the radial and tangential components of the displacement of a point B (designated d_{rb} and d_{tb}, respectively) are

---

[28] "General Circular Ring Analysis," by Leon Beskin, *Aircraft Engineering*, Vol. XVII, No. 195, May, 1945, p. 126.

$$d_{rb} = \frac{r^3}{E\,I}\left(\Sigma k_{(rb)(ti)}\, P_{ti} + \Sigma k_{(rb)(ri)}\right) P_{ri} \quad \text{(52a)}$$

and

$$d_{tb} = \frac{r^3}{E\,I}\left(\Sigma k_{(tb)(ti)}\, P_{ti} + \Sigma k_{(tb)(ri)}\right) P_{ri} \quad \text{(52b)}$$

The summations in Eqs. 52 are extended to all the loads on the ring. These displacements are relative and, to define absolute displacements, a point must be considered fixed. For instance, if the invert joint A is fixed, it is necessary to cancel its displacement d_{ra} which, under symmetrical loading, is expressed by Eq. 52*a* (except that subscript *b* becomes *a*). Adding $-d_{ra}$ to all the displacements, the final components of the displacement of point B (separated by the angle α from point A) are:

$$\bar{d}_{rb} = d_{rb} - d_{ra} \cos \alpha \quad \text{(53a)}$$

and

$$\bar{d}_{tb} = d_{tb} + d_{ra} \sin \alpha \quad \text{(53b)}$$

Coefficients k are functions only of the angle α between the point where the load is applied and the point where the deflection is calculated.

There are six different coefficients $k(\alpha)$:

$$\left.\begin{aligned}
k_{tt}(\alpha) &= \Gamma(\alpha) = \frac{1}{2\,\pi}\left[\cos\alpha\left(\frac{\pi^2}{6} - \frac{23}{8} - \frac{\pi\,\alpha}{2} + \frac{\alpha^2}{4}\right)\right.\\
&\qquad \left. + \frac{3}{2}\sin\alpha\,(\pi - \alpha) + \frac{\pi^2}{3} - 2 - \alpha\,\pi + \frac{\alpha^2}{2}\right]\\
k_{tr}(\alpha) &= \Gamma'(\alpha) = \frac{1}{2\,\pi}\left[(\pi - \alpha)(\cos\alpha - 1)\right.\\
&\qquad \left. - \sin\alpha\left(\frac{\pi^2}{6} - \frac{11}{8} - \frac{\pi\,\alpha}{2} + \frac{\alpha^2}{4}\right)\right]\\
k_{rr}(\alpha) &= -\Gamma''(\alpha) = \frac{1}{2\,\pi}\left[\frac{1}{2}(\pi - \alpha)\sin\alpha - 1\right.\\
&\qquad \left. + \cos\alpha\left(\frac{\pi^2}{6} - \frac{3}{8} - \frac{\pi\,\alpha}{2} + \frac{\alpha^2}{4}\right)\right]\\
k_{tm}(\alpha) &= \Delta(\alpha) = \Gamma(\alpha) + \Gamma''(\alpha) = \frac{1}{2\,\pi}\left[-\frac{5\cos\alpha}{2}\right.\\
&\qquad \left. + (\pi - \alpha)\sin\alpha + \frac{\pi^2}{3} - 1 - \pi\,\alpha + \frac{\alpha^2}{2}\right]\\
k_{rm}(\alpha) &= -\Delta'(\alpha) = \phi(\pi - \alpha)\\
&= \frac{1}{2\,\pi}\left[(\pi - \alpha)(1 - \cos\alpha) - \frac{3}{2}\sin\alpha\right]\\
k_{mm}(\alpha) &= \mathrm{E}(\alpha) = \Delta(\alpha) + \Delta''(\alpha)\\
&= \frac{1}{2\,\pi}\left[-2\cos\alpha + \frac{\pi^2}{3} - \alpha\,\pi + \frac{\alpha^2}{2}\right]
\end{aligned}\right\} \quad \text{(54)}$$

It is feasible then to prepare tables of deflection[28] coefficients from Eqs. 54.

Example.—To illustrate the foregoing argument the example given by Mr. Bull in Section 9 and Fig. 6 is solved by the Wise method. Since only four radial loads are applied, the adjustment for polygonal effect is not justified, and the comparison is made without adjustment (if necessary, the same adjustment can be made for both methods). The author's values are:

$$\begin{aligned}
&\text{Thrust } T = -1.08317 - 1.77015 &&= -2.85332\\
&\text{Shear } V = -4.01595 + 5.05450 &&= +1.03855\\
&\text{Moment } M = -3.14551 + 2.79700 - 0.01644 &&= -0.36495
\end{aligned}$$

The values resulting from the use of the Wise method have been computed with coefficients read from the original graphs, Table 20(*a*),[26] and with coefficients interpolated from a seven-place table (see Table 20(*b*)).

TABLE 20.—SOLUTION OF AUTHOR'S EXAMPLE, SECTION 9, BY THE WISE METHOD

The author's values and the Wise values are seen to be in very close agreement; and the charts originally prepared by Commander Wise are shown to be sufficient for all practical purposes when only a few loads are applied on the ring.

The differences in signs result from different sign conventions. The change in diameter (see Section 15) can also be determined by means of a table[28] giving the coefficients k_{tr} and k_{rr} (functions $\Gamma'(\alpha)$ and $\Gamma''(\alpha)$).

Table 21 indicates that the agreement between both methods is excellent, which simply means that the numerical tables have been computed without error.

Comparison of Table 21 with Table 7 shows that the author's method necessitates more numerical computations than the method derived from Commander Wise's concepts, because of the dissymmetry introduced by the diaphragm in Mr. Bull's method, which does not occur in the Wise method.

Another advantage resulting from Commander Wise's concepts appears from comparison of Tables 20 and 21 with the tables in the paper: The Wise coefficients have much smaller values than the author's coefficients, so that, for the same degree of final accuracy, less laborious computations are required.

TABLE 21.—COMPUTATION OF CHANGE IN DIAMETER

Forces	Angle	Kips	Function	Value	Product
P_{r7}, P_{r8}	90°	4 − 1 = 3	$\Gamma''(\alpha)$	+0.034160 × 2	+0.20496
P_{r1}, P_{r9}	45°	3 − 2 = 1	$\Gamma''(\alpha)$	+0.005140 − 0.00245	+0.00269
P_{t3}	45°	5	$\Gamma'(\alpha)$	+0.016560 + 0.018726	+0.17643
P_{t13}	90°	5	$\Gamma'(\alpha)$	0	0
Total coefficient	....	....	....	....	+0.38408
Author's value	....	....	....	+0.061890 + 0.322171	(+0.384061)

For instance, the moment coefficients are approximately seven times smaller, and the deflection coefficients are five times smaller. This disparity may mean the difference between using a slide rule or a computing machine in many practical problems.

Finally, it can be remarked that, if the C-constants were calculated by 5° increments, it would be necessary to calculate 5,184 entries instead of the 72 entries required for the $\Gamma'(\alpha)$-functions and $\Gamma''(\alpha)$-functions.[28] Also, the interpolation in a table with two independent variables is extremely laborious.

Effects of Displacement.—Mr. Bull states in Section 17 that

> "* * * when the shearing stress at any point reaches a certain limit a slip takes place between the surface and the soil particles, or between the soil particles themselves, causing the stress at that point to be relieved suddenly."

The slip between the lining and the soil particles or between soil particles actually occurs under constant shearing stress (provided the normal force is not changed), which is practically independent of the rapidity of displacement and is equal to the product of the normal pressure and the coefficient of friction.

Tangential Forces.—It is very improbable (see Section 18) that the region between the lining and the soil is free from tangential forces. It is true that an arch effect exists near the shield, but this arch effect is certainly helped by the shears developed between the arch and the soil in front of the shield as well as by the shears between the arch and the soil that have already settled at some distance behind the shield. Thus, the equilibrium cannot be examined as a plane equilibrium in sections perpendicular to the direction of the tunnel—at least when the effect of tunneling is being felt. It is highly probable that a stress redistribution occurs when the shield has moved to some distance from a given section, since the aforementioned effects disappear, and a plane equilibrium reappears. The best assumption is that of the uniform equilibrium defined by Rankine's formulas, which imply the existence of shear in all directions, except the vertical and the horizontal. A state of equilibrium without shear along the lining may be found, but that cannot be the condition assumed by the author because the normal component acting on the lining is not in equilibrium with the horizontal and vertical normal forces defined by Rankine's formulas. This is demonstrated by comparing Fig. 26(*a*), showing the loads on the lining, and Fig. 26(*b*), representing Mohr's circle of stress at any point of the lining (at an arbitrary scale). The maximum (vertical) and minimum (horizontal) pressures P_M and P_m are correlated by the formula,

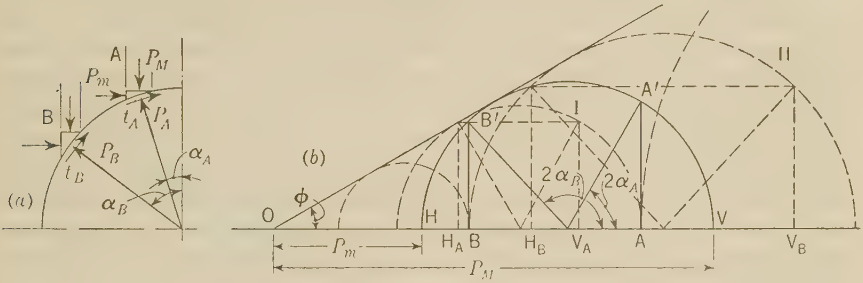

Fig. 26

$$P_m = P_M \tan^2\left(\frac{\pi}{4} - \frac{\phi}{2}\right) \qquad (55)$$

In this case ϕ is the angle of friction. The author has used the conventional values $P_m/P_M = 1/3$, or $\phi = 30°$.

At points A and B (Fig. 26(*a*)), the normal stresses are represented by OA and OB; the shears are represented by AA′ and BB′ (see Fig. 26(*b*)). With the author's assumption that $\overline{AA'} = \overline{BB'} = 0$, Mohr's circles must be modified, so that their diameters end at point A or B. There are two possible Mohr's circles at each point. Near the crown, circle I must be chosen for reason of continuity; and, near the skewback, circle II must be chosen. Thus, neglecting the dead weight between points A and B, it appears that the pressures at point B are greater than the pressures at point A. This seems to indicate that there is an arch effect—a conclusion which contradicts the fact that the pressure at the skewback is defined without arch effect. The latter (arch effect) shows that the pressure distribution does not correspond to a possible equilibrium. Another aspect of this contradiction results from the inspection of the values of the vertical and horizontal pressures at points A and B (represented by OV_A, OV_B, OH_A, and OH_B, respectively). It appears that the vertical pressure, when moving along the lining, first decreases (points V_A); then, at some unknown arbitrary point, it jumps to the values represented by points V_B, instead of remaining constant and equal to P_M (point V). Such a state of stress appears extremely improbable. In addition, the reactions of the lining must be in over-all equilibrium with the loads above the lining. More precisely, a vertical elemental prism limited to the surface must be in equilibrium with the lining reactions and the shears along its vertical faces. The author has not attempted to show that this equilibrium is consistent with the lining reactions he has chosen, although proof is essential to give the method a sound basis. Because of the aforementioned considerations, the method appears to be highly questionable. In addition, if considered approximate, the method is not conservative, since the vertical components of the lining reactions are smaller than the loads above the lining.

Soil Reactions Due to Settlement.—The author disregards tangential reactions, which must exist, since the displacement δ has the components $\delta \cos \alpha$ (normal) and $\delta \sin \alpha$ (tangential). For this reason, the directions of the forces F_1 to F_6 (Fig. 9) are incorrect, and the subsequent analysis is extremely questionable. Especially, the direction of forces F_5 and F_6 cannot be downward because the main component of displacement in the vicinity of these forces is tangential. Furthermore, the vertical component of the forces above the ring is determined by the dead weight—for example, if the direction of a force F_6 were downward, the soil reaction at point 7 would be decreased. On the basis of the foregoing reasoning, it is conclusive that Eq. 16 does not represent the soil reactions correctly.

It is impossible to obtain soil reactions on the segments near the crown since the ring settles as a whole and does not expand and since the section at its crown settles more than the other sections. The settled ring is obviously below the unsettled ring, and it is extremely probable that the maximum u (number of segments in which soil reactions are developed) is equal to 6, a fact confirmed by Table 14.

Specified Conditions.—Contrary to Eq. 22*c*, the horizontal pressure is equal to one third of the net vertical pressure (minus the hydrostatic pressure), plus the hydrostatic pressure:

$$p_H = \frac{0.100\, H_w + (0.125 - 0.063)\, (H_n - H_w)}{3} + 0.063\, (H_n - H_w)$$

$$= \frac{0.038\, H_n + 0.062\, H_w}{3} + 0.063\, (H_n - H_w) \dots\dots\dots\dots (56)$$

Eq. 56 defines a smaller pressure than does Eq. 22*c*, and the difference is especially important when H_w is small. Below the skewback, there is a vertical soil reaction, equal to one third of the net horizotnal pressure, thus, contrary to Eq. 22*a*:

$$p_v = \frac{0.038\, H_n + 0.062\, H_w}{9} + 0.063\, (H_n - H_w) \dots\dots\dots\dots (57)$$

Because of the foregoing, it is very dubious that the active forces are computed correctly. For example, if Eq. 22*c* is applied to a completely immersed material which has the density of water, a horizontal pressure greater than the hydrostatic pressure is indicated. This is an obviously incorrect result, since the material is in suspension and cannot produce an additional pressure.

If Eq. 22*a* is applied to a case in which the water level is just above the point under consideration, it indicates a pressure practically equal to zero, which is also incorrect.

Perhaps these formulas can be used when crude methods of analyses are used, but not when a refined analysis is sought.

Active Forces.—The calculations indicated by the author can be simplified somewhat. For example, the tangential forces due to the lining weight, which are sinusoidally distributed, can be replaced by radial forces following a cosine distribution of the same amplitude, without introducing any additional bending in the lining. This fact can be shown by considering the differential equation of equilibrium of the ring. The radial forces can be divided into a constant pressure, producing thrust exclusively, and a variable pressure, giving bending moments and thrust.

Conclusions.—In this paper, applied active forces, as well as reactive forces, have been estimated by methods that cannot be considered satisfactory, and errors may result in the values of the final moments. There is no doubt that the author is entirely correct when he states that conventional methods are highly conservative, but it seems nonconservative to use the author's results without an additional factor of safety that would consider the inaccuracies of the method. Happily, it seems probable that errors in the basic data do not have an excessive influence on the final moments. For instance, a variation of the moment of inertia (or of the soil compression constant) in the ratio of 4 to 1 generally produces a variation of bending moments in a ratio of less than 2 to 1.

Thus, it is probable that the additional factor of safety would be so small that it could be omitted if the active forces were recomputed more conservatively. Because of the lack of precision in the basic data, the author's method seems too intricate. However, the numerical results presented may be considered a basis for estimating the reduction of moments due to the flexibility of the lining. This estimate can be made by computing the dimensionless coefficient $\frac{K\,r^4}{E\,I}$ and by using the results obtained by the author for the same value of this coefficient. For that purpose, it would be very helpful if the author would add to his data the values of the bending moments in the case where the flexibility of the lining is disregarded.

Notation.—The author specifies that the tangential component P_t is positive when directed upward. This is contrary to the conventional positive direction, which is either clockwise (or opposite), with reference to the center of the ring. Also, this convention is not consistent with the use of the author's tables, because they thus become restricted to the invert joint. If the tables are to be applied to other points, the sign convention must be changed so that the tangential component is positive when directed away from the diaphragm. Thus, when the diaphragm is moved, the sign of a given tangential force must be changed according to the location of the diaphragm. Such cumbersome notation, which is a source of error, should be rejected, and the signs in the tables corrected in order to make them consistent with the stipulation that positive tangential forces are clockwise.

D. P. Krynine,[29] M. Am. Soc. C. E.—In describing the present state of the art of designing and building shield-driven tunnels (circular in cross section), the author of this excellent paper presents Fig. 1 showing assumed vertical and horizontal pressures on the lining. Judging from the measurements of pressure on the lining of the Lincoln Tunnel in New York City,[30,31] the shape of the vertical downward pressure diagram seems to be qualitatively correct, whereas the shapes of other diagrams shown in Fig. 1 should be considered temporarily as approximations only, until more field measurements and analyses along these lines are available. Purely theoretical attempts of establishing the shape of such diagrams are not sufficient.

Eq. 15 and the "Soil Compression Constant."—In a general case, the value of K, termed the "soil compression constant," depends on the size and the shape of the plane area abutting the soil and displaced in a normal direction. According to Eq. 15, a given unit load $\frac{F}{A'}$ abutting a given soil (constant K) always produces the same displacement of ρ inches. It is a well-known experimental fact, however, that from the two areas loaded with the same unit load, the larger area will settle more than the smaller one.

In the particular case of a shield-driven tunnel, the value of K changes also according to where the load acting on the soil is applied. The value of K will be smaller in the upward direction than in the downward direction, especially if the tunnel is shallow. The value of K in a sidewise direction, perhaps, would be between the two; also it may be smaller than the other two. The writer cannot even imagine how the value of K in the case of a shield-driven tunnel could be determined experimentally. It is impossible to organize such a test and the value of K must be guessed.

Eq. 15 means implicitly that the soil mass obeys Hooke's law which, in general, is not the case.

Reversible and Nonreversible Displacements in the Soil Mass.—If a rigid loaded plate is placed on the surface of a previously unloaded soil, a displacement occurs which consists of a reversible and a nonreversible part, the reversible (elastic) part being generally much smaller than the nonreversible. Assume that the experimental plate is first loaded with a certain unit load and thereupon a new unit load of the same magnitude is superimposed on the given acting load. The additional displacement thus caused will be much smaller than that in the original case. The reversible (elastic) part of the displacement may be the same in both cases, but the nonreversible one will decrease substantially. This is an additional reason why the concept of the "soil compression constant" should be used with extreme care.

[30] "Lincoln Tunnel. The Field Measurements and Study of Stresses in Tunnel Lining," by G. M. Rapp and A. H. Baker, The Port of New York Authority, July, 1937 (lithoprinted).

[31] "Pressure on the Lining of Circular Tunnels in Plastic Soils," by D. P. Krynine, *Proceedings*, Am. Soc. C. E., May, 1944, p. 629.

Stressed Condition of the Lining During and After Shoving.—If the tunnel is driven in a plastic mass (organic silt or plastic clay), the vertical diameter of the lining first increases, apparently due to shoving. In the case of the Lincoln Tunnel, this increase was about 0.4% of the diameter of the lining. It is not clear from the paper in what way the stresses caused in the lining by the shoving process should be estimated or computed. Apparently these stresses should be fully or partly superimposed on those caused by the loads, as in Fig. 1.

Decrease in the Weight of the Lining.—Mr. Bull proposes using scaffolding in order to decrease the weight of the lining. Granted that the weight of the lining can be decreased in thát manner, two conditions still remain: (*a*) The maximum acceptable deflections of the lining should be controlled by the shearing strength of the overburden; and (*b*) a rather heavy lining in soils possessing small shearing resistance still may be required to balance the effect of buoyancy. To clarify the statement made under item (*a*), the well-known trap-door experiment should be recalled. The bottom of a box filled with sand is provided with a horizontal trap door at the center. Some downward movement of the trap door causes the vertical pressure on it to decrease, but excessive downward movement of that door causes an increase in pressure.

The writer disagrees with the statement at the end of the paper:

> "There seems to be no good reason, however, for making material that is needed only during the erection of a tunnel an integral part of it, something that is being done in no other type of structure."

On the contrary, many types of foundations are built with excessive material which is useful only during the erection of the structure. One of such examples is the use of pre-cast concrete piles which are designed to furnish excess resistance to both handling stresses and driving stresses. A caisson (for instance, a metallic compressed air caisson) is nothing more than an excessively heavy shell of the structure, useful only during construction, but which, however, remains buried in the earth forever.

A. A. EREMIN,[32] ASSOC. M. AM. SOC. C. E.—By considering the elastic properties of soil the author has developed an interesting method of computing stresses in tunnel linings. However, the conclusion that linings designed by current methods are too heavy seems premature. Actually, the tunnel lining carries a more complicated loading than that described by Mr. Bull. The final shape of a tunnel lining often is established after pressure grouting was applied. For example, the Posey Tube[33] in Oakland, Calif., was moved laterally by the forces transmitted through the backfill. The final stresses in the tunnel lining are also influenced by the loading on the roadway slab and by the forces transmitted through the tie rods. These influences were not mentioned by the author.

The coefficient of compressibility, K, has been used widely in the past. Recent experiments, however, have revealed that this coefficient is variable.

[33] *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 747.

Therefore, it cannot be used in computing stresses by the principle of superposition of stresses and deformation.

The design loading to be adopted is often influenced by the method of erection of structure. In Section 29, Mr. Bull has stated that no other type of structure requires that erection material be made an integral part, as in tunnel lining. Unfortunately, extra material must be provided for erection stresses in several other types. Pre-cast tunnel tubes are proportioned for the maximum stresses that may be developed during the launching and while shipping the tube sections to their final location. The cantilever method of erecting continuous bridge trusses requires that various members and connections, that are not fully stressed in the completed structure, be reinforced to resist erection stresses. Extra heavy, reinforcing armature sometimes is provided in reinforced concrete arches to support the centering.

Mr. Bull believes it is erroneous to assume that the vertical soil reactions are uniformly distributed along a horizontal diameter of tube (see Section 19). The accuracy of this assumption varies with the ratio of the horizontal soil pressure to the vertical soil pressure. When this ratio is approaching unity, the error of the adopted assumption is negligible. The assumption of uniform distribution of the vertical reactions simplifies the computation of stresses in the tunnel lining.[34] Of course, deviation from this assumption is quite common when local conditions require it—for instance, when the tube is supported on a cushion or on piers. When the ratio of horizontal soil pressure to vertical soil pressure is less than unity, a simplified graphical expression of soil pressure exerted by a prism is generally adopted.[35] Such a diagrammatic expression of loading gives a convenient criterion for the stresses in the lining. The diagrammatic loading is easy to visualize. It can be compared with the actual loading encountered during erection and, later, when the structure is carrying the actual superimposed load.

G. N. Alexander,[36] Esq.—As there is no generally accepted method for designing tunnel linings, the author's analysis is very welcome in providing a rational method for determining what are generally termed passive pressures. Although there may be good grounds for maintaining that successful precedent, where such exists, is the best guide to tunnel lining design, progress depends in part on the promulgation of such theories. However, until knowledge of active pressures advances, elaborate theories regarding passive pressures tend to be academic.

The author rightly criticizes the "classical" theory[2] given by S. Johannesson and the late B. H. M. Hewett, Members, Am. Soc. C. E., because it does not consider that the deflection of the lining is sufficient to give rise to stresses. This theory depended on an assumption that, provided the total passive pressure determined from Rankine's theory is not exceeded, bending stresses due to earth pressure need not be considered. This may lead to unsafe rather than conservative designs. The late Walter C. Parmley,[37] M. Am. Soc. C. E., directed attention to the weakness of their contentions and made an analysis based on an assumed elliptical deflection curve with passive pressures depending on the deflections in the lateral quadrants. Such methods require what is variously termed the "soil constant" (M. A. Drucker), "soil compression conconstant" (Anders Bull, M. Am. Soc. C. E.), and "coefficient of horizontal soil reaction" (Karl Terzaghi, M. Am. Soc. C. E.). Unfortunately, experimental evidence concerning the value of the "soil constant" K is extremely meager and any designer using it must do some "guestimating." It therefore seems desirable to derive an expression to show rapidly the effect of varying the factors that influence passive pressures. Some consideration must also be given to the assumptions made.

[37] Discussion by Walter C. Parmley of "Notes on Tunnel Lining for Soft Ground," by S. Johannesson and B. H. M. Hewett, *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 1880.

The author criticizes Mr. Drucker[3] (see Section 3) and other exponents of theories (such as M. G. Spangler,[10] M. Am. Soc. C. E., in Section 28) who use a uniform vertical load to determine passive pressures. For analytical investigations loading may be expressed by using rectangular or polar coordinates. It would appear that the loading assumptions made may depend on the system chosen—a scarcely defensible procedure. If rectangular coordinates are used it is generally assumed that the horizontal pressure is equal to k times vertical pressure, which may be termed case I. If such a loading is expressed in polar coordinates tangential tractions are involved, but the author, by deductive processes, disposes of these which may be termed case II. Fig. 27 illustrates the two systems and the relative magnitude of the tangential tractions, at θ. Of the radial pressure OC, only the variable part EC is effective in producing distortion and hence effective passive pressures. As $\overline{CB} = \overline{CE} \cot \theta$ it cannot be neglected on the score of the relative magnitude.

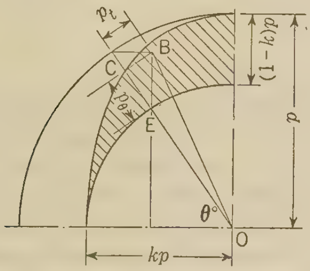

FIG. 27.—ACTIVE PRESSURE

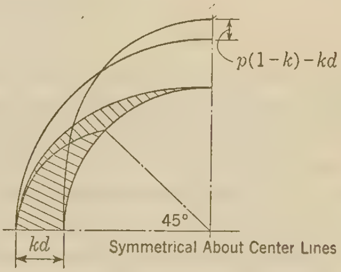

FIG. 28.—PASSIVE PRESSURE

To determine the relative importance of radial and tangential loadings it may be shown that, for a constant vertical pressure of p_v, the value of M_θ is given for case I by

$$M_\theta = \frac{p_v\, r^2\, (1 - k) \cos 2\,\theta}{4} \qquad (58)$$

For case II, for a radial pressure only, given by

$$p_\theta = p\,(1 - k) \sin^2 \theta \qquad (59)$$

the corresponding moment can be determined most readily by considering a pair of equal but opposite diametrical loads. Thus, if $P_\theta = p_\theta \, r \, d\theta$, M'_ϕ due to P_θ, with $\theta > \phi$, is given by[38]

$$M'_\phi = \frac{P_\theta \, r}{2} \left(\sin \overline{\theta - \phi} - \frac{2}{\pi} \right) \dots\dots\dots\dots\dots\dots (60)$$

Hence the bending moment at ϕ due to distributed load is given by

$$M_\phi = \frac{p \, (1 - k) \, r^2}{2} \int_{\theta=\phi}^{\theta=\pi+\phi} \sin^2 \theta \left(\sin \overline{\theta - \phi} \, \frac{2}{\pi} \right) d\theta = \frac{p \, (1 - k) \, r^2 \cos 2 \phi}{6} \quad (61)$$

Thus, the tangential tractions produce half as much moment as the radial loads and clearly should not be neglected unless more evidence can be produced to show that such tangential loadings as implied by the use of the relation $p_h = k \, p_v$ do not exist. To determine the deflections the differential curve of the ring may be used,[39] thus:

$$\frac{d^2 d}{ds^2} + \frac{d}{r^2} = - \frac{M}{E \, I} \dots\dots\dots\dots\dots\dots\dots\dots (62)$$

Substituting the value for M given by Eq. 61 and solving, the deflection at any point is

$$d_\phi = \frac{p \, r^4 \, (1 - k) \cos 2 \phi}{18 \, E \, I} \dots\dots\dots\dots\dots\dots\dots (63)$$

That is, for case *I* the value is increased by 50%.

Passive Pressures.—Deflections and moments calculated on active pressures alone will not generally be realized due to the effect of passive pressures. Various assumptions are made as to how, where, and when these passive pressures act. The use of a soil constant K seems necessary but its use involves crude approximations, and consolidation effects may mask any elastic effect. Grouting also may have considerable significance. The author assumes that passive pressures are directly proportional to the radial deflections outside the settled position of the undeflected ring. The writer also assumes that the active pressure is unchanged at the crown but the movement of the tunnel in a vertical direction may be disregarded in determining passive pressures due to deflection of the lining. In this case the active pressure $p \, k$ (Fig. 27) of the horizontal diameter is increased by a passive pressure, $K \, d$ (Fig. 28), in which d is the net maximum radial deflection. For the analytical determination of moments this passive pressure $K \, d$ can be subtracted over the entire circumference from the net active pressure causing distortion used previously, leaving a pressure difference between the crown and sides of $p \, (1 - k) - K \, d$ (Fig. 28). At first it may appear safest to consider that passive pressures are limited to the two lateral quadrants. However, such pressures can be maintained only by the deflection of the lining due to the excess of vertical over horizontal active pressures. This requires continuous contact between earth and lining and it is presumed that the final pressure curve is continuous. Therefore, the writer assumes a final pressure distribution curve of the same form as that for active pressure. The passive pressures additional to those which may undoubtedly be assumed to occur over the lateral quadrants will cause no significant distortion to the lining, as each of the four quadrants is equally loaded with these additional pressures (Fig. 28).

---

[38] "Strength of Materials," by S. Timoshenko, D. Van Nostrand Co., Inc., New York, N. Y., 2d Ed., 1940–1941, Pt. II, p. 82.

[39] *Ibid.*, p. 103.

Hence, the net deflection d due to active and passive pressures, assuming the net loading is due to radial loads only, is as follows:

$$d = [p\,(1 - k) - K\,d]\,\frac{r^4}{18\,E\,I} \quad \ldots\ldots\ldots\ldots\ldots (64a)$$

Therefore,

$$d = \frac{p\,(1 - k)\,r^4}{18\,E\,I}\,\frac{1}{1 + \frac{K\,r^4}{18\,E\,I}} = d_a \times \frac{1}{1 + n} \quad \ldots\ldots\ldots\ldots (64b)$$

In Eq. 64*b*, $n = \frac{K\,r^4}{18\,E\,I}$ and the maximum active deflection is $d_a = \frac{p\,(1 - k)\,r^4}{18\,E\,I}$;

or

$$d = \frac{p\,(1 - k)\,n}{K\,(1 + n)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (65)$$

Thus the dimensionless term $\frac{K\,r^4}{18\,E\,I}$ may be evaluated to give the effect of the passive pressures. The factors in this term deserve consideration. Clearly the most significant is r and large diameter tunnels may make much more use of passive pressures unless tie rods and roadways reduce the deflection. The moment of inertia I may have only a fraction of its theoretical value due to flexibility at the joints, especially in a cast-iron tunnel where longitudinal joints are not staggered. This flexibility (if strength is not impaired) therefore may be an advantage. It would be advisable to determine the value of $E\,I$ for a ring by experiment if Eq. 65 were to be used.

There appear to be good grounds for the author's contention concerning the advantages of steel, especially as the governing stresses in the conventional cast-iron lining are tensile. The provision for jacking stresses and the apparent unwillingness of designers to depart from customary methods would seem to be the major reason for the continued use of cast iron.

Therefore, it appears that, although it is desirable that more rational methods be applied to tunnel design than heretofore, much more experimental evidence is necessary to enable the variables to be determined before such an elaborate theory as that proposed by the author is necessary. The writer suggests that for all cases, except large shallow tunnels, the ratio of passive to active pressures, deflections, and moments is given approximately by the ratio, $\frac{K r^4}{K r^4 + 18 E I}$.

The author is to be congratulated on his extensive mathematical work and it is to be hoped that his paper will accelerate the accumulation and dissemination of data on soil pressure on tunnels to enable a theory to be developed which can be substantiated by experimental data.

LOUIS BALOG,[40] ESQ.—In the design of underground cylindrical structures the analysis can often be limited to a ring of unit length under the action of transverse forces. The method of ring analysis applied to the solution of this problem by Mr. Bull was developed for structures of circular section with concentrated supports. Inasmuch as the support conditions of the tunnel ring are continuous and elastic, it would be advantageous to begin the analysis by the theory of curved beams on continuous elastic support.

The first step in the solution of this problem by this approach—the formulation of a differential equation of the elastic line of the circular ring—was published in 1883.[41] The general solution of this differential equation for the circular beam on continuous elastic support (inverted foundation arch) was published in 1900;[42] another solution appeared in 1921;[43] and the solution of the author's problem (equations of influence lines for stresses in an elastic ring embedded in an elastic medium) was published by Adolf Voellmy in 1936.[44] Mr. Voellmy's work, including experimental verification, was completed in 1934.[45]

The carrying capacity of an elastic cylinder embedded in the soil is greatly influenced by the deformations. "Safe" design assumptions which disregard this important fact may result in weaker structures at considerably increased expense. Since the thinner cylinder is able to undergo larger deformations without failure, such deformations advantageously modify the pressure distribution on the cylinder surface. Thus, the internal stresses will be smaller than those in a structure with thicker walls. This explains the great carrying capacity of thin ductile metal cylinders and shows the importance of designing underground cylindrical structures as flexible as practicable. Therefore, a basic distinction should be made between pressures and stresses derived with or without considering the effect of deformations in the ring and the surrounding medium. The segregated determination of these two kinds of pressure and stress distributions facilitates clear visualization of the behavior of the structure as influenced by deformability characteristics—a great advantage in judging the effect of the various factors that enter into the design and in selecting the proper solution. From the design point of view, the inseparable consideration of these effects impairs the practical value of the author's method.

[45] "Eingebettete Rohre," by Adolf Voellmy, Leemann & Co., Zürich, 1937, p. 151.

As is the case for the analysis of suspension bridges, the difference between the stresses that refer to the original shape of the structure, and those that refer to the deformed shape, will be small if the ring is rigid. In designing suspension bridges, the continuous change of the deformability characteristics along the span generally makes it impracticable to use the principle of superposition, whereas the constant deformability characteristic of a circular ring facilitates design by superposition. In the latter case superposition is also best suited to the nature of the design problem under consideration. Two kinds of influence lines are required, therefore, for design purposes: (*a*) Influence lines which are generally valid for a circular ring and (*b*) one influence line for the consideration of the effects of the deformations of a given ring.

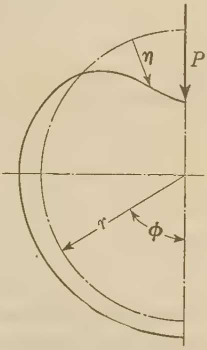

FIG. 29

The differential equation of the elastic line of the circular ring on elastic support (see Fig. 29) is:[44]

$$\eta'''' + \eta'' + \left(1 + \frac{r^4 K}{B}\right)\eta = \frac{C_1 r^2}{B} \quad \ldots\ldots\ldots\ldots\ldots(66)$$

and the general solution of Eq. 66 is:

$$\eta = \frac{C_1 r^3}{B a^2} + (C_2 \sinh v_1 \phi + C_3 \cosh v_1 \phi) \sin v_2 \phi$$
$$+ (C_4 \sinh v_1 \phi + C_5 \cosh v_1 \phi) \cos v_2 \phi \quad \ldots\ldots\ldots\ldots(67)$$

For the case of a radial load at $\phi = \pi$ (see Fig. 29), constants C_1 to C_5 are determined by the following five conditions: (*a*) $\eta' = 0$ for $\phi = 0$; (*b*) $\eta' = 0$ for $\phi = \pi$; (*c*) $V = -\frac{B}{r^3}(\eta' + \eta''') = 0$ for $\phi = 0$; (*d*) $V = -\frac{B}{r^3}(\eta' + \eta''') = -\frac{p}{2}$ for $\phi = \pi$; and (*e*) $\frac{1}{B}\int_0^\pi M\, d\phi = -\frac{1}{r^2}\int_0^\pi (\eta + \eta'')\, d\phi = 0$. Introducing the derivatives of Eq. 67 into conditions (*a*) to (*e*), the following values are obtained for the constants C_1 to C_5: From conditions (*a*) and (*c*), $C_3 = C_4 = 0$; from conditions (*b*) and (*d*), $C_2 = \frac{p\, r^3}{4\, B\, v_1\, v_2}\Phi$ and $C_5 = -\frac{p\, r^3}{4\, B\, v_1\, v_2}\Psi$; and, from condition (*e*), $C_1 = \frac{p}{2\,\pi}$. Introducing these values of the constants in Eq. 67, the influence line of the radial deflections in section $\phi = \pi$ becomes:

$$\eta_1 = \frac{r^3}{4\, B\, v_1\, v_2}\left(\frac{2\, v_1\, v_2}{a^2\, \pi} + \Phi \sinh v_1 \phi \sin v_2 \phi - \Psi \cosh v_1 \phi \cos v_2 \phi\right) \ldots(68)$$

in which

$$a = \sqrt{1 + \frac{r^4 K}{B}}; \quad B = \frac{m^2}{m^2 - 1} E I; \quad v_1 = \sqrt{\frac{a - 1}{2}};$$

$$\text{and} \quad v_2 = \sqrt{\frac{a + 1}{2}} \ldots\ldots\ldots\ldots (69)$$

Furthermore,

$$\Phi = \frac{v_1 \sinh v_1 \pi \cos v_2 \pi - v_2 \cosh v_1 \pi \sin v_2 \pi}{a (\sinh^2 v_1 \pi + \sin^2 v_2 \pi)} \ldots\ldots\ldots\ldots (70a)$$

and

$$\Psi = \frac{v_1 \cosh v_1 \pi \sin v_2 \pi + v_2 \sinh v_1 \pi \cos v_2 \pi}{a (\sinh^2 v_1 \pi + \sin^2 v_2 \pi)} \ldots\ldots\ldots\ldots (70b)$$

In Eq. 69 m is Poisson's number (10/3 for metals). If m is neglected, $B = E I$. Because the deflections and pressures are assumed to be proportional (Eq. 15), the expression for the influence line of passive pressures becomes:

$$p_1 = K \eta = \sqrt{\frac{a^2 - 1}{2 r}} \left(\frac{2 v_1 v_2}{a^2 \pi} + \Phi \sinh v_1 \phi \sin v_2 \phi \right.$$

$$\left. - \Psi \cosh v_1 \phi \cos v_2 \phi \right) \ldots\ldots\ldots\ldots (71)$$

The evaluation of this influence line for the pressures and reactions acting on the ring, assumed to be rigid, gives the passive pressures on the elastic ring. The algebraic summation of the values thus obtained and of the pressures and reactions producing them constitutes the actual load distribution on the deformed ring. The actual stresses in the deformed ring are obtained by applying this actual load distribution to influence lines which are generally valid for a rigid circular ring. The generally valid influence lines are the boundary values of Eqs. 68 and 71 and of the expressions for moment, shear, and thrust that are similar to them. These stresses refer to the conditions: $K = 0$, $B = \infty$, $a = 1$, $v_1 = 0$, and $v_2 = 1$; and, for radial loads, they become

$$M = \frac{r}{2 \pi} \left(\phi \sin \phi + \frac{\cos \phi}{2} - 1 \right) \ldots\ldots\ldots\ldots (72a)$$

$$V = \frac{1}{2 \pi} \left(\phi \cos \phi + \frac{\sin \phi}{2} \right) \ldots\ldots\ldots\ldots (72b)$$

and

$$T = \frac{1}{2 \pi} \left(\phi \sin \phi + \frac{\cos \phi}{2} \right) \ldots\ldots\ldots\ldots (72c)$$

In Section 28, Mr. Bull states that the critical stresses and cross-sectional areas indicated in Fig. 13 are in good agreement with actual sections used in large corrugated steel culverts.[6] This agreement is due only to the circumstance that the reduction of the stresses by the deformations of the culverts received consideration in the design. The support and loading conditions as well as the deformations of, and the moment distribution in, these culverts are different from those on which Figs. 12 and 13 are based. The culverts are cradled in a firm bed of soil, and the backfill around their sides is compacted to a desired density. The maximum moment in the culverts occurs at the invert and not at the crown; and it is opposite in sign to that indicated in Fig. 12.

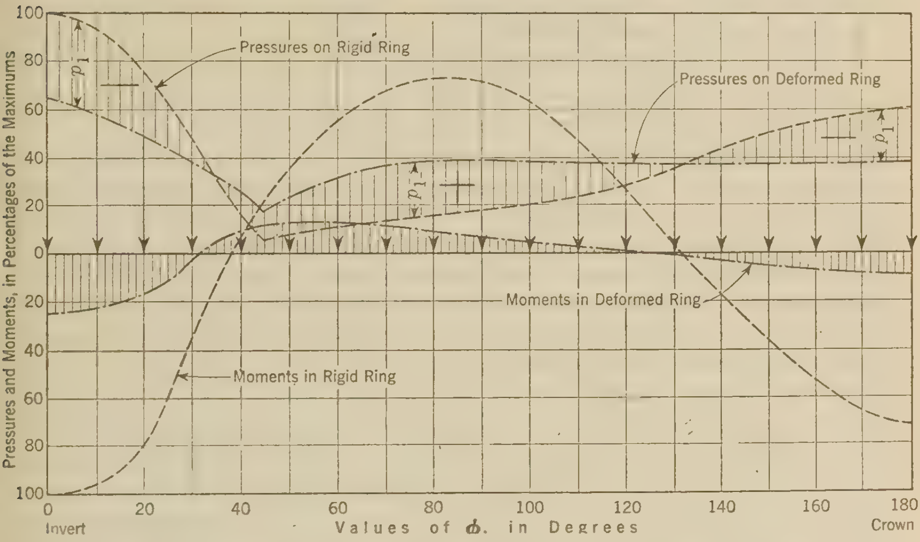

FIG. 30.—PRESSURE AND MOMENT DISTRIBUTION OF RIGID AND DEFORMED RING (FOR DEFINITION OF ϕ, SEE FIG. 29)

In Fig. 30 the pressures on, and the corresponding moments in, a ring that was first assumed to be rigid and the modification of the pressures by the deformations of the ring and of the actual pressures on, and moments in, the deformed ring are indicated in percentages of the maximum values. This diagram facilitates the visualization of the effect of the deformations. The wide-shaded areas between the pressure diagrams indicate the deformations of the ring and the pressure modifications resulting from these deformations. The close-shaded areas indicate the actual moments. The distribution of the pressures on the deformed ring, as obtained by the use of Eq. 71, is identical with the experimental results of M. G. Spangler,[7] M. Am. Soc. C. E.

The functional relations between the forces acting and internal stresses of an elastic ring embedded in an elastic medium are thus shown to be well established. Although he approaches the problem indirectly, Mr. Bull contributes to this knowledge. However, the paper does not help to dispel the uncertainties concerning the magnitude and variation of the forces acting on the tunnel ring. Until methods are found by which these forces can be determined or controlled as reliably as in the case of the culvert type of structure, claims for the rational design of the shield-driven tunnel lining are not warranted.

ANDERS BULL,[46] M. AM. SOC. C. E.—The discussions touch upon several points that were not properly emphasized or, because of space limitations, were not sufficiently elaborated in the paper. The writer welcomes this opportunity to clarify some of his statements.

The aim of the paper is to call attention to the inconsistency of the assumptions underlying the customary method of lining design, and to explain the principles of a method resting on a sounder theoretical foundation. To demonstrate the practical consequences involved, a comparison was made of the results obtained by the two methods.

Designing a tunnel lining is largely a problem in soil mechanics. To enter upon such a moot theme might have led the investigation far afield, however, and would have diverted attention from the main topic. It was stated at the outset, therefore, that the paper would be confined to the consideration of an ideal soil, subject to certain simple rules. To criticize these rules, as has been done by some of the discussers, is thus strictly outside the scope of the paper. They are engineering rules, with no pretentions to exact scientific truth; they have been used by the Board of Transportation of the City of New York and its predecessors for many years in designing subways and tunnels, including the one chosen for an example in the paper. Only by adhering to these rules could results be compared. What effect the substitution of other rules will have remains to be seen; but, although the numerical results may differ somewhat, it seems doubtful that this should materially affect the final conclusions.

The writer is grateful to Professor Van den Broek for his friendly comments on the first part of the paper, which are all the more appreciated because of his thorough familiarity with the subject under discussion. The proposed method depends on the use of numerical tables, so it is of great importance that the printed values be absolutely reliable; with the sensitive moment balance to be dealt with in a lining, a single error is likely to upset the results completely. Professor Van den Broek's numerous checks on the A-constants and B-constants should dispel any doubt on that score. The value of such checks might have been questioned had they been part of the paper, as there is always the possibility of an error in typesetting. As far as the C-constants and D-constants are concerned, the writer, after comparing the printed values with the original ones, is pleased to state that no typographical error has been found. In preparing the tables, the utmost care was exerted, the constants being computed to seven decimal places by two different methods and subjected to rigorous tests.

Raising a question of signs, Professor Van den Broek states that by the ordinary rule the product of force and deflection is considered positive when both factors are of the same direction and sense.

The statement following Eq. 1, by which a deflection component is considered positive when its direction is opposite to that of the force component, may seem to violate this rule, but is qualified by the term "(work negative)." By the ordinary rule one would write, for the condition shown in Fig. 3(a)

---

[46] Cons. Engr., Forest Hills, N. Y.

(since the total work performed by reaction and force components equals zero):

$$T\,a + (-\,P_r\,d_{Tr} - P_t\,d_{Tt}) = 0 \ldots\ldots\ldots\ldots\ldots\ldots (73)$$

which is tantamount to Eq. 1. The writer has consistently made use of this form in model analysis[47] and has found it convenient. Strange to say, the late George E. Beggs,[48] M. Am. Soc. C. E., failed to lay down any rule for signs, leaving this to the judgment of the reader.

Convenience has also been aimed at in the other sign conventions of the paper, which are stated for each symbol in the Appendix. By thus considering tangential forces positive when directed upward their sign is apparent at a glance.

Professor Van den Broek suggests that influence lines be obtained experimentally from models in analyzing rings of noncircular shape, and variable moment of inertia, conditions which render a satisfactory mathematical treatment too complicated for practical use.

By using precision equipment for distorting the model and for measuring the deflections it should be entirely feasible to determine the equivalents of the A-constants to three significant places and, similarly, also load-deflection coefficients corresponding to the C-constants. Structures of this type are usually made of reinforced concrete, for which material the customary assumptions regarding location of the neutral axis and tension in the concrete are far from true in any case; so that extreme accuracy would be of no real use.

Mr. Brodkin's proposal, to use large-scale influence diagrams, such as Fig. 17, for obtaining more accurate results when concentrated loads are applied between the sixteen tabulated points, may be of advantage when all the forces acting on a ring are known. In the case of a tunnel lining, however, the many conjectural factors involved in determining the soil reactions make such refinements futile. Furthermore, if an A-constant were to be measured between points, the corresponding sixteen C-constants would logically have to be treated the same way; but this could not be expressed by the basic Eqs. 19 which depend on a uniform spacing. To avoid this difficulty, intermediate concentrated loads are assumed to be apportioned between the nearest two of the tabulated points, considering the latter as simple supports.

Mr. Brodkin presents instructive data proving the simple relationship between the soil compression constant K and the moment of inertia I of a lining. The latter behaves in this respect much like a flat slab resting on an elastically yielding soil. Since reducing K at a given ratio has the same effect on the moments as increasing I at the inverse of that ratio, it may be shown that a flexible lining is less affected by changes in the value of K than is a stiffer one. In the lining for which $I = 0.53$ in Table 14, a reduction of K from 12 to 3 would thus change the moments to the values given for $I = 2.13$, causing the crown moment to be increased by $\frac{10.9 - 8.7}{8.7} = 25\%$, whereas in the lining referred to in Table 15 ($I = 136$), the increase is $\frac{86.4 - 58.2}{58.2} = 48\%$, or nearly twice as much.

[48] *Transactions*, Vol. 88 (1925), p. 1208.

The constant K and the moment of inertia I, being of equal importance in designing a lining, Mr. Brodkin suggests that, as a matter of prudence, a conservative value be used for K. The question then arises as to what value may be considered safe in the present case of a sandy soil. Of much interest in this connection are the results obtained from an extensive investigation of the compressive qualities of the soil underlying a 1.3-mile stretch of the Houston Street branch of the Independent Subway System of New York City. The investigation was undertaken on the initiative of the late George Paaswell, M. Am. Soc. C. E., chief engineer for the contractors (Corson Construction Corporation), for the purpose of predetermining the settlement that would be caused by future building loads. A special penetration device designed by Karl Terzaghi,[49] M. Am. Soc. C. E., was used for the tests, which were conducted by Glennon Gilboy, Assoc, M. Am. Soc. C. E.

FIG. 31.—PROFILE ALONG HOUSTON STREET, SHOWING VARIATION OF SOIL COMPRESSION CONSTANT

In Fig. 31 (a diagram prepared by Mr. Paaswell based on the tests), the vertical lines indicate the sites at which measurements were made. The soil encountered was sand of almost uniform character throughout, with no deposits of silt or clay. Although the grain size varied considerably, this was found to have no appreciable influence on the compressibility of the soil. The numbers in each of the differently shaded areas (which vary between 12 and 40) indicate the respective values determined for K, in kips per square foot per inch.

A résumé of measurements made by other investigators[50] may also be mentioned. For railroad ties embedded in stone ballast (Kiesbettung) K was found to vary between 16 and 42, depending on the nature of the subgrade; and, for plates 11 in. square, resting on ballast varying in depth from 6 in. to 22 in., the respective K-values ranged from 96 to 162. In a test made on garden soil of unspecified character, Föppl[51] found K to be as high as 208.

[49] *Engineering News-Record*, Vol. 106, 1931, p. 570.

[50] "Handbuch für Eisenbetonbau," Band 8, Ernst und Sohn, Berlin, 1922, p. 38.

In view of the aforementioned figures, the value $K = 12$ assumed in the paper would appear conservative.

Mr. Drucker considers it a discrepancy to include the weight of the concrete lining in the weight of the tunnel ring, arguing that, since the concrete is poured in normal air, its weight should not be considered in conjunction with the effect of the internal air pressure.

A newly erected ring carries various temporary loads for which no other provision is made, such as working platform, equipment for graveling and grouting, and sometimes part of the excavated soil. For this reason it is customary to include the weight of the concrete in the design load.[52] The same weight (0.22 kip per sq ft) was assumed for the lighter linings, Figs. 11(*b*) and 11(*c*), in order to provide for the weight of the scaffolding.

Another point criticized by Mr. Drucker is that the buoyant effect of the water on the soil was neglected. This practice is implicit in design specifications of the Board of Transportation which, for reasons stated previously, were accepted as a norm for this paper. There is absolutely no justification for his relating the soil compression constant K, with the angle of repose.

Mr. Drucker suggests that there may be a break in the computed stress value in passing from one side to the other of a line A–A, Fig. 22 (which represents the cross-section area at which u changes from 5 to 6), implying that the stress curve may have two branches at A–A which would yield different stresses, a and b_1. This view is easily disproved. Denoting by D the D-constants in Table 8, and considering first the case of $u = 5$, Eqs. 19 may be written in the following form which corresponds to the sequence of operations performed in lines 1 to 12 of Table 12:

$$\left.\begin{array}{r}\Big\{[D_{11}\,F_1 + D_{12}\,F_2 + D_{13}\,F_3 + D_{14}\,F_4 + D_{15}\,F_5 \qquad\qquad\qquad\qquad \\ + \Sigma(P\,D_1)]\,\dfrac{r^3}{E\,I} + \delta\cos\alpha_1\Big\}\,K\,A' = F_1 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ \Big\{[D_{51}\,F_1 + D_{52}\,F_2 + D_{53}\,F_3 + D_{54}\,F_4 + D_{55}\,F_5 \qquad\qquad\qquad\qquad \\ + \Sigma(P\,D_5)]\,\dfrac{r^3}{E\,I} + \delta\cos\alpha_5\Big\}\,K\,A' = F_5\end{array}\right\}\ldots(74)$$

---

[51] "Vorlesungen über technische Mechanik," Teubner, Leipzig, 1927, p. 279.

[52] "The Queens Midtown Tunnel," by Ole Singstad, *Transactions*, Am. Soc. C. E., Vol. 109 (1944), p. 688.

According to Section 24, the sign of the radial displacement at point 6 (line 11 of Table 12) is the criterion of whether u is equal to, or greater than, 5. At A–A, Fig. 22, therefore, where u changes from 5 to 6, the displacement must be zero, or:

$$\left\{[D_{61} F_1 + D_{62} F_2 + D_{63} F_3 + D_{64} F_4 + D_{65} F_5 + \Sigma(P\, D_6)] \frac{r^3}{E\, I} + \delta \cos \alpha_6\right\} K\, A' = F_6 = 0 \quad \text{..(75)}$$

In the case of $u = 6$, there would be six equations of a structure similar to Eqs. 74, each equation containing one more term, $D\, F_6$; but, since $F_6 = 0$, these additional terms may be dropped, leaving six equations identical with Eqs. 74 plus Eq. 75. Since the F-values in Eq. 75 thus satisfy both sets of equations there can be no splitting up of the stress curve.

It so happens that, for $A' = 17.4$, Eq. 75 gives a value for F_6 which is close to zero ($F_6 = -0.037$ kip), placing line A–A at an area about 17 sq in. in Fig. 22. Similarly, F_5 will be zero for an area of about 40 sq in., so that the stress curve for joint J will be about as shown in Fig. 32.

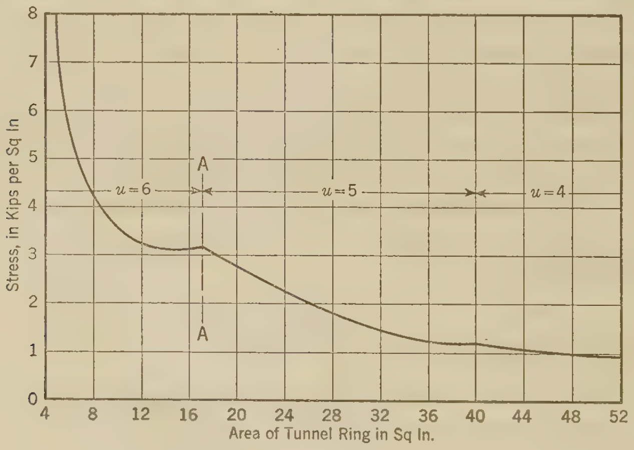

FIG. 32.—STRESS AT JOINT J

Its jagged shape results from replacing the distributed loads and soil reactions by force concentrations applied at sixteen points. If, instead, the analysis had been based on thirty-two force concentrations the resulting stress curve would have had twice the number of jags, but these would have been smaller, and the curve would have conformed more closely to the true stress curve. However, with so many uncertain factors entering the problem, an increase beyond sixteen points does not appear warranted, the arithmetical work increasing rapidly with the number of points.

Mr. Johannesson questions whether cast-iron linings could be decreased in weight materially, citing the need for a large cross section to resist the pressure of the shoving jacks. There have been cases when this was not the deciding consideration, as appears from the following statement by Ole Singstad,[53] M. Am. Soc. C. E., referring to the cast-iron linings used for the shield-driven river sections of the Queens Midtown Tunnel:

> "The heavier ring * * * with 14-in. flanges and weighing approximately 22.7 tons per ring, was used in soft ground and mixed face or where the character or thickness of rock cover required it; the lighter ring with 11-in. flanges and weighing approximately 12.5 tons was used in rock face where the cover was adequate."

The writer ventures the opinion that, since, in this case, the lighter lining was evidently strong enough to resist the pressure from the shoving jacks, a lining weighing no more might safely have been used for the entire river section of the tunnel, at a saving of more than 18,000 tons of cast iron, representing a reduction in cost of more than one million dollars.

Mr. Johannesson rightly states that the deflection of the horizontal joints under circumferential tension confounds the theoretical conclusions; but as yielding of the joints has the same effect as if the flexibility of the lining were increased it would cause a reduction in the critical moment. The stresses obtained by considering the joints stiff are, therefore, on the safe side.

Mr. Feld stresses the fact that designing a lining is a three-dimensional problem and that the forces acting in the three planes affect one another.

Longitudinal forces, apart from the temporary ones due to the shoving process, arise from axial bending of the tunnel. They may result in appreciable tangential shearing stresses in linings built up of segments of the usual shape, which makes for great axial stiffness, but are generally neglected because of the difficulty of estimating them. With a cross section like the one in Fig. 11(*c*), longitudinal forces would have less effect since the axial flexibility of the lining is greater.

According to Mr. Feld:

> "It is a serious mistake to design a tunnel without considering the feasibility of construction and also the conditions under which construction can proceed safely."

The writer agrees, of course, but questions the relevancy of the observation as he is not conscious of having advocated impracticable or unsafe methods.

Mr. Feld further states that, if it were possible to vary the air pressure at different heights within a lining surrounded by a fluid medium, a perfect balance could be obtained between the forces and the only deformation would be a radial squeezing of the ring. The same kind of balance is obtained at uniform air pressure when the weight of a lining equals its buoyancy.[54] The latter condition, which likewise results in zero moments throughout the ring, is of considerable practical interest as it is approximated in tunnels driven through river silt.

---

[53] "The Queens Midtown Tunnel," by Ole Singstad, *Transactions*, Vol. 109 (1944), p. 687.

Referring to the views of the late J. C. Meem, M. Am. Soc. C. E., on arching in soil, Mr. Feld claims that the active pressure at any point is dependent on the deflection at that point. Until more definite information is available on this subject, it seems safer to go by Rankine's theory which is still the one most widely accepted. Although Mr. Meem's views are substantiated in some degree by the behavior of temporary structures, such as sheeting, their application to permanent structures is open to serious criticism as the soil arches eventually fail.[55]

Mr. Feld concludes his comments with the statement:

> "When some methods are developed for measuring the distribution of radial forces and tangential forces during the various stages of construction, as well as for measuring the actual values of such acting forces, the necessary data will be available for a proper use of the author's design procedure. Until such information is available, it seems very doubtful to the writer that a radical decrease in tunnel lining weight and thickness can be, or should be, proposed."

Contemplating the uncertain values of soil characteristics and the great differences in the moments M attending comparatively small differences in the forces F (Table 14), it is difficult to understand what conclusions could be drawn from such measurements, even if they could be made. What is needed are not measurements (which are almost impossible to achieve under construction conditions), but experiments, undertaken with imagination and courage, as exemplified by the culverts referred to in Section 28. Following the beaten path is safe policy but it does not contribute much to the advancement of engineering art.

According to Mr. Beskin, the basic principle referred to in Section 4 is "probably" due to Müller-Breslau. It should rather be credited to Mohr, whose "Beitrag zur Theorie des Fachwerks"[56] is fundamental in that it presents the first complete theory of statically indeterminate trusses. In this work the law of reciprocity of forces and deflections is deduced independently, and, for the first time, elastic lines are used as influence lines for reactions, their practical advantage being illustrated by examples. Müller-Breslau's contribution, made some ten years later,[57] consisted in expanding the principle, thus making it applicable to moment reactions as well. In deriving Eqs. 2 to 4, the writer has availed himself of Mohr's approach by which work performed, rather than deflection, is the leading concept.

---

[54] "Elastic Energy Theory," by J. A. Van den Broek, John Wiley & Sons, Inc., New York, N. Y., 1931, p. 114.

[56] *Zeitschrift des Architekten- und Ingenieur-Vereins zu Hannover*, 1874, p. 510; and 1875, p.18.

[57] "Die neueren Methoden der Festigkeitslehre," Baumgärtner, Leipzig, 1886.

One is tempted to ask whether some of Mr. Beskin's comments are meant to be taken seriously, as, *for instance*, when he asserts that the writer has been "redeveloping conventional formulas," presented in an article by Joseph A. Wise, M. Am. Soc. C. E., and then proceeds to explain how the latter formulas may be transformed into those of the writer. Actually, the Wise formulas are for thrust, shear, and moment diagrams, whereas the writer's formulas are for influence factors, the two treatments having nothing in common.

Mr. Beskin announces the pending publication of tables of coefficients for 5° increments, intended to replace the A-constants and C-constants. He judges it to be a labor-saving feature that his coefficients are from five to seven times smaller, whereas the time saved by the writer's B-constants is considered of minor importance. The computation of the deflection coefficients is stated to have been "greatly simplified" by using only one angle instead of the writer's two (α and β in Fig. 8). Two angles are necessary for establishing the basic Eqs. 19. As far as the problem in hand is concerned, it serves no useful purpose to use a smaller increment than 22° 30′, as by so doing the number of simultaneous equations (Eqs. 19) is increased.

Mr. Beskin further endeavors to prove by means of Mohr's circle that the tangential forces referred to in Section 18 cannot be disregarded, as the radial soil reactions are not in equilibrium with the Rankine pressures assumed. Mohr's circle is not applicable to the boundary condition existing between the soil and the plastic layer of gravel and grout. Outside the boundary there is a soil mass for which the circle HA′V, Fig. 26(*b*), may be used; inside the boundary there is a semifluid mixture corresponding to a Mohr circle of zero radius inscribed in an angle of 0°.

A hopper with perfectly smooth sides (Fig. 33) presents an analogous case. When the trap door at the bottom is opened the pressures P_M and P_m are not in equilibrium with the normal pressure N, the unbalanced pressures causing the grain to slide down the sides. On closing the trap door, equilibrium is re-established by the pressure T, produced within the grain mass through the crowding of the grains.

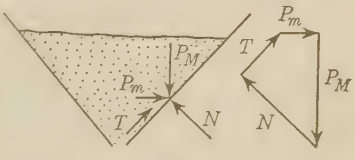

FIG. 33

In discussing Eq. 15, Professor Krynine calls attention to the experimental fact that under the same unit load a larger area will settle more than a smaller one. This is true of foundations buried to the same depth, the difference being the result of friction along their vertical faces, which is comparatively larger for the smaller area. It seems to be generally accepted, however, that in sand, with friction eliminated, the settlement by and large is independent of the area loaded. Only on that assumption could the results of penetration tests be used for predetermining the settlement of buildings, as illustrated by Fig. 31.

The K-value to be used for the design of a lining is determined by what Professor Krynine refers to as the "reversible part" of the displacement whereas the "nonreversible part," or initial consolidation of the soil, is assumed to be overcome by the pressure under which the annular space is grouted. Actually, there is no reversal of the displacements anywhere in a lining, as the pressures producing them are applied only once.

Of special interest is the minimum value that K attains in a given stretch of tunnel, this being generally the value for which the stresses are highest. It is true that this crucial value of K must be guessed. If it could be shown to be related to other soil characteristics it might be predicted more definitely. Research, thus narrowed down to minimum values, may prove fruitful of results and such research is much needed.

Some of the conclusions drawn by Professor Krynine from the field measurements on the Lincoln Tunnel are not applicable to a lining in sandy soil. Thus, in sand, the radial stresses resulting from the shoving process are negligible. Buoyancy is likewise a factor of less importance, as, in order to prevent excessive escape of pressure air, the tunnel must be kept at a low level, or blankets of clay must be provided, adding to the shearing strength of the overburden.

Mr. Eremin calls attention to the influence exerted on the final stresses in the lining by the loading on the roadway slab and by the forces transmitted through tie rods. In dealing with structures of this type it is not customary to consider internal live loads, as their transient effects are assumed to be absorbed by the inertia of the lining and the surrounding soil. The influence of tie rods may be determined easily by first assigning a value to the horizontal restraining force transmitted; this force is resolved into its radial and tangential components which are then treated as other active forces, and the resulting moment curve is plotted. By changing the assigned value successively, a series of moment curves is obtained from which the restraining force producing the greatest stress relief may be selected.

Fig. 34 shows the results of a theoretical study made along these lines; a very flexible lining ($I = 0.53$, Table 14) being assumed, which has a tie rod mounted between points 7 and 10 (Fig. 4). The curves represent the total moments produced in the lining under the combined influence of active loads, soil reactions, and tie rod forces. The latter were successively assumed to be 1, 2, and 3 kips, the corresponding curves being marked accordingly, whereas the curve marked O represents the lining without a tie rod.

An interesting feature is here revealed in that the curves intersect one another to form a number of nodal points. The moments at these points will remain unaffected by the force exerted by the tie rod and, therefore, are to be considered as irreducible minima for the particular position of the rod. Of the three cases considered, a tie rod force of 2 kips seems the most suitable, as the corresponding maximum moments—both positive and negative—are only slightly larger than the moments at the nearest nodal points.

Although the statement in Section 29, in regard to erection material being made an integral part of the structure, might have been somewhat less sweeping, the fact remains that the percentage of idle material in tunnels by far exceeds that in any other type of structure.

Mr. Alexander suggests the use of a simple expression for showing, rapidly, the effect of varying the factors that influence soil reactions. However, the loading conditions assumed in his example, Figs. 27 and 28, differ to such an extent from those applying to a tunnel lining that results are hardly comparable. Mr. Alexander thus assumes the vertical and horizontal active pressures to be uniform and symmetrical about the axes, thereby dispensing with the most important source of soil reactions—the settlement. Furthermore, he considers only reactions of a horizontal direction, acting on the two lateral quadrants of the lining.

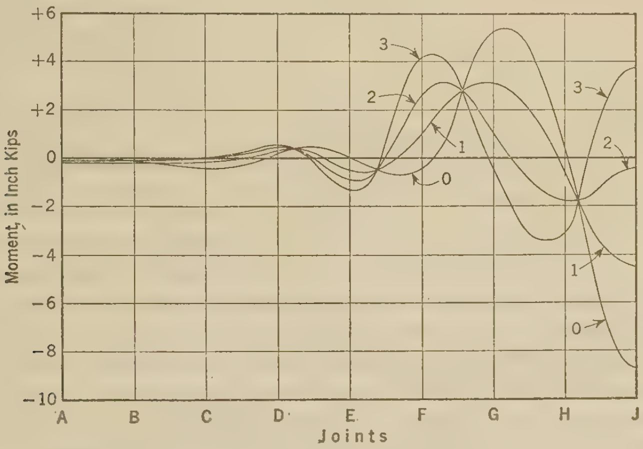

Fig. 34.—Effect of Tie Rod on Moment in Lining

The sensitiveness with which the moments M respond to small changes in the soil reactions F (see Table 14) is a feature calling for more accurate treatment. In bridge, subway, or building design, where a great number of members subjected to varying loads are to be proportioned, short cuts and slide rule computations are in order; a tunnel lining, however, constitutes a single member for the design of which a staff of specialists is usually available. To them, an elaborate treatment presents no obstacle. As several of the commentators have objected to the laboriousness of the proposed method, it seems only fair to mention here that the method by which some of the tunnels in the New York Metropolitan District have been designed is very much more cumbersome.

Mr. Alexander claims that tangential forces exert considerable influence on the moments in the lining, and that, therefore, they should not be neglected unless more evidence can be produced to show that they do not exist. Such forces are neglected, not because of their low value, but because they are prevented from reaching the lining (see Section 18).

Mr. Balog quotes at length from a treatise published in 1936 by Adolf Voellmy in which a solution of the lining problem is attempted by means of a differential equation (Eq.66). A similar equation of a somewhat simpler form—

$$\eta'''' + \frac{K}{EI}\eta = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

—has long been used[58] for the analysis of flat slabs resting on elastically yielding soil. As far as practical application is concerned, both equations are of limited scope, as will first be demonstrated for the simpler form.

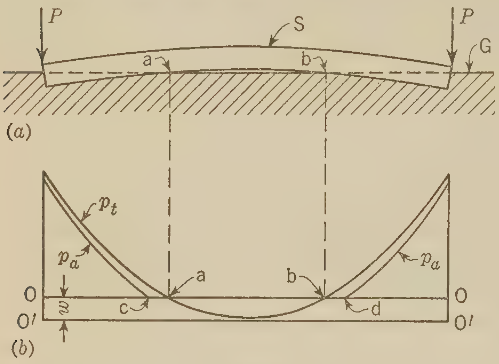

FIG. 35

Fig. 35(*a*) shows a slab S resting on the ground G and supporting two equal loads *P* at its ends. When the flexibility of the slab exceeds a certain value its middle part ab rises above ground level. Eq. 76 requires in this case that negative soil reactions be produced stressing the soil under the part ab in tension, thereby causing it to expand and exert a downward pull on the slab. As such action is incompatible with the behavior of soil the equation becomes invalid.

The theoretical pressure distribution along the slab, as obtained from Eq. 76, is shown in Fig. 35(*b*) by the curve p_t, the part ab below line OO representing the negative pressures, whereas the actual distribution would be about as shown by the curve p_a. The latter curve, which is discontinuous at points c and d, cannot be expressed mathematically, but may be approximately determined by means of a model.[59]

The scope of Eq. 76 may be extended, provided the unit weight w of the slab equals or exceeds the amount of negative soil pressure at the center of span. This weight will place the soil under an initial compression, lowering the zero line OO by an equal amount w to position O′O′ in Fig. 35(*b*).

A reversal of the sign of the soil reactions occurs wherever the deflected elastic line intersects its neutral position. Whereas this may happen in a flat slab, it is unavoidable in a lining, as it would not be possible for some parts of a ring to move outward from the center unless, at the same time, other parts were moving inward. In his treatise,[60] Voellmy states in this connection:

> "Equation (1) is assumed to hold for positive as well as for negative displacements of the lining surface. This assumption is justified when the tensile stresses due to one loading condition are neutralized by the compressive stresses due to another loading condition, as is the case in most practical applications."

[58] "Die Lehre von der Elasticitat und Festigkeit," by E. Winkler, Dominicus, Prague, 1867, p. 182.

[59] "Soil Pressure Distribution Along Flexible Foundations," by Anders Bull, *Journal of the Franklin Institute*, June, 1942, p. 579.

[60] "Erddruck auf elastisch eingebettete Rohre," by A. Voellmy, *Publications*, Vol. IV, International Assn. for Bridge and Structural Eng., Zürich, 1936, p. 596.

In the foregoing statement, which is the writer's translation of the original German, Eq. 1 is the equivalent of Eq. 15 in the paper.

In Fig. 30, the pressures on the rigid ring represent one loading condition and the soil reactions p_1, due to deflection, the other. Their algebraic sum should then, according to Voellmy, represent the total resulting pressure distribution. The fallacy in this reasoning becomes evident when the condition at the crown is considered, where the negative soil reaction is supposed to reduce the pressure by about 40%. By the same kind of logic it could be contended that the pressure at any point of a flat slab S (Fig. 36), carrying a soil load, is reduced by the amount δK, in which δ is the deflection and K the soil compression constant; or that the pressure could be relieved by anchors A, embedded in the overlying soil.

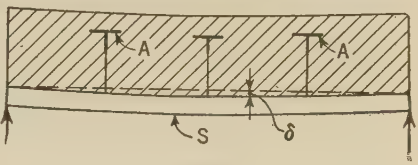

FIG. 36

The only way in which the negative soil reactions yielded by Eq. 66 can be neutralized is to provide additional positive soil reactions of a uniform intensity over the entire perimeter, such as would be produced, for instance, by a uniform radial expansion of the ring by an amount $\geqq -\frac{F'}{K}$, in which F' is the maximum negative soil reaction and is comparable to the additional pressure w in Fig. 35(b). No such measure being contemplated, the Voellmy equations are valid only for a ring embedded in a medium capable of resisting tension in accordance with Hooke's law. They do not hold for a lining in soil.

It might be argued that a uniform pressure over the entire perimeter can have no effect on the moments in the ring and might as well be omitted, but that is not the point. The pressure has a mechanical effect in that it forestalls a separation between the soil and the lining at any point, just as the pressure w in Fig. 35(b) prevents the slab and soil from separating. It is this separation, followed by a cave-in of the soil over the top portion of the lining, that upsets the mathematical conclusions.

As explained in Section 19, the extent of the ring portion on which soil reactions are produced (the angular distance between the points of intersection of lines c and d in Fig. 9, represented roughly by the number u) is a function of all the forces acting on the ring, including the soil reactions themselves. The principle of superposition does not apply, therefore, and as a consequence it is impossible to establish a generally valid influence line by which the effects of the deformation of a ring embedded in soil might be determined.

Despite the different methods of construction, there is no essential difference between the load distribution on a tunnel lining and that on a culvert. Mr. Balog's contention, that the maximum moment in culverts occurs at the invert and not at the crown, may be in accord with the Voellmy theory, but it is not confirmed by the observed fact that culverts fail by caving in at the crown.[61] No general rule can be given for the sign of the moment at the invert point, as is illustrated by Mr. Brodkin's Table 15 and Fig. 19, where a change in the value of K is shown to reverse the sign.

[61] "The Structural Design of Flexible Pipe Culverts," by M. G. Spangler, *Bulletin No. 153*, Eng. Experiment Station, Iowa State College, Ames, 1941, p. 9.

It should be noted that the same assumptions are made by Voellmy as are made by the writer, in using the same basic Eq. 15, and in neglecting tangential forces. The totally different character of the moment curves obtained by him is thus traceable to the negative soil reactions. The absence of appreciable moments in the lower portion of a flexible lining is a typical feature of the proposed method and may furnish a criterion of its soundness. It may also be of important economic value in the design of certain structures, such as culverts, as the plates stressed only in compression may be made of correspondingly lighter weight.

In closing, the writer wishes to express his sincere thanks to the discussers for their interest and valuable contributions.

FLOW IN A CHANNEL OF DEFINITE ROUGHNESS

By Ralph W. Powell,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Joe W. Johnson and E. A. LeRoux, Garbis H. Keulegan, C. J. Posey, and Ralph W. Powell.

Synopsis

Although the effect of definite roughness of the wall upon the resistance to the flow of fluids in pipes has been thoroughly studied, there seems no equally satisfactory study of the effect of known wall roughness on the flow in open channels. This paper reports the results of some experiments bearing on this question which were performed by the writer during the summer of 1940 in the laboratory of the Institute of Hydraulic Research at Iowa City, Iowa. A total of two hundred runs on a rectangular flume, with eleven different roughnesses and four different slopes, indicated that Chézy's C could be expressed as $40 \log_{10} R/\epsilon + c_s$, in which R is the hydraulic radius, ϵ is a measure of the roughness, and c_s is a small shape correction. The mean of the deviations of the formula from the data was 2.1, and the mean percentage deviation was 4.4%.

In the same flume without roughness twenty-one runs of tranquil flow gave the formula $C = 40 \log_{10} \mathbf{R}/C + c_s + 4.8$, in which $\mathbf{R}$ is the Reynolds number. The mean deviation of this formula from the data was 2.32 or about 2.0% of the value of C. Shooting flow in the same smooth flume gave the formula $C = 60 \log_{10} \mathbf{R}/C + 30\,\mathbf{F} + c_s - 175$, in which $\mathbf{F}$ is the Froude number. The mean deviation of this formula from the data was 2.44, or about 2.1% of the value of C.

If these data are correct, two surprising results follow: (1) The "universal constant," $b = 2.5$, changes from 2.5 for pipes to about 3.0 in open channels; and (2) the law of resistance to shooting flow is quite different from the law of resistance to tranquil flow.

Note.—Published in December, 1944, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

HISTORICAL

The pioneer research on the flow of water in open channels with definite artificial roughness was made by H. Bazin[2,3] between 1855 and 1860. These tests were made in a channel 2 m wide and nearly 600 m long, and the measurements were quite accurate; but only a few of the roughnesses used were so definitely described that they could be accurately duplicated today, and apparently Bazin made no attempt to reduce his results to a formula that included a definite roughness figure. In fact, the idea of a definite linear unit of roughness seems not to have originated until the twentieth century.[4]

Measurements of the resistance to flow in pipes of definite roughness seem to have been first made by L. Hopf[5] and K. Fromm[6] in 1923. A rational theory of velocity distribution and, from it, formulas for resistance to flow were later developed by Theodor von Kármán,[7] M. Am. Soc. C. E., and Ludwig Prandtl.[8] In 1933, J. Nikuradse[9] published his epoch-making paper combining Prandtl's theory with definite experimental measurements of the resistance in pipes lined with sand grains of definite size. Since then a number of studies of flow in pipes of definite roughness have been made, of which may be mentioned those by V. L. Streeter,[10] Assoc. M. Am. Soc. C. E., H. Schlichting,[11] C. F. Colebrook[12,13] and C. M. White.[13]

The corresponding problem of the effect of definite roughness on flow in open channels does not seem to have received much attention. Mr. Keulegan[3] has published a good discussion of the problem, but with no experimental values other than Bazin's. The experiments described in this paper are a preliminary attempt to do for open channels what Nikuradse did for pipes.

APPARATUS AND EXPERIMENTAL PROCEDURE

The flume used was 50 ft long, 8 in. wide, and 7 in. deep. The side-walls were of lucite and the base was a structural steel channel with its back upper-

most, painted with aluminum paint. The flanges of the channel offered attachment for the lucite side panels and for the vertical light steel angles which supported these panels at 20-in. intervals. The lucite panels were also stiffened along the upper edge by a lucite flange. A light steel strap was placed across the top at the middle of each panel and bolted to these flanges. At six points along its length the flume rested on blocks clamped to vertical trestles, as shown in Figs. 1 and 2.

The definite wall roughness was provided by square steel strips which extended down the sides and across the bottom so as to act as cleats or battens. The arrangements of the battens to create the various roughnesses are shown in Fig. 3, the larger of the two sizes being $\frac{1}{4}$ in. square and the smaller, $\frac{1}{8}$ in. square.

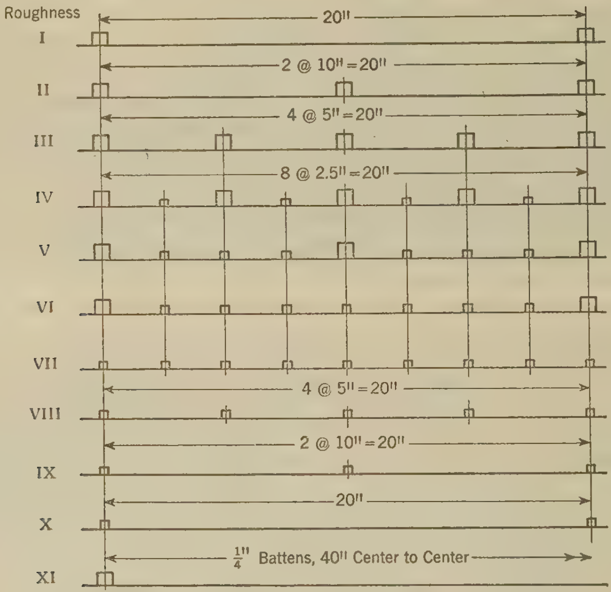

FIG. 3.—SPACING OF BATTENS TO FORM THE VARIOUS ROUGHNESSES

The water was measured by a diaphragm orifice in the 6-in. supply line just visible in the upper right corner of Fig. 1. For the larger flows the differential head on this orifice was measured by the mercury manometer shown at the right of Fig. 2. For most of the flows for which the differential head would have been less than 2 in. of mercury, it was read directly in inches of water in the vertical tubes shown to the left of the mercury manometer.

At the downstream end of the flume a control gate was arranged as shown in Fig. 4(*e*). This allowed part of the flow to pass under and part over, but by adjusting the wing nut (shown at the upper right) the depth at the downstream gage could be adjusted so that the flow throughout the flume was practically uniform. A thermometer is shown at the left in Fig. 4(*e*). The depth was read by hook gages in wells as shown at the right of Fig. 1 and the left of Fig. 2. The term "second slope" in the caption of Fig. 4 means that the bottom slope was 0.0080. The wells were connected by rubber hose with the static pressure tubes shown in Figs. 4(*a*), 4(*c*), 4(*d*), 4(*f*), 5(*a*), and 6(*d*). These were made of copper tubing, 0.187 in. outside diameter, with the upstream end plugged with solder and filed to a "streamlined" contour. Four

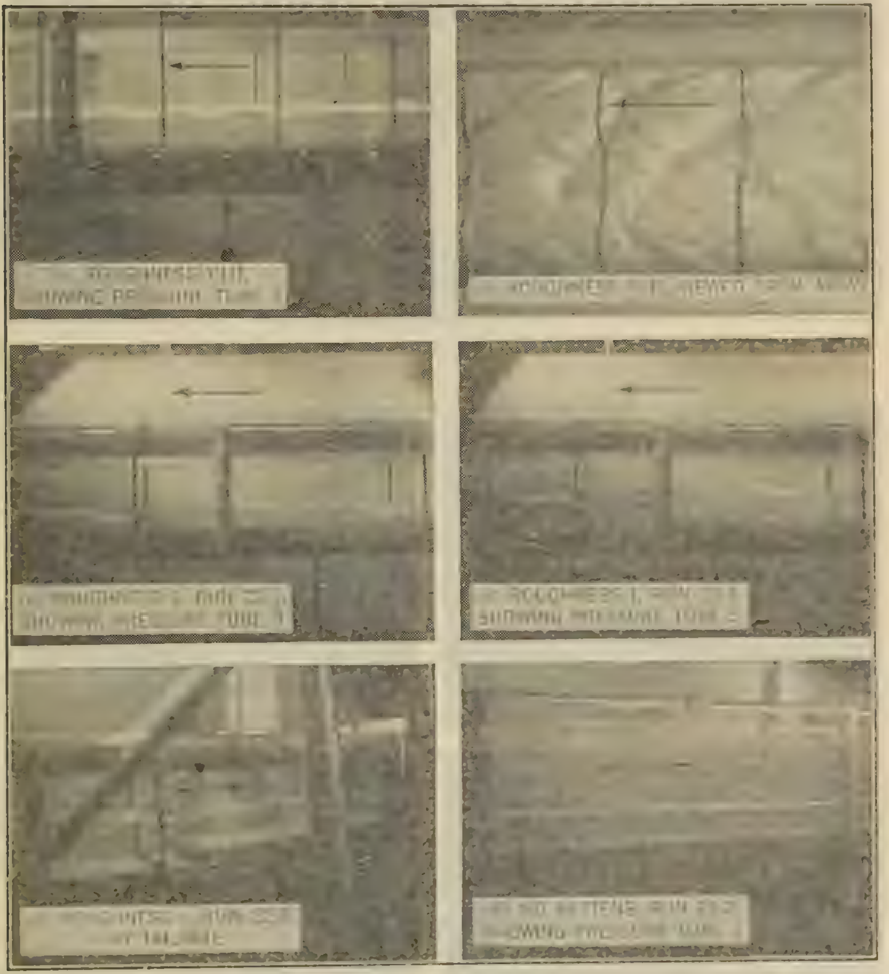

Fig. 4.—Examples of Flow at the Second Slope

holes were drilled with a No. 54 drill, 1 in. from the nose—one on top, one on the bottom, and one on each side. It was felt that some such arrangement was necessary because the pressure at an ordinary flush peizometer opening would undoubtedly have been affected by the proximity of a batten, and, with flows such as those shown in Fig. 5(*a*) (which are similar to the flow in run 5-2), it would have been impossible to estimate the depth visually through the lucite walls. The location of these pressure tubes is shown in Fig. 7. Further details regarding the apparatus and experimental procedure are given in the original draft of this paper on file in the Engineering Societies Library.

(a) ROUGHNESS IV
(c) ROUGHNESS VII, RUN
(d) ROUGHNESS

Fig. 6.—Examples of Flow at the Steepest Slope

When the work was begun the flume was set with its floor at a slope of $S = 0.0312$. This was steep enough to produce shooting flow in the smooth flume, and would not have been used to start with had it not already been set up. After runs had been made at this slope with the smooth flume and with each of ten roughnesses (with about five different depths for each roughness), the slope was changed successively to 0.0080, 0.0020, and 0.0005, and similar runs were made at each slope. At the flattest slope many of the flows were too small to be measured by the orifice meter, even with the water-air manometer. For these a deflector was arranged at the downstream end to direct the flow into a weighing tank. The time required to run 300 lb of water was measured with a stop-watch, except for a few of the smallest flows where the quantity was reduced to 200 lb, or even only 100 lb; but the time for these smaller weights was never less than 64 sec and was read to fifths of a second, so that these flows were probably determined more accurately than those measured with the orifice.

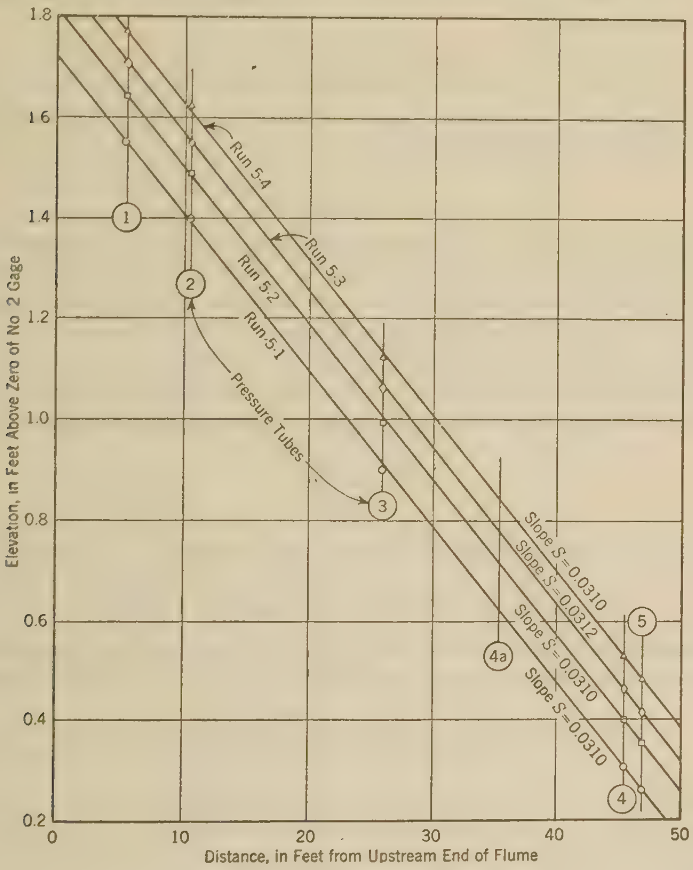

Fig. 7.—Sample of Energy Gradients

Before any runs were taken, the width of the channel was measured at ninety different sections and at two depths in each section with a micrometer gage reading to thousandths of an inch. The width at about 0.3 in. from the floor varied from 8.148 in. to 8.215 in. with a mean of 8.193 ± 0.013 in. At a height of about 4 in. above the floor the width varied from 8.114 in. to 8.210 in. with a mean of 8.166 in. In general, each 20-in. panel was sprung outward so that the channel was about 0.03 in. wider at the middle of the panel than at the junction with adjoining panels; and these junctions sometimes involved an offset of 0.01 in. to 0.02 in. Therefore, the so-called "smooth channel" was not absolutely smooth but had a slight amount of roughness and an appreciable waviness.

The orifice meter had been calibrated a few months before these experiments by a student. The result of this calibration was put into the form of a curve of values of $Q/\sqrt{H}$ plotted against $\sqrt{H}$ to such a scale that the constant could be read to four significant figures.

COMPUTATIONS

The letter symbols in this paper are defined where they first appear and are assembled for reference in the Appendix. The method of computation is described in detail in the original draft of this paper on file in the Engineering Societies Library. The most important data and results are given in Table 1 (Appendix). The slope was determined from plotted energy gradients, a sample of which is shown in Fig. 7. For the steeper slopes there seemed the possibility that the resistance might depend on the Froude number,

$$\mathbf{F} = \frac{V}{\sqrt{g\,y}} \qquad \text{(1)}$$

Therefore, this was computed in addition to the usual R, V, C, and $\mathbf{R}$.

ANALYSIS OF RESULTS WITH SMOOTH CHANNEL

The most fundamental treatment of the resistance to flow in open channels seems to be that of Mr. Keulegan,[14] whose formula for smooth walled channels is

$$\frac{V}{V_f} = a_s - b + b \log_e \left(\frac{R\,V_f}{\nu}\right) + b\,\beta - \bar{\epsilon}\,\frac{V}{V_f} \qquad \text{(2)}$$

in which: a_s and b are constants; ν is the kinematic viscosity of the liquid flowing; β is a function of the shape of the cross section; $\bar{\epsilon}$ measures the resistance of the free surface; and V_f, the so-called friction velocity, is defined as follows:

$$V_f = \sqrt{\frac{\tau_0}{\rho}} = \sqrt{R\,S\,g} = \frac{\sqrt{g}\,V}{C} \qquad \text{(3)}$$

Eq. 2 can be written

$$C = \frac{\sqrt{g}}{1 + \bar{\epsilon}} \left(a_s - b + b\,\beta + b \log_e \frac{\sqrt{g}}{4} + b \log_e \frac{\mathbf{R}}{C}\right) \qquad \text{(4)}$$

in which $\mathbf{R} = 4\,R\,V/\nu$ = the Reynolds number. Mr. Keulegan shows that for a rectangular channel

---

[14] "Laws of Turbulent Flow in Open Channels," by Garbis H. Keulegan, *Research Paper RP 1151*, National Bureau of Standards (U. S.), Vol. 21, December, 1938, Eq. 48.

$$\beta = \log_e\left(1 + \frac{2\,y}{B}\right) - \frac{y}{B} \dots\dots\dots\dots\dots\dots\dots\dots (5)$$

in which y is the depth of the flow and B is the width. Assuming that b here has the same value as that which Nikuradse[4] found for pipes, and that $\bar{\epsilon}$ is zero, the shape correction term is equal to

$$c_s = \frac{b\,\beta\sqrt{g}}{1 + \bar{\epsilon}} = 14.18\,\beta \dots\dots\dots\dots\dots\dots\dots\dots (6)$$

Values of this term were calculated for various depths and are plotted against the corresponding hydraulic radius in Fig. 8.[14a] Since this term represents such a small part of the total C, it is felt that the approximation of making $\bar{\epsilon} = 0$ and $b = 2.5$ will introduce no appreciable error. By grouping the remaining terms, Eq. 4 may be rewritten as

$$C - c_s = m \log_{10} \frac{\mathbf{R}}{C} + J \dots\dots (7)$$

in which the logarithm is now to the base 10, and

$$m = \frac{2.3026\,b\sqrt{g}}{1 + \bar{\epsilon}} \dots\dots\dots (8a)$$

The same assumptions as those in Eq. 6 would make $m = 32.65$. Define J as:

$$J = \frac{\sqrt{g}}{1 + \bar{\epsilon}}\left(a_s - b + b \log_e \frac{\sqrt{g}}{4}\right) \dots (8b)$$

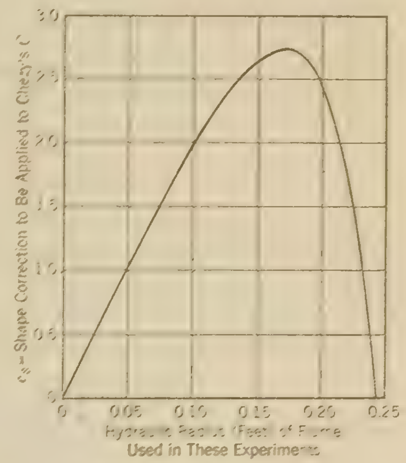

FIG. 8.—SHAPE CORRECTION

Using Nikuradse's value of $a_s = 5.5$ in addition to these assumptions, J would be $\sqrt{32.16}\,(5.5 - 2.5 + 2.5 \log_e \sqrt{2.01}) = 21.96$ and

$$C - c_s = 32.65 \log_{10} \frac{\mathbf{R}}{C} + 21.96 \dots\dots\dots\dots\dots\dots (9a)$$

It may be noted that for a semicircular cross section, Mr. Keulegan shows that $\beta = 0.259$, so that $c_s = 14.18 \times 0.259 = 3.67$, and

$$C = 32.65 \log_{10} \frac{\mathbf{R}}{C} + 25.63 \dots\dots\dots\dots\dots\dots (9b)$$

which is almost identical with the formula for flow in smooth channels derived independently by the writer[15] in 1938.

However, when $C - c_s$ was plotted against $\log_{10} \mathbf{R}/C$, the data for this smooth channel (Fig. 9) failed to agree with Eq. 9a. In the first place the points for the steepest slope, where the flow was definitely shooting (with $\mathbf{F} = 2.49$ or more), fall in a distinct region indicating an entirely different law. The others lie fairly well along a straight line, but its equation, fitted by least squares, is

---

[14a] Corrections for Fig. 8 are discussed in the closure.

[15] "Mechanics of Liquids," by Ralph W. Powell, Macmillan Co., New York, N. Y., 1940, p. 202.

$$C - c_s = 39.7 \log_{10} \frac{\mathbf{R}}{C} + 5.6 \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

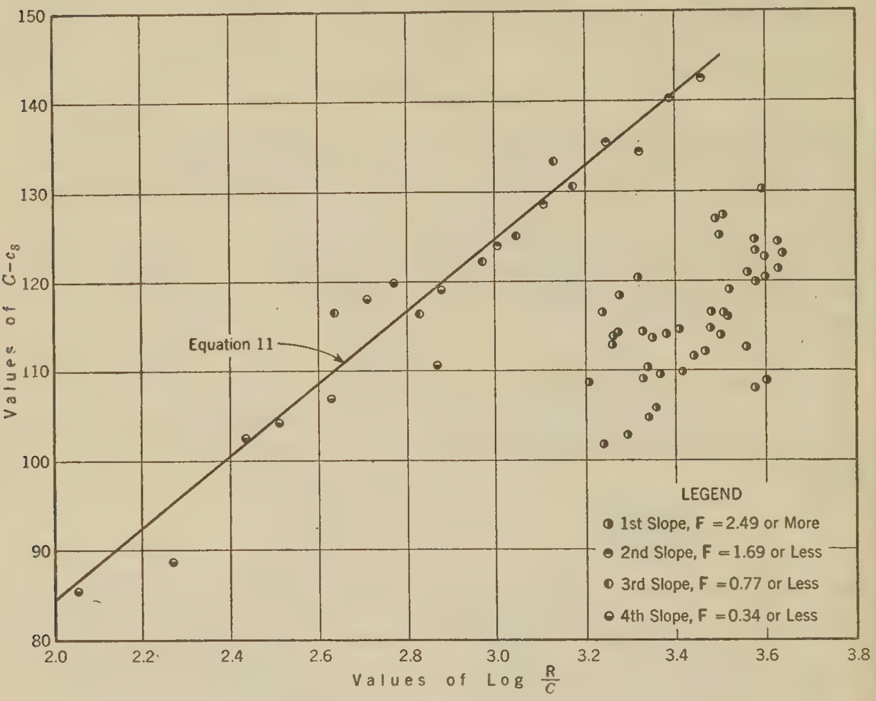

FIG. 9.—VALUES OF CHÉZY COEFFICIENT C FOR A SMOOTH CHANNEL

The probable error of m, also computed by least squares, is 1.4, so that it was decided to replace 39.7 ± 1.4 by 40. This changes the most probable value of J from 5.6 to 4.8, so that Eq. 10 becomes

$$C - c_s = 40 \log_{10} \frac{\mathbf{R}}{C} + 4.8 \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

This line is drawn in Fig. 9. Table 1(a) in the Appendix gives the values of C computed by Eq. 11 (with the help of a table of values of $C + 40 \log_{10} C$), and also the deviations from the observed C. The mean deviation was 2.32 and the "probable error" was 2.0. Since C averaged 117.4, the average error was about 2.0% and the probable error about 1.7%.

If the walls are wavy, the value of J in Eq. 7 would be expected to be less than that for straight walls, but the value of m would be expected to remain the same. However, the value of m found in these experiments is definitely more than that found by Nikuradse. The value of $m = 39.7 \pm 1.4$ corresponds to $b = 3.04 \pm 0.11$ if $\bar{\epsilon} = 0$ and even more if $\bar{\epsilon}$ has an appreciable size. Nikuradse's value of $b = 2.5$ is probably somewhat approximate (notwithstanding the numerous formulas that have been based on it), but it can scarcely be this much in error. Therefore, there are either serious systematic errors in these experiments, or b has a different value for channels than for pipes. The much more extensive tests on rough channels, reported in this paper, also indicated this same value of m. It may also be noted that the study of velocity distribution in open channels by E. H. Taylor,[16] Jun. Am. Soc. C. E., following a modification of a method proposed by M. P. O'Brien,[17] M. Am. Soc. C. E., gave an average value for the "universal constant" of 0.306, which corresponds to $b = 3.27$ and which is even more than the writer's experiments show.

As stated, Eq. 11 does not represent the runs at the steepest slope (setups 1, 2, 3, and 8, in Table 1(*b*) in the Appendix). When the discrepancies from Eq. 11 were plotted against the Froude number **F**, there was no apparent relationship for the flatter slopes (setups 23, 24, and 46, in Table 1(*a*), in which **F** varied from 0.26 to 1.69); but on the steepest slope where **F** varied from 2.49 to 3.28, there was a very definite dependence on **F**, which it seemed might be well expressed by a formula of the type

$$C - c_s = J + z \log_{10} \frac{\mathbf{R}}{C} + x\,\mathbf{F} \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Solving for the most probable values of J, z, and x by least squares gave: $x = 30.4 \pm 2.2$; $z = 58.7 \pm 3.1$; and $J = -171.5$. In view of the fairly large probable errors it seemed best to round these values to $x = 30$ and $z = 60$, which for the best fit necessitated changing J to -175 and gave the formula

$$C - c_s = 30\,\mathbf{F} + 60 \log_{10} \frac{\mathbf{R}}{C} - 175 \ldots\ldots\ldots\ldots\ldots (13)$$

The values of C computed by Eq. 13 (with the aid of a table of values of $C + 60 \log_{10} C$) and the deviations from the observed C are given in Table 1(*b*) in the Appendix. The mean deviation was 2.44 and the probable error 2.1. Since C averaged 117.9, this makes the average error about 2.1% and the probable error about 1.8%.

Eq. 13 must be regarded as tentative until checked by other investigators and at other slopes. When it is realized how wavy the water surface was in this case (no photograph was taken, but the surface was similar to that in Fig. 4(*d*), it is not surprising that **F** enters into this case although it did not enter when the flow was more tranquil. It is surprising, however, that the coefficient of $\log_{10} \mathbf{R}/C$ should change. It is also surprising that the change from Eq. 11 to Eq. 13 came between $\mathbf{F} = 1.69$ and $\mathbf{F} = 2.49$ instead of at $\mathbf{F} = 1.00$. (Tests at one or more intermediate slopes would be required to determine where the change occurs.) The six runs of setup 23, Table 1(*a*) (Appendix), had Froude numbers **F** varying from 1.45 to 1.69 and agreed with Eq. 11 with an average discrepancy of 0.87, whereas the average discrepancy from Eq. 13 was 53.4.

ANALYSIS OF RESULTS WITH ROUGH CHANNEL

Mr. Keulegan's formula for rough walled channels, in the notation of this paper, is

$$\frac{V}{V_f} = a_r - b + b \log_e \left(\frac{R}{\epsilon}\right) + b\,\beta - \bar{\epsilon}\,\frac{V}{V_f} \dots\dots\dots\dots (14a)$$

in which a_r, a constant for rough walls, takes the place of the a_s in Eq. 2, and ϵ is a measure of the roughness of the channel walls (which Messrs. Nikuradse and Keulegan represented by k). Substituting the value of V_f and rearranging Eq. 14a,

$$C = \frac{\sqrt{g}}{1 + \bar{\epsilon}} \left[a_r - b + b\,\beta + b \log_e \left(\frac{R}{\epsilon}\right)\right] \dots\dots\dots\dots (14b)$$

As in the case of smooth channels (see Eq. 6), $\frac{b\,\beta\sqrt{g}}{1 + \bar{\epsilon}}$ can be replaced by c_s and the other terms combined to make

$$C - c_s = J + m \log_{10} \frac{R}{\epsilon} \dots\dots\dots\dots\dots\dots\dots (15)$$

For roughness I, values of $C - c_s$ were plotted against $\log_{10} R$. Since roughness IX (Fig. 3) constituted a half-scale model of roughness I except for width (which was corrected for in each case by the c_s-term), the values for roughness IX, with hydraulic radii twice those observed, were also plotted on the same sheet. Similarly, roughness VIII was combined with roughness II, roughness VII with roughness III, and roughness X with roughness XI. In each case the slope of the line $m = 40$ seemed to give as good a fit as any. This value was obtained visually without a least squares solution.

For roughness III, the equation thus obtained was

$$C - c_s = 72.2 + 40 \log_{10} R \dots\dots\dots\dots\dots\dots\dots (16)$$

If ϵ were taken as 0.25 in. = 0.02083 ft, $1/\epsilon = 48$, and $40 \log_{10} 1/\epsilon = 67.25$, J would be $72.2 - 67.25 = 4.95$. On the other hand, $4.95/40 = 0.12375 = \log_{10} 1.327$ and the reciprocal of 1.327 is 0.754, so that if ϵ had been taken as about three quarters the actual height, J would have been zero. Since the measure of roughness depends not only upon the height of the particle, but also on the spacing, it is obvious that the unit of measurement of roughness is quite arbitrary, and that it would be quite allowable to take it such that $J = 0$. Therefore, the following formula was used:

$$C - c_s = 40 \log_{10} \frac{R}{\epsilon} = 40 \log_{10} R - 40 \log_{10} \epsilon \dots\dots\dots\dots (17)$$

From the aforementioned plottings, and similar ones for roughnesses IV, V, and VI, ϵ was obtained and then C was computed for each run and the discrepancy between the computed and observed values of C was arranged in

Table 1(*c*) to Table 1(*m*) in the Appendix. If there was any serious difference between the sums of the plus and minus discrepancies, the value of ϵ was adjusted to make the discrepancies balance. The final values are listed in Table 2(*a*) in the Appendix. Table 2 also gives the values of ϵ/h, s, and s/h, in which h is the actual dimension of the batten, and s is the spacing of the battens center to center. Since roughnesses IV, V, and VI consisted of both $\frac{1}{8}$-in. and $\frac{1}{4}$-in. battens, no value of h was assigned to them.

PROBABLE ACCURACY

According to probability theory, the percentage probable error of the product or quotient of two observed quantities is the square root of the sum of the squares of the percentage probable errors of the factors. Estimates were made of the probable error in each of the various kinds of readings, and, from them, of the probable errors in the computed quantities, based on the aforementioned probability theory. In the case of the slope, the deviation of the plotted points from a straight profile also gave an indication of the probable error. These estimates gave percentage probable errors, as follows: For the velocity, 1.5%; for the slope, 1.7%; for the hydraulic radius, 1.3%; and for C, 1.9%. These are only estimates and may be too low. At any rate the average deviation of the 200 runs on rough channels from Eq. 17 was 4.37%, which by C. A. F. Peters' formula (probable error is approximately 0.845 times the average deviation) would indicate a probable error of 3.7% in one observation. This includes any error due to the choice of a wrong general form for Eq. 17, any error in the value $m = 40$, and any error due to the wrong choice of ϵ for each particular roughness. As to the value of m for tranquil flow in the smooth channel, it already has been noted that the least squares solution gave a probable value of 39.7 ± 1.4, and as the average value of $\log_{10} \mathbf{R}/C$ was 3.441, the probable error in the term $40 \log_{10} \mathbf{R}/C$ might be estimated at $1.4 \times 3.441 = 4.8$; but the error in the computed value of C would not be this much as it is largely compensated for by choosing a value of J to correspond to the m used. No study was made of the accuracy of the value $m = 40$ in Eq. 17, but from the plotting the writer would judge the probable error to be about 1.5.

The shape correction, c_s, is of the same order of magnitude as the discrepancies, so that the data are insufficient to check its correctness; but a plotting of the discrepancies against values of the depth y showed no systematic relationship, so that there is no evidence against its correctness. It may be mentioned again that the relation $c_s = 14.18\,\beta$ was based on Nikuradse's value of b. The writer's value of $m = 40$, instead of 32.65, is an increase of 22.5% and would increase the coefficient of β from 14.18 to 17.37. On the other hand, $\bar{\epsilon}$, the free surface effect, was taken as zero. If it has an appreciable value, part or all of the difference would be compensated for. At any rate the maximum change in c_s could be only 0.6, so that it was thought unnecessary to recompute all the data.[17a]

In general, it must be admitted that the accuracy of the experiments recorded herein is only of about the same order as those of Osborne Reynolds[18] on pipes in the 1880's. It can only be hoped that, in this case too, they may lead to more accurate measurements by other observers which will clear up the uncertainties.

[17a] This statement is corrected in the closing discussion.

[18] "An Experimental Investigation of the Circumstances Which Determine Whether the Motion of Water Shall Be Direct or Sinuous, and of the Law of Resistance in Parallel Channels," by Osborne Reynolds, *Philosophical Transactions*, Royal Soc. of London, Vol. 174, Pt. III (1883), p. 935.

It might be urged that, since quite large standing waves formed on the surface at the higher velocities in the rough channel, a term involving the Froude number should be included in Eq. 17. However, a plotting of the discrepancies from Eq. 17 against **F** showed no systematic relationship. This was to be expected because, since $\mathbf{F} = V/\sqrt{g\,y}$ and $C = V/\sqrt{R\,S}$, and since R varies nearly as y, resistance depending on **F** could hardly be distinguished from other resistance except by the difference in slopes, and in these tests there was only one slope at which **F** was large enough to have much effect.

Comparison with Bazin's Results

Runs 12 to 17 of Bazin's tests[2] were on rectangular plank channels with wood strips 1 cm thick and 2.7 cm wide nailed crosswise on the bottom and sides. His results, therefore, should be comparable to those herein presented except that the battens were not square. Since it seems that this might make relatively little difference, Table 1(*n*) (Appendix), has been computed. The value of ϵ which gave the best fit in Eq. 17 was selected (and listed in Table 2(*b*) in the Appendix), and the computed C and the deviations from the observed C are given in Table 1(*n*). The mean discrepancy was only 1.6, as compared to 2.1 for the writer's data.

The ratios of the equivalent roughness to the actual height of the "roughness particle" and the ratio of spacing to height, as given in Table 2 in the Appendix, are plotted in Fig. 10. The dashed portion of this curve is admittedly uncertain, but it indicates that the spacing of square battens that would give the maximum resistance is about twelve times the height of the battens, and that the maximum "equivalent roughness" is about 0.83 of the height. It must be remembered that the scale of measurement of "equivalent roughness" was taken arbitrarily to make J in Eq. 15 equal to zero, and that therefore this last result would not necessarily agree with Nikuradse's sand grain size and his formula for pipes. The facts that Schlichting[11] obtained a value of $\epsilon/h = 11.9$ for the flanges of a small angle section placed across his pipe, and that Mr. Streeter[10] found values of ϵ/h as high as 4.57 for square circumferential grooves, both investigators using ϵ equal to Nikuradse's k, indicate that the unit of ϵ used in Eq. 17 may be, say, from five to ten times as large as that used by Nikuradse. Although a standard

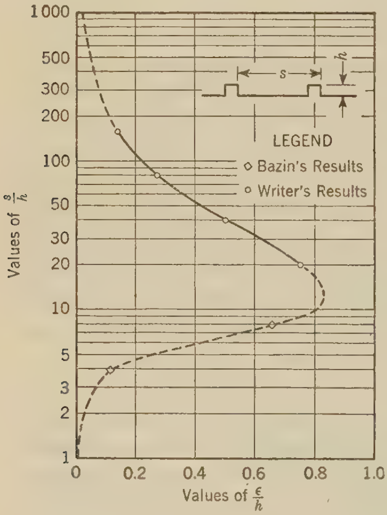

Fig. 10.—Relation of Relative Roughness to Spacing

value would be desirable, it would not seem feasible to adopt one until some one geometrical type of roughness (such as the one used in this study or some other that could be reproduced as easily) has been carefully calibrated by the Schlichting method in a pipe, and by some method comparable to that of the writer, in open channels. Then all other roughnesses could be referred to this scale.

CONCLUSIONS

The discrepancies of Eq. 17 from the observed data average nearly twice as much as would be expected from the probable inaccuracies of the measurements as estimated by the observer; but these are only estimates and it may be that Eq. 17 is entirely correct and the discrepancies entirely due to errors in observation or to errors of observation plus errors in the chosen values of ϵ. It seems more probable that the discrepancies are partly due to these two factors and partly due to wrong values in the constants of Eq. 17, but that the form of the equation is satisfactory, at least for tranquil flow.

For the case of the depth half the width, c_s is 2.74. The resulting formulas for this case are:

For tranquil smooth channels,

$$C = 7.54 + 40 \log_{10} \frac{\mathbf{R}}{C} \quad\text{.................... (18a)}$$

and, for rough channels,

$$C = 2.74 + 40 \log_{10} \frac{R}{\epsilon} \quad\text{.................... (18b)}$$

For laminar flow, assuming that the slope of the hydraulic gradient is the same as for a square pipe flowing full[19]

$$C = \sqrt{\frac{8\,g\,\mathbf{R}}{57.0}} = 2.12\,\sqrt{\mathbf{R}} \quad\text{.................. (18c)}$$

It should be noted that Eqs. 18*a*, 18*b*, and 18*c* apply only when the depth is half the width. For smaller depths the constant in Eq. 18*c* is less, approaching the value

$$C = \sqrt{\frac{8\,g\,\mathbf{R}}{96}} = 1.64\,\sqrt{\mathbf{R}} \quad\text{.................. (18d)}$$

when the width is infinite compared with the depth. Eqs. 18 are plotted in Fig. 11, which sums up most of the results of this paper. It must be understood that, as in the corresponding case for pipes, the same channel may act as rough or smooth. For example, a channel 4 ft wide flowing 2 ft deep, with an absolute roughness (ϵ) of 0.0010 ft, would have $R = 1.0$ ft and $R/\epsilon = 1{,}000$, and C would be 122.7 for any Reynolds number greater than 92,900; but, for Reynolds numbers less than this, it would behave as a smooth channel with C decreasing as $\mathbf{R}$ decreased down to about 67 at $\mathbf{R} = 2{,}000$, when Eq. 18*c* would begin to apply. Of course, the region from $\mathbf{R} = 2{,}000$ to $\mathbf{R} = 8{,}000$ is uncertain. It has been studied by L. Hopf,[20] H. Jeffreys,[21] R. E. Horton, M. Am. Soc. C. E., the late H. R. Leach, Assoc. M. Am. Soc. C. E., and R. Van Vliet,[22] and by L. G. Straub,[23] M. Am. Soc. C. E. Professor Straub, however, used a different definition for Reynolds number and also seems to have used the constant for a round pipe in his equation for laminar flow.

---

[19] "A Review of Flow in Pipes and Channels," by S. J. Davis and C. M. White, *Engineering*, Vol. 128 (1929), p. 71. This simply puts into English the results of J. Boussinesq, *Journal de Mathématiques pures et appliquées de M. Liouville* (1868), p. 393.

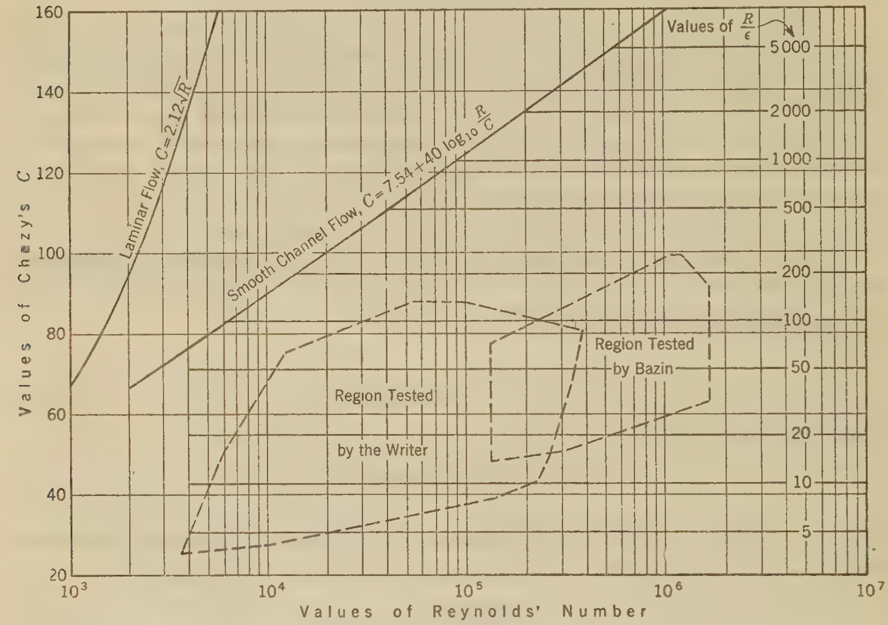

FIG. 11.—RELATION BETWEEN C AND R FOR RECTANGULAR CHANNELS WITH THE DEPTH EQUAL TO HALF THE WIDTH

By analogy with pipes one may suppose also that the region just to the right of the smooth channel line is probably not given correctly by the lines as drawn. One would expect that for uniform roughness there would be an upward bend (just as Nikuradse[9] found a downward bend for the friction coefficient f in pipes) and that for irregular roughnesses the bend would be in the opposite direction, as found by Messrs. Colebrook and White.[13] This transition range in pipes has been discussed quite fully by Mr. Colebrook[12] and by Hunter Rouse,[24] M. Am. Soc. C. E. Unfortunately, the writer's tests did not include any case in which the rough channel acted as smooth. It would be a difficult condition to arrange for water, but very easy with a liquid of the right viscosity.

[24] "Evaluation of Boundary Roughness," by Hunter Rouse, *Proceedings*, 2d Hydraulic Conference, Iowa City, Iowa, 1943, pp. 105–116.

In all the computations of this paper the area and hydraulic radius are based on the gross section of the channel without the battens. If the battens were quite close together there certainly would be a question as to whether computation should not be based on the net section, or on some kind of average section. This knotty question is left for further study.

If Fig. 11 correctly represents the flow of liquids in channels, the implications for river model studies are evident. If the prototype acts as a rough channel, it is not sufficient to give the model the same relative roughness, because, at its smaller Reynolds number, it might be acting as a smooth channel. The only solution seems to be to use a sufficiently large model to bring it into the rough channel range.

ACKNOWLEDGMENTS

The writer wishes to express his grateful appreciation of the generosity of the Iowa Institute of Hydraulic Research which placed its facilities at his disposal, and met the incidental expenses of the study; especially to F. M. Dawson, M. Am. Soc. C. E., Director of the Institute, E. W. Lane, M. Am. Soc. C. E., then Associate Director in Charge, and to Hunter Rouse, M. Am. Soc. C. E., and A. A. Kalinske, Assoc. M. Am. Soc. C. E., and to A. M. McLeod. He also wishes to thank Paul Nemenyi and James Robertson, Jun. Am. Soc. C. E., at that time both connected with the Institute, and to express his appreciation of the work of E. W. Thomas and Dale Harris, technicians, who assisted in the construction of the apparatus. Several students, working under provisions of the National Youth Administration, assisted with the computations.

APPENDIX

NOTATION AND TABLES OF OBSERVATIONAL DATA

The following symbols, used in the paper, conform essentially to American Standard Letter Symbols for Hydraulics,[25] prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:

a = a constant used by Mr. Keulegan,[3] subscript r denoting rough channels and subscript s denoting smooth channels;
B = channel width;
b = a constant, the reciprocal of von Kármán's "universal constant";
C = the Chézy coefficient in the formula $V = C\sqrt{RS}$;
c = a correction; c_s = a small shape correction;
$\mathbf{F}$ = Froude number = $V/\sqrt{g\,y}$;
f = coefficient of pipe friction in the formula $S = \frac{f\,V^2}{D\,2\,g}$;
g = acceleration of gravity;
H = head on the measuring orifice;
h = height of roughness particles, or battens;
J = a constant defined by Eq. 8b;
k = a symbol for roughness used by Messrs. Nikuradse and Keulegan (see ϵ);
m = a constant in Eq. 7, defined by Eq. 8a;
Q = rate of flow;
R = hydraulic radius;
$\mathbf{R}$ = Reynolds number;
S = slope of the energy gradient;
s = spacing of roughness battens (center to center);
V = mean velocity in the cross section of a flume or channel; V_f = friction velocity as defined by Eq. 3;
x = the unknown coefficient of $\mathbf{F}$ in Eq. 12;
y = depth of flow; that is, vertical measurements or measurements parallel to the Y-axis;
z = an unknown coefficient in Eq. 12;
β = a function of the shape of the cross section as defined by Eq. 5;
ϵ = absolute or equivalent roughness; that is, a measure of the roughness of the channel walls (see k);
$\bar{\epsilon}$ = a measure of the resistance of the free surface;
ν = kinematic viscosity of the flowing liquid;
ρ = density of the flowing liquid;
τ = shearing stress; τ_s = shearing stress at the liquid boundary.

DISCUSSION

JOE W. JOHNSON,[26] ASSOC. M. AM. SOC. C. E., AND E. A. LEROUX,[27] ESQ.—The author is to be congratulated for a splendid experimental investigation which is a welcome contribution toward a better understanding of the problem of channel roughness. Similar investigations in the University of California Fluid Mechanics Laboratory at Berkeley were made with water in both open and closed channels, and with air in closed channels. Various types of artificial roughnesses were used. Experiments by V. J. Skoglund[28] were made with water in rectangular channels roughened by 60° V grooves transverse to the direction of flow. The grooves were 0.060 in. apart with an average depth of 0.0125 in. The hydraulic radius was varied from 0.030 ft to 0.230 ft. Later experiments were made by J. E. Ogden[29] using this same apparatus but with a groove spacing one half that used by Mr. Skoglund; that is, the roughness grooves were 0.030 in. center to center. Tests were made with the hydraulic radius of the channel equal to 0.019 ft. The results of experiments in a a triangular open channel with the roughness formed by attaching sand grains of constant mean diameter to the channel walls have been published by T. DeF. Rogers.[30]

Other open-channel experiments were made by M. E. Fuller and R. E. Graham, Juniors, Am. Soc. C. E., in a rectangular flume $9\frac{1}{2}$ in. by $9\frac{1}{2}$ in. in cross section and 70 ft long.[31] The type of roughnesses included the following combinations: (*a*) Smooth sides and bottom coated with enamel; (*b*) sides and bottom covered with a 90-lb Flintkote roofing paper with rough side exposed; (*c*) enameled sides with bottom covered with the roofing paper; (*d*) enamel sides with $\frac{1}{2}$-in. mesh hardware cloth tacked over the roofing paper on the bottom. These roughnesses are not "definite" in the sense implied by the author; hence, the results are not summarized herein.

Of particular value in connection with a discussion of the author's data are the results of various investigations on roughnesses, rectangular in cross section. Although most of these data have been discussed elsewhere,[32] a summary (Table 3) in terms of the author's notation is necessary for comparative purposes. For each of the roughnesses tested by the various experimenters, the data in Table 3 include the following terms (see Fig. 12): Center-to-center spacing, s, of the roughness battens; the batten height, h; the batten width, t; the width-height ratio, t/h; and the spacing ratio, s/h. The observa-

tions of W. Tripp[33] and F. Jonassen[34] were similar to those of Mr. Skoglund, except that air was used in wooden rectangular conduits roughened by saw cuts transverse to the direction of flow (Fig. 13). The investigations by C. A. Smith, Jr., and C. Warren, Juniors, Am. Soc. C. E., and by the writers were made in a wooden flume $9\frac{1}{2}$ in. by $9\frac{1}{2}$ in. in cross section and 70 ft long.[35] In the experiments by Messrs. Smith and Warren the roughness was formed by saw cuts made in removable planks fastened to the flume bottom.

FIG. 13.—VARIOUS RECTANGULAR ROUGHNESSES TESTED AT THE UNIVERSITY OF CALIFORNIA (NOTE SCALE CHANGES)

Different spacing ratios (s/h) were made by removing alternate ridges between saw cuts (see Fig. 13). It is of interest to note that the average value of Manning's n for the enameled surface was 0.0091, whereas the value of n for the bottom after all roughness ridges had been removed was 0.0104. In the writers' experiments the roughness was made by nailing redwood strips to the bottom of the flume transverse to the direction of flow. Strips 1 in. by $\frac{1}{4}$ in. were used for roughnesses in the Johnson experiments; whereas $\frac{3}{4}$-in. by $\frac{1}{4}$-in. strips were used by Mr. LeRoux (Fig. 13).

The method of calculating the hydraulic radius, Manning's n, and the equivalent sand roughness in the experiments of Messrs. Smith and Warren, and of the writers, have been described elsewhere;[32] however, because of differences in the experimental equipment and the method of analysis of the data a brief review is of interest. In the author's experiments both the bottom and sides of the flume were covered by roughness battens, and the results were analyzed with G. H. Keulegan's formulas as the basis. In the writers' experiments only the channel bottom was roughened. The side-wall effect first was "eliminated" by the method suggested by H. A. Einstein,[36] Assoc. M. Am. Soc. C. E., and then the hydraulic radius of the bed, R_b, Manning's n of the bed, n_b, and the equivalent sand roughness of the bed, k, were computed, the latter term being computed by the Nikuradse equation:

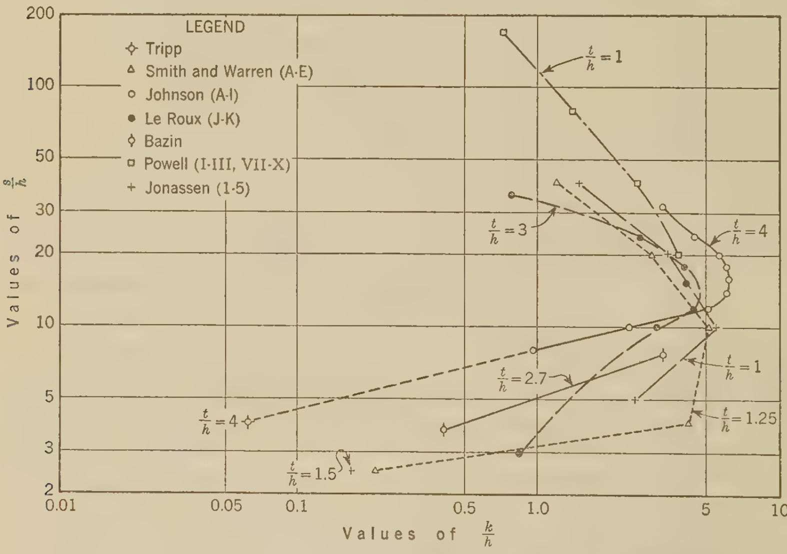

FIG. 14.—RELATION OF RELATIVE ROUGHNESS TO SPACING FOR VARIOUS DATA

$$\frac{1}{\sqrt{f}} = 2 \log_{10}\left(\frac{2\,R_b}{k}\right) + 1.74 \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

---

[36] "Formulas for the Transportation of Bed-Load," by H. A. Einstein, *Transactions*, Am. Soc. C. E., Vol. 107 (1942), pp. 575–577.

in which

$$f = \frac{8\,g\,R_b\,S_e}{V^2} \qquad (20)$$

and S_e is the slope of the energy grade line.

The data in Table 3 are of value in giving a more complete picture of the relation of relative roughness to spacing than that given by the author in Fig. 10. Fig. 14 shows a plot of these data and indicates that the author's data and Bazin's results probably are not part of the same curve but appear to be branches of two separate curves. The author has called attention to the uncertainty of a single curve. Fig. 14 indicates that the width-height ratio, t/h, may be of importance. The various curves indicate that the maximum relative roughness occurs in the vicinity of s/h equal to approximately 15 instead of 12. The value of the maximum relative roughness appears to be approximately a constant regardless of the value of t/h. On either side of the point of maximum roughness there is considerable variation in the curves; however, for a particular value of s/h, the roughness appears to be larger with the smaller values of t/h.

It is to be noted that the values of k and n_b (Table 3) are averages. The values of relative roughness for the data of the author and H. Bazin plotted in Fig. 14 are not the values given in Table 2. The appropriate values are:

Roughness	s/h	k/h
Bazin—		
Close spacing	3.7	0.41
Wide spacing	7.7	3.36
The author—		
III and VII	20	3.89
II and VIII	40	2.60
I and IX	80	1.40
X and XI	160	0.72

The author previously has converted the values of ϵ in Table 2 to the corresponding values of the Nikuradse k.[37]

It is important to note that in the author's experiments the water depth was measured from the water surface to the flume bed without battens in place; whereas, in the writers' experiments, the depth was measured to the top of the battens. At small depths of flow relatively large differences in the results from the two experiments may occur if comparisons are attempted. The author has recognized the uncertainty in determining the true depth and has suggested that the problem be given further study.

Garbis H. Keulegan,[38] Esq.—It is appropriate to discuss briefly the meaning of the coefficients appearing in Eq. 2 which form the basis of the author's working formula, Eq. 7. The characteristic waviness of a smooth wall, which is generally due to imperfections in construction, is expressed by a_s.

---

[37] Discussion by R. W. Powell of "Rectangular Artificial Roughness in Open Channels," by J. W. Johnson, *Transactions*, Am. Geophysical Union, Section of Hydrology, 1944.

[38] Physicist, National Bureau of Standards, Washington, D. C.

The effect of waviness of the walls may be augmented by standing waves in the flowing water. In any event waviness produces a periodic variation in the thickness of the laminar sublayer. The constant b is a measure of the convection path l at points near the walls. According to experiments the dependence of l upon z (the distance of a point from the wall) is given by $l = z/b$. The Nikuradse value of b for the flow in a circular pipe of constant diameter is 2.5. In divergent channels the value of b varies with the angle of divergence. This fact might suggest that a more rigorous expression for b should contain a term involving the space rate of variation of the shear velocity V_f. In all probability the correction obtained in this manner is small and may be safely ignored. The coefficient β takes the ratio of depth to width into consideration. The coefficient $\bar{\epsilon}$ is introduced to correct, approximately, the deviations in the velocities imposed by the free surface of the water and by the angles between the walls and the bottom of the channel.

In effect, the author's method of treating the observed data consists of plotting the quantity $V/V_f - b\,\beta$ against the logarithm of the Reynolds number, the latter being based on the shear velocity. In the event that the accidental deformation of the walls with increase of water depth is negligible, the surface of the water is smooth, the correction coefficient $\bar{\epsilon}$ is sufficiently small, and the locus of observed points is a straight line, then the slope of that line determines the value of b. The author establishes in Fig. 9 a straight line which yields a value for b of 3.04 ± 0.11. Since this value is at variance with the Nikuradse determinations, the author has concluded that there are either serious systematic errors, or b has values for channels different from those for pipes.

Ignoring the possibility of any systematic errors, the writer desires to examine the effect of a finite value of $\bar{\epsilon}$ on the magnitude of b. The consequences of such an effect are not fully discussed by the author. As was mentioned previously, $\bar{\epsilon}$ is supposed to correct for the dynamic differences produced by the free surface of the water and by the angles between the walls and the bottom of the channel. Since the free surface effect is probably small, consider the nonuniform distribution of wall shear produced by the corners in the channel cross section. The shear is minimum at the corners. Denoting the local shear velocity at any point by v_f,

$$v_f = V_f\,(1 + e) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

and $\bar{\epsilon}$ is given by

$$-\,\bar{\epsilon} = \frac{1}{A}\int e\,dA \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

in which dA is an elementary area of the channel cross section and A is the total area.[39]

It is obvious that if y/B is small, the correction due to $\bar{\epsilon}$ may easily be ignored. However, if y/B approaches 0.5, the value of $\bar{\epsilon}$ can be appreciable. By making certain simplifying assumptions the error may be evaluated. Suppose that the width of the channel is 2, the depth of water is 1, and the mean shear velocity is $V_f = 1$ (see Fig. 15). These magnitudes may result by selecting proper units of length and time. The shear velocity distribution along the wetted perimeter may be represented with sufficient accuracy by the expressions

---

[39] "Laws of Turbulent Flow in Open Channels," by Garbis H. Keulegan, *Research Paper RP 1151*, National Bureau of Standards (U. S.), Vol. 21, December, 1938, Eq. 46.

$$v_f = a_0 + a_2 \sin\left(\frac{\pi}{2} j\right) \qquad \text{(23a)}$$

and

$$v'_f = a_0 + a_1 \sin\left(\frac{\pi}{2} j'\right) \qquad \text{(23b)}$$

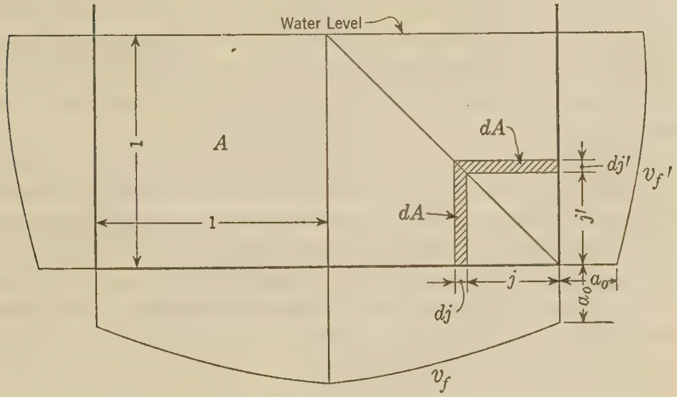

FIG. 15.—DISTRIBUTION OF SHEAR VELOCITY ALONG THE WETTED PERIMETER

of which the first evaluates the shear for the bed, and the second for the side walls. For the meaning of j and j', see Fig. 15. From

$$v_f = 1 + e \qquad \text{(24)}$$

the deviations are

$$e = a_0 + a_2 \sin\left(\frac{\pi}{2} j\right) - 1; \qquad 0 \leqq j \leqq 1 \qquad \text{(25a)}$$

and

$$e' = a_0 + a_1 \sin\left(\frac{\pi}{2} j'\right) - 1; \qquad 0 \leqq j' \leqq 1 \qquad \text{(25b)}$$

Since the average shear velocity along the perimeter is 1, it can be shown readily that

$$\pi a_0 + a_2 + a_1 = \pi \qquad \text{(26)}$$

In the present case, because of symmetry, A may be taken as half of the cross-sectional area and Eq. 22 will be written as

$$-\bar{\epsilon} = \int_0^1 e\, j\, dj + \int_0^1 e'\, j'\, dj' \qquad \text{(27a)}$$

Substituting from Eqs. 25,

$$-\bar{\epsilon} = a_0 - 1 + \frac{4}{\pi^2}(a_2 + a_1) \qquad \text{(27b)}$$

Substituting from Eq. 26,

$$-\bar{\epsilon} = \left(1 - \frac{4}{\pi}\right)(a_0 - 1) \qquad \text{(28a)}$$

or

$$\bar{\epsilon} = 0.274\,(a_0 - 1) \qquad \text{(28b)}$$

Accordingly, the value of $\bar{\epsilon}$ is readily obtained once the shear velocity at a corner is known. Let it be supposed, as a matter of illustration, that, when $y/B = 1/2$, a_0 equals 0.5. From Eq. 28*b* it is then seen that $\bar{\epsilon} = -0.13$. If y/B is made smaller, $\bar{\epsilon}$ becomes correspondingly smaller. When the corrections are introduced into Fig. 9, the following changes become apparent. All the points of the diagram are moved downward. The points that were obtained for the greater depths show the greater displacements. Thus, the new line through the corrected positions of the points will have a smaller slope as the result of the unequal displacements of points. Accordingly, the new determination of *b* may show a smaller disparity from the Nikuradse value. The true modifications can be discussed with certainty only when a_0 is determined experimentally.

The thought expressed by the author on the influence of the Froude number is fruitful. Eq. 12 gives his law of resistance for shooting flow in a smooth channel. There is the possibility, however, that the proposed formula is too restricted and therefore in its present form may be misleading. This misgiving has led the writer to the following simple analysis. It may be assumed, as a matter of hypothesis, of course, that the greater resistance encountered in the tests of shooting flow is due to the waviness of the standing waves in the channel. In the formula for the Chézy coefficient

$$C = J' + m \log_{10} \frac{\mathrm{R}}{C} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

m has the same value as in tranquil flow ($m = 40$), but the value of J' is changed through the induced waviness of the surface waters. Values of J' obtained from the data in Table 1(*b*) and computed by Eq. 29 are shown in Fig. 16.

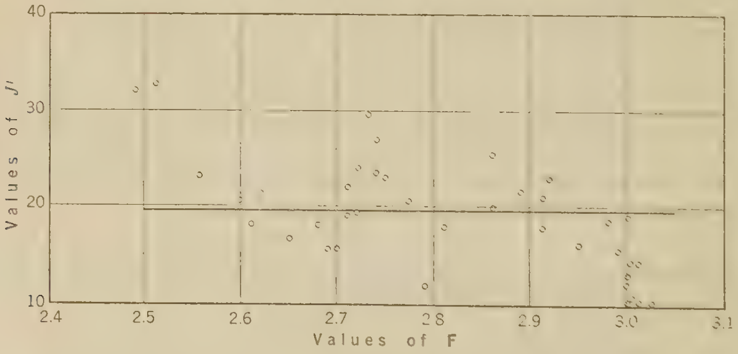

FIG. 16.—RELATIONSHIP OF J' TO FROUDE NUMBER FOR SHOOTING FLOW

As the scatter of the points for the small range of the Froude number considered is pronounced, the line of constant ordinate drawn through the points is judged to be sufficiently representative of the data. This ordinate, which is the average of all the points, has the value of − 19.5. The resulting resistance law

$$C = -20 + 40 \log_{10} \frac{\mathrm{R}}{C} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

is offered as an alternate to the author's law as expressed by Eq. 12. A graph of the quantity J', as obtained from all the tests with the smooth channel, is shown in Fig. 17. The interpretation of the diagram is that, at some critical value of the Froude number, J' changes suddenly, but after the change has occurred its new value probably is independent of the Froude number; or, if J' does depend on the Froude number, the relationship between them is of a nature different from that implied by the author's relation given by Eq. 12. The importance of the problem is great enough to require extensive new experiments on the régime of shooting flow.

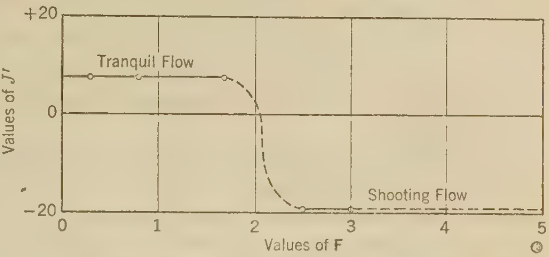

Fig. 17.—Relationship of J' to Froude Number for Tranquil and for Shooting Flow

The need for various studies in the field of flow in open channels is great. Undoubtedly, men of the profession will feel that the author has made a valuable contribution.

C. J. Posey,[40] M. Am. Soc. C. E.—Engineering uses of the science of hydraulics have about reached the point where improvement of the favorite open-channel friction formulas is economically justified. Professor Powell's paper should help to convince the complacent that research on this fundamental problem is badly needed. Although the Kutter coefficient can be predicted to within a thousandth or two, under favorable circumstances, the corresponding uncertainty in the major variables is appreciable. Where long channels form important links in great projects, this lack of precision can be costly.

The two important variables that give trouble, in evaluating friction flow in open channels, are the roughness and the shape of the cross section. Thorough investigation of the effect of the latter has been avoided, in obtaining results for practical use, by testing shapes similar to those used in design. The effect of channel shape has been oversimplified in the "rational" formulas for open-channel flow. A reliable means of evaluating the effect of channel shape, well substantiated by experimentation, would seem to be a necessary part of any satisfactory solution of the roughness problem. It would also free the designer from adherence to traditional shapes, and enable him to take full advantage of new developments in construction methods.

Ralph W. Powell,[41] M. Am. Soc. C. E.—If the writer had known of the work on this subject being done at the University of California, at Berkeley, he would certainly have mentioned it in the paper. Because of this omission he is very grateful to Messrs. Johnson and LeRoux for putting their results (including Mr. LeRoux's hitherto unpublished data) in the form of a discussion of this paper; and the writer agrees heartily with their comments. Fig. 14 is a great improvement over Fig. 10 and shows that the width of the roughnesses cannot be neglected. The writer has already discussed the methods used at the University of California and will not repeat his remarks,[37] except to state that Eq. 17 agrees with his data much better than does Eq. 19. Data are not available to the writer to test this opinion in regard to the investigations listed in Table 3.

---

[40] Associate Prof., Hydraulics and Structural Eng.; Research Engr., Iowa Inst. of Hydr. Research, State Univ. of Iowa, Iowa City, Iowa.

[41] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

The writer also wishes to thank Mr. Keulegan (whose original paper[14] formed the theoretical basis for much of the writer's paper) for his discussion, especially for his method of obtaining numerical values of $\bar{\epsilon}$. The value of $\bar{\epsilon}$ given in Eq. 28*b* applies, of course, only when $y/B = \frac{1}{2}$. The statement that, if y/B is made smaller, $\bar{\epsilon}$ becomes correspondingly smaller is ambiguous when applied to a negative number, and the writer has therefore investigated the question as follows.

Assuming that Eqs. 23 and 25 apply for any depth of water, y (which is not greater than 1), and that $a_1 = a_2$, and continuing the other assumptions made by Mr. Keulegan:

$$1 + y = \int_0^y \left(a_0 + a_2 \sin \frac{\pi}{2} j' \right) dj' + \int_0^1 \left(a_0 + a_2 \sin \frac{\pi}{2} j \right) dj \ldots (31)$$

which leads to

$$a_2 = \frac{\pi\,(1 - a_0)\,(1 + y)}{2 \left(2 - \cos \frac{\pi}{2} y \right)} \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Also,

$$-\,\bar{\epsilon}\, y = \int_0^y e'\, j'\, dj' + \int_0^y e\, j\, dj + y \int_y^1 e\, dj \ldots\ldots\ldots\ldots (33)$$

Substituting from Eqs. 25, integrating, and substituting the value of a_2 from Eq. 32:

$$\bar{\epsilon} = \left[1 - \frac{\left(\frac{4}{\pi y} \sin \frac{\pi}{2} y - \cos \frac{\pi}{2} y \right) (1 + y)}{2 - \cos \frac{\pi}{2} y} \right] (1 - a_0) \ldots\ldots (34)$$

For all values of y from 0 to 1, the quantity inside the brackets in Eq. 34 is negative; and, since a_0 is less than 1, $\bar{\epsilon}$ is negative. The values of the ratio of $\bar{\epsilon}$ to $(a_0 - 1)$ are plotted in Fig. 18. As y/B decreases from 0.50 toward zero, the absolute values of $\bar{\epsilon}$ increase slightly to a maximum of about 0.283 $(1 - a_0)$ at $y/B = 0.35$; from this they decrease slowly at first, and then more rapidly, toward zero. The experiments included very few values of y/B less than 0.15, for which $\bar{\epsilon}$ is 0.214 $(a_0 - 1)$.

As Mr. Keulegan states, experiments would be necessary to determine the value of a_0, but it would seem to the writer that it is probably at least 0.6. If $a_1 = a_2$ and $a_0 = 0.6$, Eq. 26 would require a_2 to be 0.628 for $y/B = 0.50$; and v_f would vary from 0.600 at the corner to 1.228 at the middle of the bottom. Since the shear varies as the square of the friction velocity, this would make the shear at the middle more than four times the shear at the corner. For the same case Mr. Keulegan's suggestion of $a_0 = 0.5$ would make the shear at the middle of the bottom 6.6 times the shear at the corner.

The writer had not realized that $\bar{\epsilon}$ would be negative, so that two remarks in the paper are in error, one in the paragraph after Eq. 11 and the other in the second paragraph of the section headed "Probable Accuracy." With b increased 22.5% and $\frac{1}{1 + \bar{\epsilon}}$ increased 12.3%, the maximum value of c_s given by Eq. 6 would be increased from 2.74 to 3.77, making a maximum error of 1.03 instead of 0.6 as stated. Without developing a new curve to replace Fig. 8, it may be stated roughly that the values of c_s should be increased by corrections varying from 0.5 to 1.0. It still seems not worthwhile to recompute the data to eliminate errors of this size when the mean deviations were 2.1, 2.32, and 2.44.

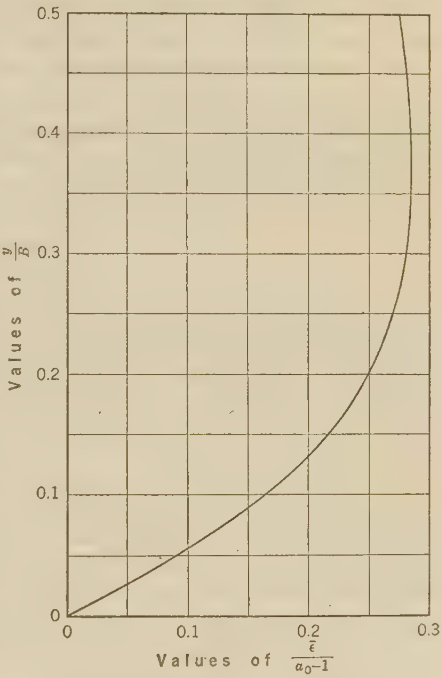

FIG. 18.—VARIATION OF $\bar{\epsilon}$ WITH DEPTH

The apparent drag at the free surface and the resulting depression of the point of maximum velocity puzzled the writer for a long time, but he has come to the conclusion that the late F. P. Stearns,[42] M. Am. Soc. C. E., and Max Möller[43] were right, and that the reduction in surface velocity is due to double spiral flow carrying slow moving liquid from the bottom up along the sides and inward along the surface. The cause of these spirals is still obscure but seems to be tied to the matter of unequal shear around the boundary, since the only case where the spirals are not present—that of the circular pipe flowing full—is also the only case of uniform distribution of boundary shear. The best discussion of the question that the writer knows is by Paul F. Nemenyi.[44]

At first the writer did not understand Mr. Keulegan's suggestion that the more accurate values of $\bar{\epsilon}$ would change Fig. 9 enough to explain the deviation from Nikuradse's results; but, in a subsequent correspondence with the writer, Mr. Keulegan has made his point clear. If, in Eqs. 8, $(1 + \bar{\epsilon})$ is omitted,

[43] "Studien über die Bewegung des Wassers in Flüssen mit Bezugnahme auf die Ausbildung des Flussprofiles," by Max Möller, *Zeitschrift für Bauwesen*, 1883, p. 201. (A summary in English is given in "Hydraulic Laboratory Practice," edited by J. R. Freeman, A.S.M.E., 1929, p. 70.)

[44] Discussion of "Transportation of Suspended Sediment by Water," by Paul F. Nemenyi, *Proceedings*, Am. Soc. C. E., June, 1945, pp. 865–874.

Eq. 7 is changed to

$$C\,(1 + \bar{\epsilon}) - c_s = C + \bar{\epsilon}\,C - c_s = m \log_{10} \frac{\mathbf{R}}{C} + J \ldots\ldots\ldots (35)$$

Although $\bar{\epsilon}$ is quite small, $\bar{\epsilon}\,C$ is not small, and plotting values of $C + \bar{\epsilon}\,C - c_s$ in Fig. 9 instead of $C - c_s$, Mr. Keulegan finds that a line with a slope of $m = 32.65$ gives a good fit. Therefore, the universal constant remains 2.5 for channels as well as for pipes, and point (1) of the Synopsis is disproved. Eqs. 11, 13, and 17 remain true as empirical formulas representing the results of the experiments, but equations with an ($\bar{\epsilon}\,C$)-term would be more scientific. How these could be adapted for practical use is a matter for further study.

The writer does not agree with the suggestion that, for shooting flow, Eq. 13 should be replaced by Eq. 30. The values of C in Table 1(*b*) were recomputed by Eq. 30, and it was found that the average discrepancy from the observed values was 4.28, as compared with 2.44 given by Eq. 13.

The writer wishes to add one suggestion: Eqs. 18*a* and 18*b* can be merged, following the method used by Hunter Rouse,[45] M. Am. Soc. C. E., for pipes, into

$$C = c_s - 40 \log_{10} \left(\frac{\epsilon}{R} + 0.7586\,\frac{C}{\mathbf{R}} \right) \ldots\ldots\ldots\ldots\ldots (36)$$

When ϵ and $\mathbf{R}$ are large, Eq. 36 practically reduces to Eq. 18*a* for rough channels; and, when the values of ϵ and $\mathbf{R}$ are small, it practically reduces to Eq. 18*b* for smooth channels. In fact, when $\mathbf{R}$ is small enough, the channel acts smooth even if ϵ is not very small. It is believed that Eq. 36 may be found useful for practical work; but, in the transition range between "smooth" and "rough," it would probably apply only to nonuniform roughnesses such as occur in nature. For the uniform roughnesses used in this experiment the fit is not improved by replacing the straight horizontal lines of Fig. 11 by the curves of Eq. 36. In fact, there is an indication in roughness X (the one nearest the smooth channel case) that the lines might turn up slightly before turning down to join the smooth channel curve, just as Nikuradse's uniform sand caused his curves to dip rather than to agree with those in Professor Rouse's formula.

The writer agrees with the remarks of Professor Posey. Even more important than the effect of the shape of the cross section, however, is the question whether the channel is acting as "smooth" or "rough," or whether it is in the transition range between. From analogy with pipes, it can be determined quite accurately that whether a channel acts as "smooth" or not depends not only on the absolute or relative roughness of the surface; but also on the thickness of the boundary layer which depends on the Reynolds number of the flow. It is too much to expect that formulas like Kutter's formula or Manning's formula can handle all the cases that may arise if n is assumed to depend on the roughness only.

It should be noted, however, that the proper value of ϵ for any particular surface in Eq. 36 is only about one fifth of the k-value for that same surface as given by Professor Rouse. The one case for which the writer has determined this relationship[37] gave $k = 5.16\,\epsilon$.

ECONOMICS OF PHOTOGRAMMETRY

By Leon T. Eliel,[1] Esq.

With Discussion by Messrs. Raymond A. Hill, Raymond L. Moore, Ralph S. Pearse, George D. Whitmore, Benjamin A. Wasil, Charles H. Davey, Robert H. Randall, W. J. Ryan, Oliver S. Reading, and Leon T. Eliel.

Synopsis

Contour mapping is rapidly becoming mechanized by the application of photogrammetric methods. Mosaic maps are widely accepted today. Planimetric maps are made and used extensively by many government agencies. There are a variety of photogrammetric processes which are quite controversial. The economics of the various photogrammetric methods and plane table surveys show why the different methods are used.

General

"Aerial photography" encompasses everything in the entire process of taking pictures from the air. When the original picture itself is all that is desired, the work pertaining to it lies entirely in the realm of aerial photography. When this picture is to be transformed into an instrument of precision, however, such as a precise mosaic, a planimetric or contour map, the work is known as "photogrammetry." Fundamentally the word means: "Picture measuring."

Photogrammetry in the United States dates from the early 1920's. In Europe it was practiced prior to World War I, and from the Europeans and, in fact, alas, from the Germans, the United States received most of its original knowledge of photogrammetry.

Only a few years ago most engineers were being disillusioned after their introduction to aerial photography. They had been led to believe that the aerial photograph, which was then procurable, was, in fact, the equivalent of a map. How far from the truth this was they soon found out. They discovered that the picture had certain errors and distortions. They found that the scale of the picture varied with differences in the elevation of the ground. Pictures were assumed distorted near the edges, although the center was known to be reasonably free from these aberrations.

Note.—Published in March, 1945, *Proceedings*. Positions and titles given are those in effect when paper or discussion was received for publication.

[1] Vice-Pres., Fairchild Aerial Surveys, Inc., Los Angeles, Calif.

These early undesirable characteristics of the aerial photograph proved to be a blessing in disguise. The distortion is geometric, of course, and the picture is nothing but a conic projection. Thus points are located along radials from the principal point or center of the picture, in accordance with their elevations. Consequently, a vertical object, such as a telegraph pole, an oil derrick, or the Washington Monument, photographs as a radial image, the top being radially displaced in relation to the base.

In fact, it is this so-called parallax of the picture which makes possible the viewing of an over-lapping pair of vertical photographs stereoscopically. This same parallax can be measured to determine differences in elevation from a stereoscopic pair of pictures, and these geometric qualities are the foundation of all photogrammetric systems.

Mosaic Maps Have Arrived

The mosaic map of the early days was the work of an artist dedicated to the principle that no error was serious unless it could be seen. Thus, these early mosaicists were in reality a breed of prestidigitators—so clever that they made things look all right even when they were all wrong.

Today, cleansed by the blessing of a scientific approach, the mosaic has been accepted in practically all circles as a good map for many purposes, and good maps have been needed, especially by the U. S. Army. Only about 25% of the United States was adequately mapped prior to World War II. Since that time the precise mosaic, accurate and quickly made, has become a map acceptable for many military purposes.

Mosaics are built on a graphical triangulation net known as radial control, which depends upon the fact that all displacements due to difference in ground elevation are radial, and consequently the angle subtended at the center of the picture by any two points is approximately a true angle. Thus, by using merely the direction of various image points from the center of the picture, rather than the images themselves, as a triangulation net, it is possible from the pictures themselves to establish the true position of any number of points in each picture. An occasional point of known position establishes the desired scale and the necessary geodetic ties. The true position of various points in a picture can now be compared with the image position, and a computation made by which the picture may be brought to scale. It is enlarged or reduced, and, in case of sloping ground, tilted so that the scale of one side is corrected more than the other. In mountainous terrain, pyramiding is utilized, whereby the picture is broken up into small sections, each of which can be brought to a uniform scale so that the picture can be laid accurately to the radial control.

Slotted Templet Method of Control.—One widely used method of radial control is known as the "slotted templet method." By this method a templet, usually cardboard, is made from each individual photograph. The principal point, or center point, of the photograph is pricked through from the picture to the cardboard, and at least eight radial points around the edges are similarly designated. A hole is punched in the center of the picture, and through each of the outlying points a radial slot is cut. Due to the overlap of the pictures, each of these points is common to several pictures—sometimes as many as six. The templets are then "buttoned up" with connecting studs through the slots, so that all the slots representing a given common point from the various pictures are assembled over a stud. Thus an entire map can be "buttoned up" and, due to the freedom of the slots, can be enlarged or reduced accordion-like, so that the entire area automatically conforms to a given scale. A very few control points, established by conventional surveying, serve to establish the map scale, and the map stretches or shrinks with movement in its radial slots to conform to these pre-established points.

When the entire area is covered by the templets, each one of which represents one of the pictures, the studs that hold the templets together represent the true position of an infinite number of myriad points. These studs have a hole through which a pin can be applied to the board beneath the templets. The points are pricked through each stud and properly designated, thus becoming the field notes, as it were, from which the ultimate map can be compiled. Typical mosaic specifications may require that 90% of all points shall be within 0.05 in. of their true location.

Planimetric Maps

Planimetric maps are compiled in much the same way as mosaics. Ordinarily, the first step in the compilation of a planimetric map is to make the radial control, or slotted templet, base. This base is traced on to tracing cloth or acetate sheets, and the planimetric detail is added by projecting the photographs on to the sheets in such a way that the control points on the photographs conform with their map positions as established on the radial control plot. Government agencies, such as the U. S. Geological Survey and the Soil Conservation Service, have done considerable planimetric mapping since about 1936.

Mechanized Contour Maps

Whereas the main problem in constructing mosaic and planimetric maps is to eliminate the effects of parallax, the contour map, on the other hand, is made by measuring this parallax. The aerial photograph, when properly taken, is a perfect triangulation record, made as though a transit were set at the same point in space as the lens of the camera. Two such pictures taken from the extremities of the air-base line afford the means by which all of their common points may be located by photogrammetry which, in common language, is triangulation by photography. To be sure, the modern photogrammetric machine does its work automatically, so that it is unnecessary to solve triangles for each individual point. However, were one inclined to this tedious process, a perfectly satisfactory answer could be derived in this way.

Two-Dimensional Processes

The Stereocomparagraph.—Contour drawing machines are essentially of two types. The first is the parallax measuring stereoscope, which is a two-dimensional machine, drawing its contours to the same conic projection as the picture itself. The most widely known machine of this type is the stereocomparagraph (not to be confused with the stereoplanigraph), a device by means of which a pair of stereoscopic prints is pinned to a board, and by the simplest of processes viewed stereoscopically with a couple of measuring dots in contact with the picture. These dots merge into a single dot appearing to float at a given distance. Their separation may be varied with a micrometer screw, and this micrometer is set according to the parallax of the pictures, for any desired elevation. Work done with the stereocomparagraph can be quite accurate, providing the pictures have been first restituted accurately; that is that the pictures have been corrected for the tilt of the camera at the instant of exposure. Even without restitution, a reasonably accurate job can be done by parallax methods, providing a great abundance of control has been established. However, it is generally accepted that the stereocomparagraph is inefficient for precision work.

The Brock Process.—The parallax principle is also incorporated into a very precise system known as the Brock process. This system involves the substitution of glass plates which have been carefully restituted for the simple paper prints of the stereocomparagraph method. The stereoscope by which the image is viewed is an extremely precise affair. With the multiplex and the stereoplanigraph methods, the entire map is drawn from beginning to end in one operation and in one machine, whereas the Brock system breaks this process down into a number of operations. This has the advantage of simplicity in that less highly skilled personnel is required, and it also affords opportunity for more operators to work simultaneously on different steps of the operation for each plate pair. The first major step of the Brock process is to determine the tilt of the aerial photograph, and to make a restituted aerial photograph, on glass. Next, this pair of stereoscopic glass plates is placed in the stereoscopes, and the same floating mark is made to follow the contours by an operator turning two wheels. The operator actually causes the floating mark to traverse perhaps one-half inch of the picture, and then with pen and ink draws this half inch of contour on a piece of overlaid tracing paper or acetate sheeting. Then he proceeds to cause the floating mark to indicate another half inch of contour, and draws this with pen and ink. After all the contours from one plate pair have thus been drawn, the result is put in a projecting machine, and each contour is projected at the proper ratio to transform it from the conic to the orthographic projection. The contour is thus traced off, and at the same time the planimetric detail, such as roads and streams, are plotted off, the detail falling between a given pair of contours being drawn at the setting of each contour. Thus, if a 20-ft contour is being traced, the planimetric detail falling within half a contour interval each side of the contour would be drawn at this same setting.

THREE-DIMENSIONAL PROCESSES

The stereocomparagraph and the Brock processes are two-dimensional methods which measure the parallax of the conic projection all in the horizontal plane and subsequently convert to the orthographic projection by differential enlargement.

Multiplex System.—Perhaps the most widely known of the three-dimensional processes is the multiplex system, which has been adopted by the U. S. Geological Survey, and by the U. S. Corps of Engineers. The photographs are reduced to a small glass diapositive about 2.25 in. square. This miniature, which is one fourth the original size, is then placed in a small projector. Its stereoscopic counterpart is placed in a second adjacent projector, and the two images are projected simultaneously on to a screen of adjustable height. On this screen the two images merge into a three-dimensional miniature of the ground. The two projections are made through complimentary colored filters, and the operator wears spectacles with a red and a blue glass, whereby each eye sees its separate image. Thus a stereoscopic effect is obtained. On the screen is a tiny illuminated dot, called the "floating mark," which rises and falls with the screen. The screen is carried by a stand, which can be pushed around over the table on which the map paper is placed. In the center of this stand is a pencil. The screen is elevated by a thumbscrew to a height representing a desired contour at the scale of the map (1:10,000, for example) and then the stand is pushed around under the direction of the observer, who causes it to move in such a fashion that the floating dot follows the undulating surface of the ground. This floating dot, moving parallel to the horizontal surface of the table, can only move in this one contour level. Thus the operator, by moving the dot continuously over the miniature surface of the ground, getting neither below it nor above it, causes the pencil to draw that particular contour. When this contour is completely drawn, the thumbscrew is turned and the screen and floating dot are raised to the next contour elevation. For example, if the contours are 20 ft apart, the screen and floating dot will be raised by the amount 20 ft ÷ 10,000 or 0.002 ft, which is 0.024 in. Planimetric details, such as roads and streams, are drawn by causing the floating dot to follow the stereoscopic image of these features, rising and falling with the feature by manipulating the thumbscrew.

There are several hundred multiplex units in the various mapping agencies of the United States government, and this system, by reason of its general familiarity, is unquestionably the most popular in the United States.

Stereoplanigraph.—Another three-dimensional method for stereoscopic contour mapping is the stereoplanigraph method,[2] which involves the same general type of stereoscopic pictures as all the other methods. The machine is by far the most elaborate of any of those described, and the most difficult to operate. Its compensating features are great speed and accuracy.

The stereoplanigraph uses a pair of glass diapositives the same size as the original photographs. As in the case of the multiplex, these two diapositives are placed in projectors, although the projectors are four times as large, and consequently four times as far apart. The image from these photographs is projected down on to mirrors, on which is the ubiquitous floating mark. Image and floating mark are observed through an enlarging optical system, by means of which the image appears from five to ten times its original size.

---

[2] "Stereo-Topographic Mapping," by C. H. Birdseye, *Transactions*, Am. Soc. C. E., Vol. 98 (1933), p. 771.

Contours are traced by an operator turning a pair of hand wheels—the left-hand wheel controlling the "X" motion, and the right-hand wheel controlling the "Y" motion. Elevation is changed by a foot wheel. Drawing is done on a separate table connected with the stereoplanigraph. This table has an X and a Y slide actuating a pencil, under the surveillance of an assistant. Thus the stereoplanigraph is a two-man machine, whereas all the others heretofore described are operated by only one person.

The stereoplanigraph method is similar, in function, to the multiplex, in that the complete operation performed on one plate pair consists of first making the stereoscopic model; that is, bringing the two pictures into perfect correspondence by tipping them and tilting them, and ultimately, by trial and error, returning them to the exact relative position they occupied in the air. In the Brock process this same thing is accomplished by the first step of making the diapositive, the position of which has been determined by calculation. Then, in the multiplex and stereoplanigraph operations, the pair is "horizontalized." This means that the two pictures which have been placed into perfect relative position are now set in their correct relationship to the horizontal reference plane. Then the next step in both the multiplex and stereoplanigraph operations is to draw all the detail on the map. The stereoplanigraph differs most widely from the multiplex at this stage of the proceedings. Whereas the multiplex operator is pushing his screen stand, or pencil stand, around over the map, causing it to draw, the stereoplanigraph operator is doing his drawing by turning a pair of hand wheels. It is the speed of this hand-wheel operation, the fine accuracy, and the optics of the stereoplanigraph, which are responsible for the much greater production per man-hour than can be achieved with any other type of machine. Production, per man-hour, with the stereoplanigraph, on comparative types of mapping, is from five to ten times faster than on the multiplex.

Comparison of Operating Costs

A comparison of the merits of the various systems described briefly herein involves, first, an understanding of some of the fundamental criteria used, in evaluating the work.

The most efficient system of mapping is that by which a given map made to a given degree of accuracy can be produced cheapest and fastest. The principal comparative items of cost in compiling a contour map by photogrammetric processes may be classified roughly as follows: (1) Amortization of the capital investment; (2) flying cost; (3) control cost; and (4) plotting cost.

Other items of cost, such as drafting and the routine editing, are more or less similar for all systems of mapping, and consequently do not constitute one of the bases of comparison.

(*1*) *Amortization of Cost.*—The stereocomparagraph costs about $300. The Brock equipment is not listed, only one unit of this equipment being in existence. The writer estimates that it might cost $25,000 or $30,000 to duplicate one of the Brock units. The multiplex costs about $10,000 a unit; and the stereoplanigraph costs about $45,000 per unit. Assuming that the equipment will be used for ten years, there is no amortization to be worried about on the stereocomparagraph; the multiplex must be written off at the rate of $1,000 per yr; the Brock equipment at the rate of about $2,500 per yr; and the stereoplanigraph at the rate of about $4,500 per yr. On the assumption that the equipment will be used only one shift (say, 2,000 hr per yr) the multiplex has an amortization charge of 50¢ per hr; the Brock equipment has an amortization charge of $1.25 per hr; and the stereoplanigraph an amortization charge of $2.25 per hr.

(*2*) *Flying.*—Since the stereocomparagraph is rarely, if ever, used for precision mapping, the remaining comparison will be confined to the other processes and instruments. For multiplex work, flying is generally undertaken at an elevation of from 700 to 1,100 times the permissible tolerance in the contours, as compared with 2,500 times for the stereoplanigraph. The net area covered per photograph can be compared on the following basis: The multiplex method covers the least area per photograph. Thus, if the multiplex covers 810 units of area per stereoscopic model to a given degree of accuracy, the stereoplanigraph method will cover 1,620 units of area. These figures can be clarified somewhat by stating that the multiplex, flying 1,000 times the permissible tolerance, uses a 6-in. lens covering a 9-in. by 9-in. photograph. The stereoplanigraph flies at 2,500 times the permissible tolerance, using a 6-in. lens on a 9-in. by 9-in. negative. The different systems also use a different overlap which is taken into consideration in the foregoing figures. The number of pictures required and the degree of control required will be in the following ratio: Stereoplanigraph 0.64 and multiplex 2.00.

The relative separation between the photographic strips will be 7.2 for the multiplex, as compared with 14.4 for the stereoplanigraph. The actual amount of flying to be done will be inversely proportional to these figures; in other words, the most flying must be done for the multiplex work.

(*3*) *Control.*—Although there is some difference of opinion among experts as to the most economical method to control a photogrammetric survey, the cost of doing the work for the different methods, according to the standard of any expert, will be substantially in the same proportion as the area covered per photograph. Control generally involves about four known points per stereoscopic pair. Since most of these points are common to a number of stereoscopic "models," the net by almost all systems will prove to be approximately one and one-half control points per picture. So, by almost any conceivable method of control, the relative cost will be approximately twice as much per unit of area for the multiplex method as for the stereoplanigraph method. (Note: It should be kept in mind that the writer is most familiar with the stereoplanigraph process. Much has been published on the multiplex process, and persons familiar with the multiplex system will have an opportunity to discuss this paper. Little has been published as to the cost of the Brock process, and it is hoped that someone thoroughly familiar with the Brock process will take this opportunity to present its case in the form of a discussion.)

(*4*) *Plotting the Map.*—The fact that a map can be plotted by stereoplanigraph from five to ten times as fast as by multiplex is due to many factors. First and foremost is the relative speed of the hand-wheel control as compared with the clumsy job of pushing the multiplex stand around by hand. Second, the time is affected by the greater area per stereoscopic model which is available to the stereoplanigraph, and consequently less time is needed in the preparatory setting up work, as it takes about as long to set up one model as another, regardless of scale or flying altitude. Another advantage of the stereoplanigraph is that it affords a means of enlargement between the picture scale and the plotting scale. Usually the map is drawn directly by the stereoplanigraph at a scale about six times larger than the original picture scale. The multiplex, on the other hand, is at a distinct disadvantage in that it first reduces the pictures to one-fourth size, and then has a limited range of enlargement due to the shallow depth of focus of the multiplex projectors. Therefore, it will be seen that, in plotting the same map, the multiplex operator actually will have to draw from two to three times the number of linear inches of contour that the stereoplanigraph operator will have to draw.

Although no data are available on the actual rate of drawing in the Brock stereoscope, the writer believes that the drawing is probably the slowest of any of the three methods. The Brock process does not permit the continuous drawing of a contour line, as do the other two processes. In the Brock process, the contour line must be drawn by short increments, the operator turning the hand wheels of the stereoscope and observing where the contour line goes for a short distance such as one-half inch, and then drawing that contour line by hand. Then he observes another half inch and draws that by hand.

There is another factor which enters the cost of the drawing by the three machines, however: Whereas the stereoplanigraph permits much faster drawing, it also can be operated only by a much higher type of personnel, the training period for efficient operators being about two years. One of the great advantages of the multiplex is that the method is simple and very apparent, and that reasonably alert operators can be trained in probably one quarter of the time that it would take to train them for the stereoplanigraph. In this respect the Brock process has an advantage over both other methods in that an ordinary topographical draftsman with good eyes can be taught to become a Brock operator in a comparatively short period of time—probably in one tenth the time that it would take to train a stereoplanigraph operator. The reason for this is that the Brock plates come to the operator with the tilt entirely eliminated, so that all the operator has to do is to set them in the machine and start to draw. On the other hand, both the stereoplanigraph and the multiplex operators must learn to set up the stereoscopic model and to horizontalize it—processes which take a considerable period of time to master. The stereoplanigraph must be set up with the greatest precision of any machine, because the pictures are taken at such very high altitudes and are observed under such high magnification. The optical qualities of the multiplex image are not nearly so good as those of the stereoplanigraph, and consequently the stereoscopic model cannot be established with the same degree of precision. Therefore the instrument can be set up more quickly and with less experience.

In summary, all three methods will produce an excellent map. The multiplex appears to be the least efficient from the standpoint of the flying and control required, and second in the time required to plot. The stereoplanigraph will actually permit plotting the map much faster per man-hour than the Brock process; but in so doing it utilizes a machine that has a high rate of amortization. It involves an operator and an assistant to run the machine, in comparison to a single lower-salaried operator on the Brock process. If the stereoplanigraph can be kept in use continually, so that the amortization charge is not a major factor, it is the most efficient method now known, by a considerable margin. However, if the machine is only to be used occasionally, it is conceivable that the Brock process, or even the multiplex, if the period of use compared with the total available period is small enough, might be more efficient, due to the amortization charges.

Comparison with Ground Methods

So far, this paper has considered only a comparison of the different photogrammetric methods. The subject could not be considered thoroughly covered without making some comparison between photogrammetric methods and the older and more conventional ground method—that is, the plane-table method—of drawing a contour map. There are undoubtedly many situations in which the plane table is more efficient than any photogrammetric method. Any very small area can be surveyed more economically by a plane table. The job is done completely and finished by the man in the field. With the photogrammetric method, it is necessary first to send an airplane to the area to be photographed. Subsequently control parties are sent out to establish ground control, and finally the data are put through a machine to produce the map. Just where this line of demarcation is between the efficiencies of the two, according to scale and number of acres, is difficult to determine. The smaller and farther away an area is from the flying base, the more relative efficiency favors the plane-table method.

As an hypothetical illustration, consider an area of four hundred acres right beside the flying field, to be done either by plane-table methods or by photogrammetric methods for a map scale of 1 in. = 200 ft, and 5-ft contours. If this area were rolling to mountainous, the photogrammetric method probably would only cost half as much as the plane-table method. On the other hand, if it were reasonably flat to rolling, and open, the costs would probably be about the same. Remove this same four hundred acres two hundred miles away from the flying field, and the costs by the two methods might be about the same. The cost of using the airplane will be perhaps $50 an hr, and five hours may be required to complete the job—providing the photographers record all the data correctly on the first attempt. Perhaps, also, an allowance of 50% should be made for possible re-takes, which would be 7½ hr, at $50 per hr. Thus, there is a charge of about $1 an acre for the flying, really before the work is started.

It may also be said that, in areas which are very flat with contours far apart, plane-table methods probably are more efficient than any photogrammetric method.

The plane-table method may be more efficient in the case of a road location which had already been substantially staked out; for example, for a strip of topography only 100 ft wide and 20 miles long. In this instance, the photogrammetric survey would cost almost as much as if the width of the strip to be mapped were the entire width that could be covered by a picture, which might be 2,000 ft or 3,000 ft. The plane-table operator can confine his cost to the actual width of 100 ft. Consequently, there are many cases where, in locational surveys, it will be found more economical to run a plane-table survey, or to cross section the location, than to make a contour map by photogrammetric methods. This is not universally true, however, as many circumstances, such as accessibility to the ground, etc., will often favor the photogrammetric method.

It can be stated definitely that for final determination of canal grades, where the fall of the canal must be confined to a few inches per mile, photogrammetric methods are of no avail except in the preliminary stages of the survey. The final location must be established by level.

SUMMARY

Today in the United States it is probable that nearly all topographic mapping is being done by photogrammetric methods. The U. S. Geological Survey is the only organization among many now engaged upon the federal mapping program that still utilizes the plane-table method to any extent. This organization operates what is probably the largest multiplex unit in the world, so that even within the Geological Survey a large percentage of the total work is being done by photogrammetric methods. Other federal organizations and private organizations under contract to the government use the photogrammetric methods almost exclusively.

During the cantonment construction program for World War II, when detailed contour maps were required in a great hurry, the photogrammetric method was not found wanting. The speed of photogrammetric mapping has proved a surprise to people unfamiliar with the methods, and the uniform accuracy of the results has made design from photogrammetric maps a pleasure to the engineer. Photogrammetric maps are being made with a guarantee that 90% of all points checked shall be within one-half contour interval of their true position. Photogrammetric maps have been made at scales ranging from 1 in. = 20 ft, with 1-ft and 2-ft contours, to scales of 1:62,500, with 100-ft contours.

Photogrammetry has finally arrived at the age of full maturity. Although the methods will unquestionably continue to improve from year to year, they are already thoroughly practicable, and afford a tool which will find continuing and increased acceptance at the hands of thoughtful engineers.

DISCUSSION

Raymond A. Hill,[3] M. Am. Soc. C. E.—Aerial mapping was a "child" of World War I; and, as described by the author, it has since grown to full stature even though most engineers have no appreciation of that fact. Those engaged in the photogrammetric field have suffered many disappointments because of the lack of interest shown by most engineers and because of the lack of understanding on the part of the few interested engineers. These disappointments should have been expected, however, because most engineers are not concerned with maps, and even those who use maps in their work often have no part in the preparation of maps. Hence, only a few engineers have had more than an academic interest in aerial surveys and photogrammetry, and it was not natural that all of them would turn from conventional methods and accept something which was new and untried. Furthermore, it must be confessed that even the small number of engineers who today rely greatly upon photogrammetry do so more because of faith in the result rather than because of understanding of a method that depends upon an optical illusion.

If a poll were taken of all members of the Society, the writer believes that a substantial number would be found to have no acquaintance with photogrammetry, that half of the membership would not distinguish between modern photogrammetry and aerial photography, and that half of the remainder would state that the same information could be obtained more cheaply and equally well by conventional ground methods. The author is thus to be commended for presenting, clearly and fairly, the distinction between the "child," aerial mapping, and the "adult," photogrammetry.

It is not likely that the majority of engineers will ever be interested more than academically in photogrammetry, any more than most engineers are concerned with developments in hydraulics, or in other specialties foreign to their own fields of endeavor. On the other hand, every engineer who uses maps should acquire an appreciation and understanding of both the advantages and the limitations of modern developments.

It should not be presumed from the statements of the author that aerial photography has been supplanted by photogrammetry. On the contrary, aerial photography probably has more applications to engineering problems than do the contour maps produced with a photogrammetric instrument. This is natural, because the relative positions of physical features and types of culture are generally more important than absolute elevations. Many illustrations may be cited: Changes along a shore line due to erosion or deposition; general routes for railroads, highways, and transmission lines; city planning, as distinguished from site planning; and general surveys, such as land and soil classifications, agricultural censuses, etc.

In most of the foregoing instances, the contact print from an aerial photograph presents, directly, more information than could be obtained by ground methods without excessive cost. When successive photographs are examined stereoscopically, the land form is clearly disclosed. The observer then has before him an accurate relief map on which is located every natural feature and all culture in the proper relationship.

---

[3] (Leeds, Hill, Barnard & Jewett), Los Angeles, Calif.

Too little attention has been given to the interpretation of aerial photographs. Those in the industry, by reason of their own familiarity, took it for granted that any one could read an aerial photograph, not appreciating the fact that familiar objects viewed horizontally become strange when seen vertically. It should have been recognized that people must be taught how to read maps, even though maps have been in use for thousands of years. It is only natural that most people should look upon aerial photographs as interesting pictures and not as maps, because they have not been taught to interpret the shades and shadows which take the place of conventional symbols on a map.

Assembly of contact prints of aerial photographs into a mosaic produces a map that is frequently of great value in spite of inherent distortions. The accuracy of a mosaic, of course, depends upon the degree of control and the extent to which each part is brought to a common scale. A rough mosaic is little more than a rephotograph of overlapping contact prints placed in approximate relation one to another. A matched mosaic presents a better picture in that, to the eye, it has the appearance of a single photograph. For many purposes such a mosaic is ample, because the engineer who uses the map, as distinguished from the engineer who prepares the map, is generally most concerned with the relative position of natural features and cultures. Such mosaics are particularly valuable in general planning. They have been used extensively in flood control studies, in rerouting highways, in locating industries, and for many other purposes where a bird's-eye view of large areas was helpful.

The development of the controlled mosaic and the precise mosaic was in response to the demands of those who made maps rather than to satisfy the needs of those who used maps. Most of the former think in terms of the accuracy of the survey for which they are responsible; and, hence, they are prone to demand comparable accuracy when aerial methods are used. Actually, the comparison should be on the basis of the finished and reproduced map. A ground survey may be made at an accuracy of 1:5,000, but no man can plot an observed distance on a map with one tenth of that accuracy. Furthermore, when a draftsman completes a map on tracing cloth, it is of little value until reproductions are made. Changes in humidity and temperature cause some distortion of the tracing even before prints are taken. Unless these prints are made entirely by a dry process, large distortions result; and, even under the best conditions, the map that is available to the user is neither true to scale nor free from distortion. It has been the writer's experience that a reproduction of a carefully made, matched mosaic can be used with confidence for almost all the purposes, excepting only elevations, for which any reproduction of any map at the same scale would be used.

Whenever either the absolute elevation or the relative elevation of features must be obtained from maps, the engineer responsible for the preparation of the map should ascertain whether photogrammetric methods should be used. As stated by the author, if the area is small, the answer is probably "no." Likewise, if the terrain to be mapped is open and relatively flat or if only a narrow strip of topography is needed, the answer is again "no." On the other hand, if a substantial area of broken terrain is to be mapped, the answer is probably "yes." In some cases, the nature of the cover will determine whether ground methods would be cheaper and faster or whether photogrammetric methods would be better. The writer could cite the case of one Army cantonment where the required contour map was prepared photogrammetrically because of the presence of a mantle of brush but where, otherwise, plane-table methods would have been more suitable.

In general, ground surveys, supplementing aerial photographs and matched mosaics, will usually be found most advantageous in the solution of specific engineering problems. On the other hand, photogrammetry will probably supplant ground surveys of large areas, and the future of photogrammetry is limited only by the extent of all the continents.

RAYMOND L. MOORE,[4] ESQ.—The multiplex "aero-projector" method is probably the most widely used of the three types of precision equipment described in the paper. The method is also the most recent addition to the field of photogrammetry although the spatial model was first constructed by dichromatic projection in 1858. Practical equipment for utilizing this principle in the production of topographic maps did not become available in the United States, however, until about 1935.

In general, the equipment of 1944 is similar to that of 1935, but vast improvements, both optical and mechanical, have been incorporated in later models. The most important change has been the result of improved lens design, not only in the projector unit but in the aerial camera itself, by increasing the effective field of coverage.

Early multiplex equipment was designed for aerial photography obtained with the multi-lens camera, of which the 9-lens tandem T-3A camera is probably the best known in the United States. Photography of this type necessitated two general projector designs—one for use with the vertical center chamber, and the other for use with oblique wing prints. Since distortion, displacement of images due to relief, and generally unsatisfactory quality were present in the oblique photographs, accurate mapping with these projectors was extremely difficult. The multi-lens camera is considered obsolete for general mapping purposes and it has been replaced by the so-called wide-angle, single-lens camera. This camera provides an effective field of coverage between 90° and 100°, depending upon the camera type; and the field of coverage for a single vertical photograph is about equal to the usable field of the older multi-lens cameras. Although most of the older normal-angle equipment is still being used, the newer wide-angle equipment is found in most multiplex mapping laboratories. This equipment makes possible aerial photography with most favorable base-altitude ratios—which results in greater contour accuracy and materially reduces the number of photographs required.

In comparing the relative merits of the different systems of photogrammetric plotting devices on a cost basis, it is necessary to examine the fields in which each system is used. Both the Brock equipment and the stereoplanigraph are suitable for the production of large-scale contour maps—a field in which the multiplex has not been used extensively. Sufficient mapping by both the Brock process and the stereoplanigraph has been published and tested to prove conclusively that exceedingly high standards of accuracy can be obtained. In this field the multiplex has not yet been used extensively enough to compete on a cost basis with the other methods.

Within the continental limits of the United States, more medium-scale mapping (that is, mapping on scales of 1:24,000 to 1:62,500) has been completed by multiplex than by either of the other two processes. Many factors have influenced the widespread acceptance of the multiplex method for this type of mapping. Multiplex maps have met rigid accuracy standards, and the comparatively low initial cost of equipment undoubtedly has been considered; but these factors alone do not entirely account for the popularity of the method. Availability of the equipment on the domestic market is a primary asset. Neither additional stereoplanigraphs, which are of foreign manufacture, nor Brock equipment, which was custom-built and not a standard commercial product, is available. Before the priorities of World War II made acquisition difficult, multiplex equipment was available to those organizations that had occasion to do topographic mapping and is the only precision plotting equipment that has been in actual production during the war.

The availability of photogrammetric operators has been a major problem of all agencies utilizing stereoscopic plotting equipment, since trained operators are not available and must be educated within the organization. As in all types of precision work, there are certain basic requisites of knowledge and aptitude that potential operators must possess. Only part of the people with this knowledge and aptitude will develop the acuity of vision necessary to become capable "photogrammetrists." Nevertheless, a larger percentage capable of operating the multiplex will be developed than would be developed if the training were on other types of equipment. If candidates are selected carefully, the average operator will be able to draw contours on oriented models after about three months; he will become a reasonably skilled "phototopographer" in six months; and he may be expected to do satisfactory extension work in nine months or one year.

Inherent in the multiplex method are operational features which are not provided (or are difficult to execute) by the other types of equipment, the most important of which is the capability to "phototriangulate" or "bridge" field control both vertically or horizontally. Secondly, and of considerable importance in military mapping, contour plotting may progress simultaneously on a large number of stereoscopic models for later assembly into the finished map.

The cost of field control is a primary consideration in the planning of any mapping operation and may well be the deciding factor in determining which method, or methods, should be utilized. In general, the amount of field control is decreased as the scale of the map is reduced and the contour interval increased. Thousands of square miles of mapping have been produced by the multiplex method since 1936 with a publication scale of 1:24,000 and an average contour interval of 20 ft. For this type of mapping horizontal control is generally placed along the 7.5-min quadrangle with boundaries normal to the direction of the flight lines. Horizontal control, for the orientation of interior models, is obtained by "bridging" this control without the necessity for additional horizontal field control, although for this scale and contour interval it is still accepted practice to obtain a limited amount of vertical control on each interior photographic pair. Much work has been completed during this same period on standard quadrangle maps published on a scale of 1:62,500, with contour intervals averaging about 50 ft. Control lines are placed along the 15-min quadrangle borders crossing the flight lines; and, because of the greater contour interval, little or no vertical field control is required on the intermediate models. In planning projects of this type, both vertical and horizontal control bands are placed about 15 miles apart. Between these control bands the multiplex bridge, or "phototriangulation," produces adjusted positions and elevations upon which the intermediate models for drawing the topography are oriented.

Military and civilian practice differs somewhat inasmuch as time is frequently the paramount consideration in any military mapping project; and, for this reason, methods are frequently used which do not necessarily produce maps in a minimum number of man-hours. More frequently, the problem is the production of a map in the absolute minimum lapsed time even though the number of man-hours may be excessive. To produce a maximum amount of work in the minimum over-all length of time, control bridge work is conducted independently of contour mapping by an organized bridging section. Only the highest types of operators are assigned to this section. In general, the same type of equipment is used as that used in the plotting section, except that the multiplex bars are longer. In an emergency, projectors normally used in bridging work may be diverted to contour plotting, provided a sufficient number of additional operators are available.

The multiplex has been used to a limited extent in the field of reconnaissance mapping with highly satisfactory results. A brief description of a project recently completed will illustrate the potentialities of the method in this field. The topography of an area approximately 500 miles long and 10 miles wide was required for publication on a scale of 1:250,000, with a contour interval of 100 ft. The need for this work was urgent; the area was inaccessible; and part of the route was over terrain probably never before traversed by white men. There were available, within the area, seven control points of known geographic position and a few elevations of somewhat doubtful quality. Some additional elevations were secured by prorating known or assumed river grades. The longest single multiplex bridge extended 285 miles, and a single horizontal control point was available on each of the terminal models. This bridge did not run in a straight line but traversed river valleys and high mountain passes. Aerial photographs for the project were taken in the middle of the winter with the sun never more than 5° above the horizon. Although the multiplex work was completed in a remarkably short time, subsequent field work has indicated that this map is surprisingly accurate.

Although it was designed for the production of topographic maps, numerous other uses have been found for the multiplex. By a rather simple method it has been used in the production of mosaics. With the multiplex bridge adjusted for horizontal scale, sufficient planimetry to fix the orientation of each photograph is drawn for transfer to the mosaic base. With dianegatives substituted for diapositives, projection prints can be made directly below the projectors. These prints are both adjusted as to scale ratios and horizontalized; and they may be pasted down in the normal manner.

Unfortunately, many topographic maps are actually obsolete before they are published; and, to preserve their maximum usefulness, frequent revision of cultural detail may be necessary. This revision work will be a major mapping problem in some localities. For example, in California, several areas were mapped very accurately as recently as 1925. Because of development, cultural details in some of these areas have changed to such an extent that, without revision, an entirely erroneous picture of the terrain is presented. The work in some of these areas has been revised easily, and with utmost accuracy, by the multiplex method. After the war a large amount of map revision will be required where wartime activities have caused major cultural changes.

With large areas of the United States still unmapped, there is ample work to keep all types of plotting equipment in use for some years. It is obvious that, in particular instances, certain types of equipment are preferable to others. For some time after the war the popularity of the multiplex method will probably continue, if for no other reason than the availability of equipment and operators. In the field of large-scale mapping the method remains to be proved. It may be found that large-scale work by the multiplex method will be less economical in the long run and that this particular type of work should be left for instruments of greater precision. In the intermediate-scale field—which includes most of the mapping to be done in the continental United States—there is ample proof that the multiplex method can compete with other methods, both in economy and accuracy. Economy in field costs is possible because, unlike the other methods, the multiplex does not require survey control on every stereoscopic model. When contour intervals of 50 ft or more are used, costs of aerial photography will be the same for the multiplex as for the stereoplanigraph, inasmuch as photographs for both methods will be taken close to the service ceiling of the aircraft employed, and this ceiling will be the deciding factor in determining the number of models and the unit area covered by each model.

A discussion of existing photogrammetric plotting devices should not be concluded without some mention of the K.E.K. Plotter (named for J. E. King, J. W. Elliott, and P. B. Kail) being used by the United States Forestry Service in the production of standard quadrangle maps in some parts of California. This plotter was developed by personnel of the Forestry Service and might be considered a much-refined and enlarged stereocomparagraph in which certain of the most undesirable characteristics have been eliminated. The principal improvements incorporated in the K.E.K. Plotter are: (1) An arrangement by which contours are drawn to correct orthographic scale, rather than on the conic projection (which is one of the principal disadvantages of the stereocomparagraph); and (2) a system of restitution by an appropriate inclination of the contact prints with respect to the operator's point of view. As with other devices, except the multiplex, vertical control is required on each model. Little information is available as to the amount of horizontal control necessary, but it is probably about the same as that required for the other processes. Comparatively low initial cost and portability may make the K.E.K. Plotter a most valuable instrument for some types of work.

Ralph S. Pearse,[5] Jun. Am. Soc. C. E.—It is gratifying to find a paper on photogrammetry in the publications of the Society, since engineers are relying more and more on accurate, complete maps. Two additional methods should be included in this discussion. For example, the K.E.K. Plotter is an improved form of the stereocomparagraph incorporating the third dimension, together with an accurate means of correcting the photographs for tilt. A pair of contact prints are oriented and corrected for any tilt, the resulting model then being viewed through a stereoscope. A lens with a small dot in the center is suspended under each eyepiece of the stereoscope between it and the image. These dots fuse to form a floating mark with which the operator traces planimetric detail and contours. The pair of photo-tables on which the photos are fastened are raised or lowered, according to a varying scale, to compensate for the conic projection, thus allowing the floating mark to trace the contours directly to scale. The floating mark is connected to a pencil or pantograph which permits drawing the detail on to the map. A considerable amount of control is required for this method, at least two horizontal and four vertical points being needed for each pair of photographs. An accurate map may be obtained and the instrument may be moved easily from place to place. The cost of the K.E.K. Plotter is several hundred dollars—considerably less than that of either the multiplex or the stereoplanigraph.

The aerocartograph is an instrument quite similar to the stereoplanigraph, incorporating a similar optical-mechanical system for obtaining map detail from glass diapositives. There are three in the United States, but they are not much used. The advantages and disadvantages of this method over the other methods are similar to those of the stereoplanigraph.

Several items concerning the comparative economy of the multiplex and stereoplanigraph methods should be mentioned. The cost of $10,000 for one multiplex unit is extremely high, $5,000 or $6,000 being more nearly correct. In many instances, it has become the practice to equip one unit for bridging (described more fully in a later paragraph) and to streamline four or more units, thus reducing the cost of an average unit to $3,000 or $4,000.

The flying costs will be greater for the multiplex than for the stereoplanigraph because of the lower flying height, which necessitates more pictures and more flying to cover a given area. However, the cost of the flying, especially for extensive areas, is a minor item in the total cost of the finished map. With an increase in flying height, some detail is very likely to be sacrificed regardless of the magnification of the pictures in the plotting machine. In many instances, the detail thus lost is of minor importance or of no value at all. However, at other times this detail is of major importance, outweighing the cost of extra control and flying.

---

[5] Photogrammetric Engr., U. S. Geological Survey, Arlington Va.

The multiplex adapts itself to bridging over an area of several consecutive models, since a number of stereoscopic models can be set up simultaneously. Thus, considerable horizontal control is eliminated. The stereoplanigraph can accomplish the same result if an adjacent model is set up on the established control, which is a system of "pass points." However, as the stereoplanigraph can accommodate only one stereoscopic pair at a time, a number of single models, requiring considerable time and repetition, must be set up and oriented.

The multiplex tracing table, or stand, is far from clumsy. Sliding on quartz feet, it moves smoothly and easily, being limited in speed only by the skill of the operator. Although the multiplex may require more models, the time of operation represents only from about 5% to 8% of the total time consumed. The increased flying height at which the pictures for the stereoplanigraph are taken necessitates a much more precise setup of the model to obtain the desired accuracy. With the multiplex, the average operator can place the floating mark in the model on the ground to an accuracy of ±0.05 mm which, at a scale of 1:10,000, represents about 3 ft. Assuming the contour interval to be 20 ft, this is well within the accuracy of 90% of the contours in one half of an interval. In setting up a model in the stereoplanigraph, the floating mark would have to be set accurately to ±0.025 mm—a very limited tolerance.

One distinct advantage of the multiplex is that the operator is working directly over the map and with a flip of a switch can see what he has drawn, whereas the stereoplanigraph requires an assistant whose job is to observe the actual drawing, the operator not being in a position to view his work readily. Although the multiplex system can be used by somewhat less skilled personnel with less training, it has proved highly desirable to utilize only the higher type of personnel—preferably operators with a working knowledge of topographic features. The stereoplanigraph has an advantage over the multiplex in that it can accommodate a wide range of scales from a given pair of photographs, whereas the range of the multiplex is very limited, the flight height depending on the scale and contour interval desired.

Two factors that have a tremendous bearing on the comparison of the two methods—photogrammetric versus ground—are the extent of the area and the scale. The multiplex is adaptable to scales from 1:2,500 to 1:24,000; the stereoplanigraph has a slightly wider range; and neither of them is as economical for small areas as for large areas—say, 60 sq miles or greater. Flying, sending control parties into the field, etc., to map only a few square miles by the multiplex or other photogrammetric method are not economical procedures under present conditions as compared with field or ground methods. In numerous instances, a planimetric base map has been prepared by the multiplex method and assigned to a field party for addition of the contours, especially in flat areas.

Another factor that is important in comparing the economies of the multiplex with those of the stereoplanigraph is the photographic laboratory and its skilled personnel. In connection with a large or medium sized multiplex organization, a complete photographic laboratory is maintained under the supervision of a highly trained laboratory photographer with several assistants. Since there is only one stereoplanigraph in the United States and since there is little likelihood of ever having many assembled in one place, it would appear that either economy or the advantage of a highly skilled photographer would have to be sacrificed unless photographic work of a similar nature were available to occupy part of the photographer's time.

To summarize: For small areas up to several square miles the ground method should be far more economical. In flat areas either the ground method or a combination of ground and photogrammetric methods should prove most satisfactory. Over extended areas, especially where the terrain does not permit easy access by foot, the photogrammetric method should be superior and more economical. As to which is the most suitable photogrammetric method, one must take into consideration the conditions pertaining to each particular assignment. The tremendous first cost of obtaining equipment, plus the training of personnel, must be considered along with the type and extent of mapping to be done before the most economical method can be ascertained. For example, the U. S. Geological Survey is engaged in a continuous and extensive mapping program where expensive equipment and trained personnel will be utilized over a long period of time; thus, the multiplex method combined with ground methods has proved the most economical. On the other hand, for a private company interested in a small local area on a job of short duration, the ground method, the stereocomparagraph, or the K.E.K. Plotter should prove more economical.

George D. Whitmore,[6] M. Am. Soc. C. E.—This discussion of Mr. Eliel's excellent and comprehensive paper is limited to that part which deals with comparisons and relations between contour mapping by photogrammetric methods and by ground-survey methods.

Mr. Eliel's explanations may leave an impression, with those who are not professional mappers, that a modern contour map may be completely and finally compiled by stereoscopic plotting instruments, without recourse to any follow-up ground surveys. The topographic mapping program of the Tennessee Valley Authority, directed by its Maps and Surveys Division, has included standard contour maps prepared by all three of the principal processes Mr. Eliel describes—that is, (1) multiples, (2) stereoplanigraph, and (3) Brock and Weymouth. This experience makes it seem virtually mandatory that all contour maps compiled by stereophotogrammetric processes be field inspected and field checked. Otherwise, there is no positive assurance that the map as drawn in the photogrammetric laboratory does correctly represent the terrain, and unless certain field checks are made as to contour accuracy, there can never be any real assurance that the stereoscopically compiled contours are accurate within specifications. Thus, it would seem proper to state that, except in emergencies or other rare occasions, the photogrammetric mapping procedures should always provide for the follow-up field inspection and field checking. Accuracy checks are often obtained by random transit and vertical-angle profiles, by numerous side "shots" from a few well-selected plane-table setups, and by other means.

---

[6] Prin. Civ. Engr., Maps and Surveys Div., TVA, Chattanooga, Tenn.

Incidentally, the field engineers who are responsible for field inspecting and field checking operations, commonly called field completion, require as much training and skill as do plane-table topographers. Hence, the skilled topographers, who at one time may have thought that photogrammetry would force them "out of business," instead will probably be more in demand, and for work that should be more interesting.

Another matter not mentioned by Mr. Eliel, but obvious to most experienced mappers, is that probably in most cases a combination, in some degree or other, of photogrammetric contouring and ground-survey contouring will be best. For example, most map sheets will include certain flat or relatively flat areas. It is well known to experienced photogrammetrists that, with present equipment, these flat areas quite often present a difficult problem—that is, it is relatively more difficult to obtain satisfactory contours in flat areas than in rugged terrain by stereophotogrammetric instruments (unless special lower-altitude photographs are provided for those areas). On the other hand, such areas are usually most important economically and, therefore, extra precautions should be taken to make sure that the contours in such areas are relatively more exact. Fortunately, in this case, what is difficult for the stereoscopic plotting instruments is easy for the plane-table topographer. Therefore, many experienced mappers today choose this combination method—that is, the "rolling to steep" terrain to be contoured by the stereoscopic plotting instruments; the flat terrain to be contoured by plane table, usually during the later field inspection and field checking processes.

Another well-known combination of photogrammetric and ground-survey methods that has proved efficient on large projects is that of first preparing a detailed planimetric manuscript base sheet by stereophotogrammetry, on which all contours and elevations are later added in the field by plane-table topographers. After the planimetric base sheet is completed in the laboratory, it is usually reduced photographically to the field scale, the topographer being furnished a blue-line print on drawing paper mounted on aluminum or other scale-holding material. This eliminates the need for long plane-table traverses, and usually results in more accurate planimetry with respect to horizontal position. Of course, it is especially advantageous and economical in flat or gently rolling terrain, and where contour intervals of 10 ft or less are required.

Mr. Eliel did not mention the difficulty of obtaining accurate contours through heavily wooded areas by photogrammetric processes. Densely wooded terrain represents one of the unsolved problems of photogrammetric contour mapping. If the pictures are taken during summer, with the trees tall and closely spaced, and the ground surface irregular beneath the trees, it is extremely difficult for the photogrammetrist to compile standard accuracy contours. He can do better if the pictures are taken during the winter, when the leaves are off the trees, and when snow is not too deep on the ground. Obviously, however, it will be a difficult matter to schedule extensive flying in northern latitudes for satisfactory winter pictures, because of the predominance of cloudy weather during the winter season, because the flying days are short and the shadows long, and because of risk of deep snow. Also, regardless of latitude, an evergreen forest photographs no better in winter than in summer. Unfortunately, ground-survey plane-table methods are also at a disadvantage in mapping contours in wooded areas. It is true that any desired degree of accuracy can be obtained by ground-survey methods, but the costs accelerate rapidly. The development of a procedure for obtaining accurate contours in densely wooded terrain is the real challenge to photogrammetry today.

BENJAMIN A. WASIL,[7] JUN. AM. SOC. C. E.—The problems of present-day photogrammetric economics are presented admirably in this paper, which affords an opportunity to look into the future—into postwar mapping—and to appraise the war mapping program as it applies to the future possibilities of making a cheaper map having the same standards of accuracy.

The cost of field control is a major portion of the total cost of a map. Any reduction in field control necessarily would mean a reduction in the accuracy of the map. However, if an office method can be substituted in establishing a part of the control and still maintain the same standards of accuracy, the cost of the map would be lowered. Two office methods now used to establish secondary control are "multiplex bridging" and "radial plotting." Operators of the multiplex do not try to bridge more than twelve photographs. By radial plotting one can do better if perfectly vertical photographs are available. The basic principle to multiplex bridging and radial plotting is the same. The multiplex is an optical method involving three dimensions. Radial plotting is a mechanical method involving two dimensions; the third dimension of relief is projected orthographically on to the plane of the photograph. An advantage of the multiplex is that, in bridging forward, the entire overlap can be seen at once and it is as if an infinite number of pass points were used. However, the greatest advantage of multiplex bridging, as against radial plotting, is that it permits the elimination of tilt. Disadvantages of multiplex bridging are: (1) The final images as viewed have passed through three sets of lenses—the aerial camera lens, the diapositive camera lens, and the multiplex projector lens; and (2) only one flight can be scanned at a time.

In radial plotting, as many adjoining flights can be used as the operator can handle. Adjoining flights help to tighten up the network of secondary control. However, the always present accidental tilt of vertical photographs limits the work of radial plotting.

If the accidental tilt of the photograph were known, it would be possible to use a rectified photograph in the radial plot with the radial center as the nadir point. This would increase the accuracy and span of the radial plot manyfold. The usual methods of determining the tilt of a nearly vertical photograph require at least three ground-control points to each photograph. The necessity for this ground control defeats the purpose of expanding secondary control. However, there is a method of determining the tilt of a nearly vertical photograph without the aid of ground control. The answer is "tri-metrogon photography."

---

[7] Asst. Civ. Engr., TVA, Chattanooga, Tenn.

Tri-metrogon photography presently will be used for reconnaissance mapping. It is used in construction of planimetric maps of scales of from 1 : 250,000 to 1 : 1,000,000. Tri-metrogon system consists of exposures made with three cameras, one camera facing vertically downward and two cameras turned away from the vertical, facing perpendicular to the line of flight. The oblique cameras are faced so that the horizon and a small portion of the vertical are photographed. All three cameras are exposed simultaneously, photographing a strip of ground from horizon to horizon perpendicular to the line of flight.

Inasmuch as all three pictures of a tri-metrogon series are taken from the same photo station they have the same nadir point. The tilt and thus the nadir point can be determined from the oblique photographs because the horizon is visible. By a simple raying-in process the nadir point can be determined on the vertical photograph. A check is possible inasmuch as two independent determinations of the nadir point can be made from the two obliques. The nadir point of the central photograph having been determined, the tilt can be found easily and the photograph rectified.

Therefore, by taking oblique photographs, together with the verticals just for the purpose of determining the tilt of the vertical, the operator can determine the degree of tilt without ground control. The flying should be done in the usual manner, with the vertical flights overlapping 40%. The additional cost of photography is negligible. Flying cost, in a mapping project, is a small part of the total cost, and it is just as easy to take three pictures at one time as it is to take one. The additional cost of films, processing, and amortization of two added cameras will be slight. Of course, there is the added cost of constructing the radial plot, but this will be greatly overbalanced by the saving in the cost of the horizontal field control that can be eliminated. Another saving would be in the elimination of scaling in the multiplex work, for the radial plot will establish many secondary control points to each model. It may also mean a greater use of the K.E.K. Plotter, a cheaper apparatus that requires control on each model.

Charles H. Davey,[8] Esq.—Mr. Eliel's interesting technical paper is timely and should serve to focus attention on a development in the engineering and scientific field which, from day to day, is finding wider application. In general, the presentation can be accepted without debate, although in detail it is believed that the author's extended knowledge of the stereoplanigraph method has resulted in conclusions that cannot be fully accepted by those who are thoroughly familiar with other methods.

The stereoplanigraph is acknowledged widely among photogrammatrists to be a versatile and probably the most accurate plotting instrument yet devised. It can be accepted as a standard of comparison, if the comparisons are restricted to demonstrated values. Some of the author's statements bear the implication of demonstrated facts, whereas, actually, they partake more of the nature of personal opinions or theoretical considerations that differ materially from practical applications. For instance, under "Comparison of Operation Costs," item (2), citing the relative flying altitude required for each method, in much of the country that is best adapted for mapping by photogrammetric methods and for contour intervals of 50 ft or more, both methods require photographs taken at altitudes that exceed the practical operating ceiling of commercially available planes and here the theoretical advantage of the stereoplanigraph over the multiplex method disappears at once. It is here that one outstanding advantage of the multiplex method comes into play as it is possible to set up, at one time, a complete stereoscopic model of a strip exceeding 30 miles in length, at a scale of 4 in. equals 1 mile, and adjust this model to horizontal control as a unit. This is an advantage possessed by no other method and, in practical application, it upsets much of the theoretical advantage as to control required, cited by Mr. Eliel, for the stereoplanigraph.

---

[8] Chf., Section of Photo-Mapping, Geological Survey, U. S. Dept. of the Interior, Washington, D. C.

In item (4), "Plotting the Map," Mr. Eliel states as a fact that a map can be plotted by stereoplanigraph from five to ten times as fast as by multiplex. He has not demonstrated this statement by any logic and it is extremely doubtful if any impartial test has been made under comparable conditions from which a factual comparison could be made. It is most debatable if impartial observers would concede the argument that it is easier and faster to perform the drawing of a map by controlling one's motions through the use of hand wheels operating in the X-direction and Y-direction than to control them directly by moving the plotting pencil at will. It is further stated in the same paragraph that the multiplex operator will have to draw from two to three times the number of linear inches of contour that the stereoplanigraph operator will have to draw. The writer is not too familiar with operations of the stereoplanigraph, but using Mr. Eliel's data the comparison is about as follows under the comparable condition of mapping with a 20-ft contour interval: The scale of the photographs would be approximately 1 : 27,000 for the multiplex and 1 : 50,000 for the stereoplanigraph; the stereoscopic model would be viewed at a scale of 1 : 10,000 for the multiplex and 1 : 5,000 or 1 : 10,000 for the stereoplanigraph; and the map would be drawn at a scale of 1 : 10,000 and 1 : 8,330, respectively. Thus it would appear that the drawing by the multiplex is less than by the stereoplanigraph. The critical point to consider is that the stereoscopic model is scanned by the operator at the same scale in both instances and for work performed with the same care and attention to detail there appears to be little advantage of one method over the other aside from the admitted advantage of the better optical model which is present in the stereoplanigraph.

It is regretted that definite costs are not available for a careful analysis and comparison of the two methods, for it is the opinion of the writer that each method would be found to have its own particular sphere, where it would operate to best advantage, with perhaps a broad middle ground where there would be little choice between the two. It follows, therefore, that in any extensive project it would be most advantageous to have both types of equipment available.

Mr. Eliel may convey a slightly misleading picture in his statement in the "Summary": "Today in the United States it is probable that nearly all topographic mapping is being done by photogrammetric methods." It is true that photogrammetric methods have a part in nearly all mapping operations at present and in most cases play a major rôle; but the plane table is by no means obsolete. The Geological Survey has maintained an open mind regarding the relative merits of the plane table and photogrammetric methods and it is believed that, for most economical operation, the best features of both methods should be utilized as conditions dictate, either singly or in combination. It has been demonstrated amply that there are extensive areas in the United States where at the present stage of the art photogrammetry alone cannot compete successfully with the plane table used in combination with photogrammetry.

ROBERT H. RANDALL,[9] M. AM. SOC. C. E.—Mr. Eliel's paper fills a very real need. His clear description of the principal photogrammetric methods used in United States mapping operations is of value not only to the engineering profession as map makers—for most of the practicing photogrammetrists are engineers—but also to those in the profession who are users of maps.

Although Mr. Eliel's paper is valuable as a clear description of photogrammetric processes, its principal contribution is in the comparative analysis it affords of the economy of these different procedures. The author's conclusions are presented as the result of analyses based upon comparison of the innate characteristics of the various types of equipment, supplemented and reinforced by a wide acquaintance with the various methods in actual practice. For those who, like him, are concerned with the progress of photogrammetry, it may be interesting to note that there is a large and growing volume of cost information by which the economy of the various procedures used, now or in the future, can also be gaged.

All topographic quadrangle mapping now done by or for the United States Government is done to standard specifications. (Mr. Eliel summarizes these specifications, in respect to vertical accuracy, when he states that 90% of the elevations tested must be correct within one half the contour interval.) Further, federal topographic mapping is tested for compliance with specifications, and any federal agency producing and testing such a map is entitled to certify its accuracy by the following statement printed in the margin of the reproduced copy: "This map complies with the national standard map accuracy requirements."

Federal map-making agencies keep cost and performance records of the principal operations involved in topographic mapping, according to a uniform system which they devised jointly at the suggestion of the Bureau of the

---

[9] Chf. Examiner, U. S. Bureau of the Budget, Washington, D. C.

Budget. Records of work done by contract for federal agencies (as, for instance, the so-called strategic mapping program financed by the War Department but actually performed by five federal mapping agencies and by commercial contractors as well) are also available.

From records such as the foregoing the effectiveness of various photogrammetric methods and combinations of methods may be appraised. In addition to information on work done by the stereoplanigraph, multiplex, and Brock systems, information is accumulating in respect to work done by other methods. Among these may be mentioned the Forest Service method, which employs the K.E.K. Plotter; the stereoscopic plotting equipment of the Coast and Geodetic Survey, which employs photographs taken by a 9-lens camera; and, of course, combination methods involving the use of aerial photographs and plane-table operations.

Mr. Eliel's closing remarks, to the effect that photogrammetry has reached the age of full maturity, are very much to the point. Perhaps it could also be said that photogrammetry, in its present stage, is like a man in the full possession of his powers who is fortunate enough to be situated in virgin territory, with all the opportunities of pioneer enterprise before him; for, although photogrammetry has unquestionably "arrived," further developments are sure to increase its potentialities. New opportunities for its use are constantly arising, and new and improved equipment is being tested. In the matter of control, for example, radar, or some procedure related to it, may greatly improve and cheapen the process of locating the plane at the instant a photograph is being taken; or, to some degree, radar may replace present methods of locating ground points.

W. J. Ryan,[10] M. Am. Soc. C. E.—The difficulties involved in mapping heavily wooded areas are worthy of note in any discussion of photogrammetry. These difficulties are much more serious in the Pacific Northwest than in other parts of the United States. The Corps of Engineers, U. S. Army, has mapped a large part of the Pacific Coast area on the scale of 1 : 62,500 with 100-ft contours. Although these maps have great value, they are not entirely dependable because the actual position of the ground cannot be determined through a cover of dense coniferous forest. The method most generally used is: First, mapping the tree tops and then correcting for the height of the timber (which may vary from 25 ft to 250 ft, resulting in large errors).

Photogrammetric mapping is also under a heavy handicap because of the small number of suitable flying days. Forests are frequently covered with smoke during the late summer and fall, and the days or hours of bright weather during the spring are limited. In the latitude of Oregon and Washington the winter months do not provide satisfactory light.

Heavy forest areas also make suitable ground control difficult. In many cases, it is impossible to identify picture points without artificial marking, which sometimes involves climbing and topping trees. Some controls have been established by building towers of trees topped 100 ft or more from the ground. These factors make aerial mapping less satisfactory, because they may delay a project a full year beyond the planned time for completion.

---

[10] Chf. Engr., Weyerhaeuser Timber Co., Tacoma, Wash.

If a map is to be of practical value to the logging industry, it must necessarily have the section corner positions as established by the General Land Office (GLO). The proper location of these corners on the map is one of the most difficult factors in mapping. The original surveys were frequently made with little care, and the accepted plat often does not represent the position of the corners on the ground. For commercial use, a map with a scale of anything less than 1 in. equals 400 ft is more valuable for representing the positions of the section corners with relation to geographical points than for providing extreme accuracy in the actual distances on the map. It has been found possible to place section corners on these aerial maps on the basis of the information available from ground surveys and from stream crossings shown on the GLO plat, thus preparing maps of value for reconnaissance work. Such maps must give the drainage and the shape of the terrain, but extreme accuracy in elevation or position are not necessary. The specifications for such work could be much less rigid than those adopted as a standard by mapping agencies of the U. S. Government, if methods were offered for doing the work more rapidly and economically. The U. S. Geological Survey is using a combination of aerial and ground methods that seems to be the most practical answer to the problem if federal requirements for map accuracy are to be maintained. This process is slow and expensive.

If the vast area still unmapped could be covered by another system, and if maps could be made available for this generation instead of the next, it would be a genuine economic accomplishment.

In forest surveys, the preparation of mosaics seldom seems worth the effort, as individual pictures, properly indexed on a planimetric map, are usually more serviceable. For any larger scale than that used for a purely reconnaissance map, the study of the individual prints through a stereoscope is frequently more satisfactory than the contour map that can be made in a heavily timbered area.

In the case of actual working maps for locating roads, railroads, logging plans, and forestry developments, it is still necessary to use ground methods. The writer has found that contour maps made by the strip method, using a slope level and chain, are more dependable and more economical than maps made by the use of plane table. On a scale of 400 ft to the inch with 10-ft to 25-ft contours, such maps cost as much as one dollar per acre. When photogrammetry can develop a method for making such maps, it should be economically advantageous.

In spite of difficulties, there is still a large field for aerial photography in the logging industry. Possibilities of distinguishing the type and conditions of the forest through photographs are unlimited and the further development of color and filters will add to the value of these studies.

The author has stressed the relative value of the various types of equipment, thus clarifying the possibilities that are available to the engineer. Consideration of the subject from the viewpoint of cost is commendable, and further reports are needed to define the relationship between cost and accuracy before any economic procedure for a project can be established.

Oliver S. Reading,[11] M. Am. Soc. C.E.—An excellent description of present photogrammetric practices and of their varied applications and limitations is presented in this paper. Comparisons of the relative economy or efficiency of the different instruments and combinations of methods emphasize the great flexibility of photogrammetry. As Mr. Eliel has shown, excellent work may be done by almost any combination of methods.

Many factors in addition to the methods described in the paper cause wide variations in efficiency. The character of the terrain, size and location of project, skill of personnel, quality of photographs—any of these factors are capable of causing a greater range in cost than the variation in efficiency of the methods used. Although many of these factors will average out as cost data are accumulated for a very large number of projects, fully adequate data for determining costs are not yet available. To the present time most photogrammetric work has been so sporadic and subject to such fluctuation of funds and to such urgency for production regardless of cost, training, or skill when funds have been available, that present cost data probably are misleading.

Arguments based on theoretical considerations are likely to err both from lack of consideration of factors which may have been unimportant on projects with which the individual is familiar, and from differences in evaluation resulting from special conditions that may prevail in certain organizations. Thus, the factor of smaller scale and larger area in air photographs is limited by the ceiling of the aircraft and the resolution of the lenses and photographic materials available. The ratio of control cost to number of photographs is important, but this argument favors extrawide-angle, or multi-lens photographs requiring different instruments. Also, where many roads and adequate breakdown of geodetic control exist, the cost of supplemental control may become a minor consideration. Again, if it were easier and faster to trace, accurately, the lines of a map by the manipulation of wheels moving the tool in the X-direction with one hand and in the Y-direction with the other hand than to guide the tool directly by hand, probably the wheel drives would be widely used for engraving. However, more information on this question will be available soon from a direct comparison of two plotting machines under construction in the photogrammetric office of the United States Coast and Geodetic Survey. One of the machines will use direct motion of the hand, accompanied by motion of the head in tracing the lines of the map; and the other will drive the tracing point by an X-handwheel and a Y-handwheel, while the operator's head remains stationary as with the stereoplanigraph.

Until recently there has been but one stereoplanigraph in the United States, and it has been operated much of the time by a man who admittedly has exceptionally acute stereoscopic vision and skill as an operator. The capture and importation of several stereoplanigraphs from Germany to the United States will allow a direct comparison in the same office, on the same projects, of the different machines and methods. Thus, much more reliable data should be obtained on the most economical field of application for each instrument or combination. Such direct comparisons of the stereoplanigraph, wide-angle multiplex, and 9-lens stereoplotters are contemplated in the Division of Photogrammetry of the U. S. Coast and Geodetic Survey during 1946 and 1947. Other organizations also will doubtless make direct comparisons.

---

[11] Chf., Research Section, Div. of Photogrammetry, U. S. Coast and Geodetic Survey, Washington, D.C.

Incidentally, recent surveys indicate that multi-lens cameras and equipment are more efficient than the 95° single-lens equipment for many projects. Multi-lens photographs are far from obsolete, although possibly further development of extrawide-angle lenses with admitted distortion in the air photograph corrected in subsequent printing, or of lenses using spherical focal surfaces may lessen the advantages of multi-lens cameras.

Certainly, photogrammetry has arrived at maturity in that no sizable mapping project can be executed with maximum efficiency unless some use is made of photographic surveys; yet those who are concerned with improving the efficiency and usefulness of photogrammetry are eagerly trying so many promising ideas (new lenses, camera stabilization, simpler plotters, color film, and radar control) that the economics of photogrammetry will surely require frequent discussion in the future.

Leon T. Eliel,[12] Esq.—It is very gratifying to the writer that his paper provoked so much excellent and constructive discussion. He is especially grateful that all the discussion on such a controversial subject has been presented with great temperance and restraint.

The twelve stereoplanigraphs captured from Germany should yield some fine comparative data between the different photogrammetric systems, as suggested by Mr. Reading. It is to be hoped that they will actually produce very efficiently—which objective certainly transcends, in importance, all academic considerations.

Among the discussions were six by map makers and two by map users. The latter, by Messrs. Hill and Ryan, have been especially constructive. Mr. Hill's remarks are of special importance to users who are less interested in how aerial photography is done, than they are in what it can do.

Mr. Ryan has given a thoughtful and thorough analysis of the application of photogrammetric methods to the problems of the forest engineer. The difficulties of control, inability to see the ground through the trees, and the problems of weather apply almost universally, as well as to forest problems.

Frequent reference has been made to the advantage the multiplex enjoys in "bridging" and thus minimizing control. Reports presented to the American Society of Photogrammetry show that the Germans (who invented and use both the stereoplanigraph and the multiplex) when under the pressure of war preferred the stereoplanigraph to the multiplex for bridging, using the multiplex to fill in the details.

---

[12] Vice-Pres., Fairchild Aerial Surveys, Inc., Los Angeles, Calif.

The multiplex gives about half the vertical accuracy obtainable from the stereoplanigraph when the flight altitude is the same. For comparable accuracy, in other words, multiplex pictures are taken from half the height required for stereoplanigraph flying. In the bridging method, the accuracy is found to be somewhat less than if control had been available for each model. Assuming that a "bridge" of a certain length gives half the accuracy obtainable from control in every model, the altitude for stereoplanigraph flying and a "bridged" multiplex series would be 4 to 1. Thus, the stereoplanigraph area per model, compared to the "bridged" multiplex area per model, at comparable vertical accuracy, might be 16 to 1.

In this hypothetical case, bridging causes such a sacrifice in flight altitude that the "bridge" would have to be sixteen models long to have the same control economy as the stereoplanigraph with control in each model. Whether the bridge involves sixteen models, or some greater or smaller number, it is apparent that there is a diminishing return that may actually prove that the stereoplanigraph requires less control. Add the inefficiency of handling all the additional models required with the lower flight altitude and the "bridging" argument can readily "boomerang" in favor of the stereoplanigraph.

Probably W. Schermerhorn of the Dutch University at Delft, Holland, and Prime Minister of Holland, has conducted more research on bridging than any one. He concluded that, if bridging must be done, the stereoplanigraph was better for the purpose than the multiplex. He operated both instruments, as well as many others, very extensively. Of course, his experiments were with the Zeiss narrow-angle multiplex which Americans who have used both consider inferior to the Bausch and Lomb's wide-angle instrument.

The writer sees little justification for bridging as an economy measure. Only under war conditions or when the terrain is inaccessible because of natural conditions does there seem to be a clean-cut case for bridging; and, if bridging must be done, many authorities prefer the stereoplanigraph to the multiplex.

Little information was available on the K.E.K. Plotter or the Reading 9-lens plotter, when this paper was first written. Fortunately, these new instruments have been described in the discussion.

The writer recommends a "decent burial" for one plotting instrument—the aerocartograph, which was mentioned in one discussion as comparable to the stereoplanigraph. Having had the two instruments side by side for twelve years, the writer considers that they are alike only in complexity of appearance and nomenclature. In fact, the aerocartograph is so completely obsolete that sometime soon the writer will be glad to offer a good one to a museum.

Mr. Davey made it very clear that, for small-scale mapping, the airplane cannot fly high enough to exceed the efficient limits of any of the methods. Thus, for 50-ft contours the multiplex flying could be from 30,000 ft aboveground, whereas the stereoplanigraph flying should theoretically be done at 62,500 ft. The latter is obviously impossible as 30,000 ft is substantially the limit of presently available aircraft. Thus, the contour interval must be less than 50 ft before the efficiency of the stereoplanigraph can be realized.

In summary, no photogrammetric method is a cure-all for mapping problems. Photogrammetry is a new and useful tool, and it richly supplements all the other well-known methods. Under many conditions, photogrammetric methods are superior. Sometimes the methods are not practicable, and yet again, a combination of methods is best. In discussing photogrammetry, engineers should not lose sight of the many valuable applications of aerial photography. A great many more square miles are studied usefully from aerial photographs and mosaics than from contour maps.

Each of these new aerial tools should be placed carefully in its proper category of usefulness.

Paper No. 2278

FLOW FROM DRAINAGE BASINS DETERMINED BY SHORT-TERM RECORDS

BY LLOYD L. HARROLD,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. SAMUEL ROBERTS, AND LLOYD L. HARROLD.

SYNOPSIS

A small number of short-term records of runoff of less than 10 years' duration are becoming available from the agricultural watersheds of Soil Conservation Experiment Stations, U. S. Department of Agriculture, throughout the various climatic regions of the United States. Data from one of these stations, at LaCrosse, Wis., are presented utilizing these relatively short records to derive values of maximum rates of flow for various recurrence intervals.

INTRODUCTION

Long-term records of peak rates of runoff, and flood-crest elevations for large drainage areas, have been published for years. These data frequently have been used as the basis of the hydraulic design of large flood-control and power projects as well as large culvert designs for highways and bridges. They have also been the subject of numerous scientific papers. Where actual runoff records were not available it has been common practice to derive peak runoff values for various recurrence intervals by using the rational method[2] with rainfall-intensity values published by the late David L. Yarnell,[3] M. Am. Soc. C. E. More recently the design of extremely costly flood-control projects in some cases has warranted the more detailed analysis as applied by W. W. Horner, M. Am. Soc. C. E., to storm sewers[4] and to large agricultural watersheds.[5]

Unlike the records for large drainage areas, those for small areas have not been published widely; nor have they been used extensively in designs for small hydraulic structures. The difference is due primarily to the fact that, until recently, data of this type were collected for only a few localities and for short periods. The need for runoff data from small urban areas has long been

---

recognized in connection with the design of storm sewers, but the need for runoff data from small rural areas has not been so apparent in connection with the design, construction, and maintenance of highways, railroads, and drainage systems. This latter need became more urgent when programs for soil and water conservation came into front-page prominence in the early 1930's. Works by C. E. Ramser,[6,7] M. Am. Soc. C. E., based on rainfall and runoff data from six watersheds ranging in size from 1.25 to 112 acres on the Lexington silt loam soil of the Murchison farm near Jackson, Miss., contributed much toward meeting the need in this field of soil and water conservation. These data formed the basis for the first runoff values used widely throughout the United States in the design of gully control structures, terrace outlet ditches, road culverts, and other hydraulic construction on small drainage areas.

As it was realized that similar data should be obtained on other soil types and in other climatic and agricultural regions, ten soil and water conservation stations were established in cooperation with the various state agricultural experiment stations, and hydrologic observations were begun on small agricultural watersheds at each station, under the Bureau of Chemistry and Soils and the Bureau of Agricultural Engineering, U. S. Department of Agriculture. In 1935 these stations were transferred to the Soil Conservation Service. Records from the LaCrosse station, one of the original ten stations, are used herein to present a procedure for deriving values of peak runoff for various recurrence intervals.

Description of Watersheds

Watershed No. 1 (Fig. 1) was established in 1932. The records used in this example are for the 10-yr period, January 1, 1933, to December 31, 1942. Prior to November 2, 1934, the area comprised 2.713 acres, reducing to 2.412 acres after that date. It was pastured during 1933 and from 1935 to 1942. Pasturing was discontinued and hay was cut periodically from January 1, 1934, to July 17, 1935. Traces of an old road across the watershed were removed in June, 1936. The average land slope is 24%. Dubuque silt loam predominates.

Watershed No. 2 was established in 1932. Records used for this area shown in Fig. 2 are for the 10-yr period, 1933 to 1942. From March 22, 1934, to April 13, 1938, the area comprised 2.335 acres, reducing to 2.245 acres thereafter. This drainage area, on an average land slope of 15%, was entirely cultivated on the contour from 1933 to 1937. By the fall of 1937 the lower third of this area had been so severely eroded that it was seeded to meadow. The meadow was cut periodically for hay after 1938, and the upper two thirds remained in contour cultivation with a 3-yr rotation of corn, small grain, and hay. During the 4-yr period, 1934 to 1937, the 7-in. depth of topsoil on the lower third of the area was reduced by erosion to 3.5 in. This does not mean that land of 15% slope or more cannot be cultivated. Conservation measures, such as stripcropping and terracing, are proving quite effective on steep slopes in this region. As shown in Fig. 2, the soil of the upper portion of the area is Clinton silt loam and that of the lower is Dubuque silt loam.

Fig. 2.—Unterraced Cultivated Watershed No. 2

Watershed No. 3 was established on January 1, 1937. Records used for this area shown in Fig. 3 are for the 6-yr period, 1937 to 1942. The drainage area of 2.705 acres on an average land slope of 17% lies on Dubuque and Clinton silt loam soils. The lower third of the watershed was continuously in alfalfa

FIG. 3.—CONTROLLED (STRIP-CROPPED) WATERSHED NO. 3

Rainfall records were obtained from automatic weighing and recording rain gages near the watersheds. Runoff was measured in Parshall flumes and trapezoidal flumes. Hydrographs and summary tabulations of rainfall and runoff for watersheds Nos. 1, 2, and 3 for the period, 1932 to 1938, have been published.[8]

PEAK FLOWS

The purpose of this paper is to present a method for the derivation of runoff values for various recurrence intervals for cultivated, strip-cropped, and pastured areas of different sizes, and for cultivated terraces, using short-term records of different lengths from small watersheds. All of the peak runoff rates greater than 1 in. per hr in each year for each watershed and terrace were tabulated in chronological order (see Table 1). These data were then arranged in descending order of magnitude (see Table 2) for either the period of record or the period during which there was no material change in land use. If the data given in Table 2 are used for purposes other than the method presented in this paper, careful attention should be given to the description of land cover. It is likely that a cultivated watershed, at times when small grain or hay is on the area, may have a better hydrologic cover than the permanent meadow watershed. Only the number of highest values corresponding to the number of years of record were used, as additional values would not appear in the plotting. From this duration type of tabulation the data were plotted on logarithmic probability paper (Fig. 4), as described by the late Allen Hazen,[9] M. Am. Soc. C. E., and as illustrated in an army manual.[10] Plotting points were derived from the equation—

[a] Lower third in meadow and upper two thirds in contour cultivation.

$$F = \frac{N - 0.5}{t} = \frac{2\,N - 1}{2\,t} \qquad (1)$$

in which: F = the plotting point; N = the order number of the peak (highest value = 1, next highest = 2, etc.); and t = the number of years of record. This formula for the plotting position of peak runoff values is based on the assumptions that the 10-yr record is one of ten such periods in 100 years, that the highest value in the actual 10-yr record is the median of highest values in each of ten 10-yr periods in 100 years, and that in a period of 100 years the actual recorded peak value for the 10-yr record will be equaled or exceeded about five times (recurrence interval 20 years).

The records for cultivated watershed No. 2 show that the entire area was cultivated for the first 5 years, 1933 to 1937, and that only the upper two thirds of the area was cultivated in the last 5 years, 1938 to 1942. Curve A (Fig. 4) resulted from using the 10-yr (1933 to 1942) record for watershed No. 2 as one period and, as it represents two widely different watershed conditions, it should not be used. Curves B (1933 to 1937) and C (1938 to 1942) are those for the separate periods and represent therefore the specific watershed conditions for the separate periods. Curve C represents all points based on watershed No. 3, which was strip-cropped for its entire period of record, and on watershed No. 2 during the period when its lower third was placed in permanent meadow and the upper two thirds was devoted to contour crop rotation (which is somewhat similar to strip-cropping).

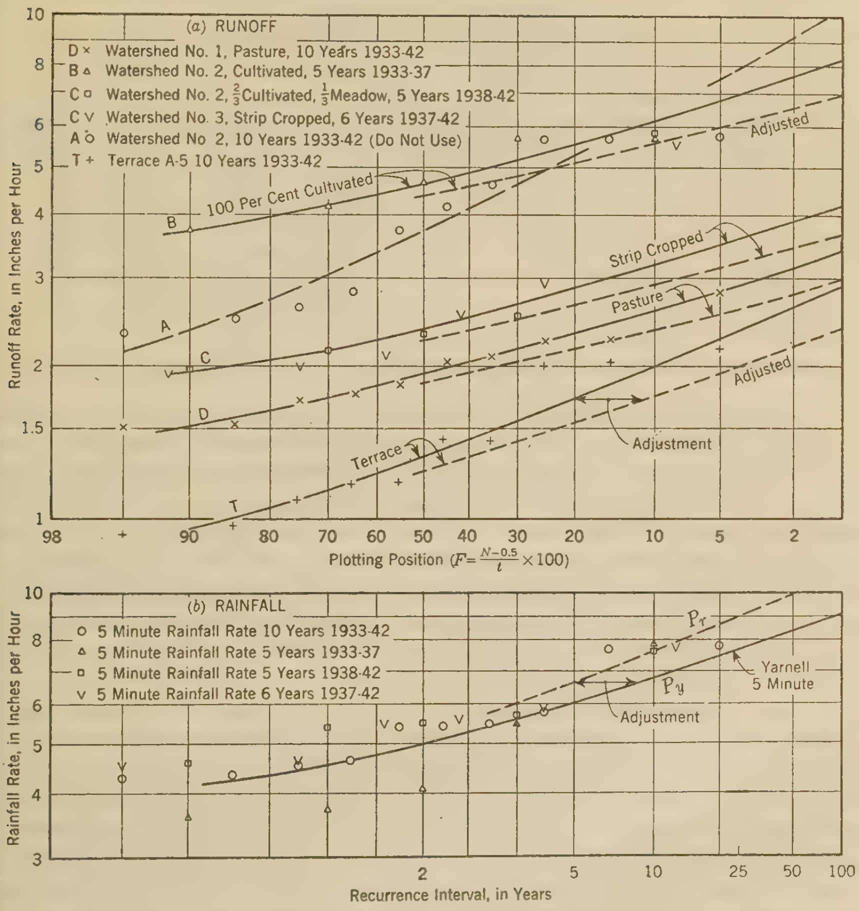

Fig. 4.—Values of Peak Runoff for Various Recurrence Intervals, Eq. 1

Values of runoff for various recurrence intervals may be derived directly from the curves in Fig. 4. However, these values may be too high or too low depending on whether the period of record was normal or of high or low rainfall intensity. To determine this factor, the rainfall intensity data for all the maximum 5 min (approximate time of concentration) for each of the periods of years used in the runoff plotting were arranged in descending order of magnitude (Table 3) and plotted on logarithmic probability paper, as shown by the points near curve P_r on the lower part of Fig. 4. It is assumed that curve P_r represents the rainfall potentiality of the period of record to produce high runoff rates. A comparison of curve P_r with curve P_y which represents Yarnell's[3] 5-min rainfall values for the LaCrosse area shows whether the rainfall potentiality of the period was above or below normal.

TABLE 3.—MAXIMUM RAINFALL RATES FOR FIVE MINUTES, IN DESCENDING ORDER OF MAGNITUDE

3	5.72	25	4.08	50	5.52	50	5.52	42
4	5.52	35	3.72	70	5.43	70	5.43	58
5	5.43	45	3.60	90	4.64	90	4.64	75
6	5.42	55	....	....	....	....	4.56	92
7	4.64	65	....	....	....	....	....	....
8	4.56	75	....	....	....	....	....	....
9	4.35	85	....	....	....	....	....	....
10	4.32	95	....	....	....	....	....	....

It should be noted that the rainfall intensities used for curve P_r do not necessarily belong to the same storms as the peak runoff values plotted in Fig. 4. In other words, the highest rainfall value recorded in the 10 years may belong to a 1938 storm, whereas the highest peak runoff value recorded in 10 years may belong to a 1936 storm. Although 5-min rainfall values recorded in the various periods reveal the potentiality of that period (as far as rainfall is concerned) to produce high runoff peaks on these small areas, additional factors (such as land cover, soil moisture, and degree of aggregation, and rainfall amount and intensities preceding the maximum 5 min) play a large part in the determination of the magnitude of the peak flow.

In Fig. 4, inasmuch as the rainfall-intensity values (curve P_r) greater than (to the right of) a 2-yr recurrence are higher than the Yarnell values (curve P_y), it was assumed that the rainfall recorded in the 10-yr period was abnormally high. It was concluded, therefore, that the runoff curves were also abnormally high and should be adjusted to represent a normal period. As the recurrence interval of rainfall-intensity values for this period of record are considerably lower than (to the left of) the Yarnell curve (P_y), the runoff curves were raised (moved to the right) by recurrence-interval amounts equal to the horizontal difference between the rainfall curves P_y and P_r at various points. For example (Fig. 4), the recurrence interval for a rainfall intensity of 6.6 in. per hr for the period of record is 5 years, whereas the Yarnell recurrence interval for this same intensity is about 10 years; therefore, all 5-yr runoff values were raised to about 10 years. Similar adjustments were derived for other points on the rainfall curve and applied to corresponding points on each runoff curve. The unadjusted and adjusted runoff curves are shown on arithmetic coordinates in Fig. 5, which is the form most commonly used in field application.

It was considered better to make adjustments to normal in the recurrence interval values than to adjust the runoff values (curves in Fig. 4) by the same amount as the vertical differences between curves P_r and P_y at corresponding recurrence intervals. The latter method appears illogical as it assumes that, if the rainfall experience (for example) was 1 in. per hr greater than normal, the normal runoff value should be 1 in. per hr less than that on the observed curve.

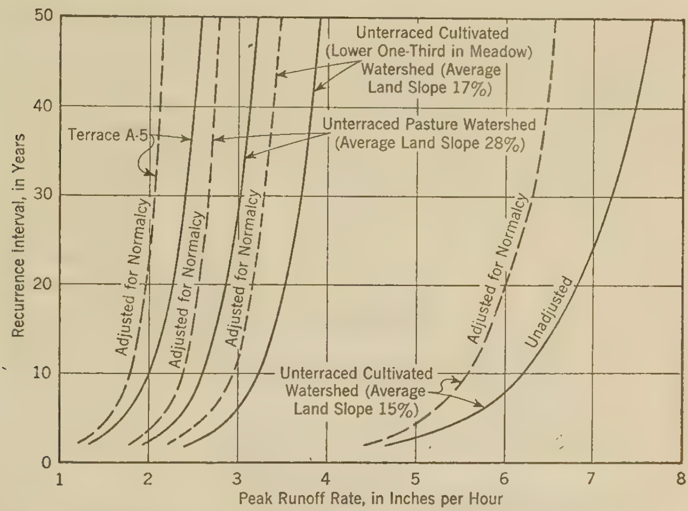

FIG. 5.—PEAK RUNOFF VALUES FOR VARIOUS RECURRENCE INTERVALS DERIVED FROM PLOTTING EQ. 1

Curves of recorded peak flows and maximum 5-min rainfall for various recurrence intervals derived from plotting values in the equation—

$$F = \frac{N}{t} \qquad (2)$$

along with the Yarnell 5-min curve are shown in Fig. 6. Although the Yarnell rainfall curve in this figure is the same as that in Fig. 4, the rainfall curve P_y and the runoff curves differ from the corresponding curves in Fig. 4. The data plotted in Fig. 6 are based on the assumption that the highest value in a 10-yr record has a recurrence interval of 10 years (will be equaled or exceeded once every 10 years on the average) and that in 100 years this runoff value will be equaled or exceeded ten times.

As in Fig. 4, the runoff values in Fig. 6 for various recurrence intervals must be adjusted for normalcy. Inasmuch as the rainfall rates recorded in the period of record were abnormally high when compared with the Yarnell curve (P_y), it was concluded that the runoff values were also higher than those to be expected on the average. Rather than to adjust the runoff value, the values of the recurrence interval for the various runoff rates were adjusted as explained for Figs. 4 and 5. Unadjusted and adjusted runoff curves are shown in Fig. 7.

The procedure discussed hereinbefore has shown how peak runoff values for various recurrence intervals may be derived for drainage areas of nearly the same size as those on which the basic data were collected; namely, about 2 or 4 acres. Further "stretching" of the original data may be required to furnish peak runoff values for drainage areas of different sizes. Some data have been gathered on watersheds from 2 acres to 300 acres in size, but the periods of record are too short to provide a reliable method of extending the results on small areas to larger ones. It is expected that a few more years of record on these watersheds will provide sufficient data to establish such a method.

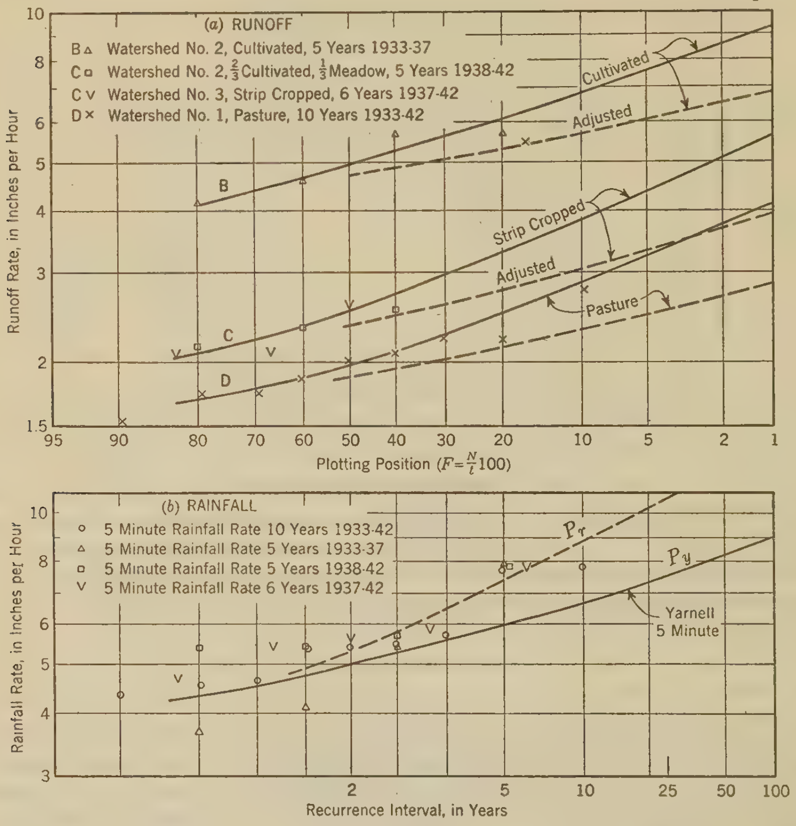

FIG. 6.—PEAK RUNOFF VALUES FOR VARIOUS RECURRENCE INTERVALS, EQ. 2

It is recognized that Mr. Yarnell's values for rainfall intensity and recurrence interval may not serve as a satisfactory basis for the determination of normalcy of the period of observation. However, it is used herein and probably will continue to be used until a more reliable basis is established. Where a long record of rainfall intensity data is available at near-by weather stations, it should probably be used in preference to the Yarnell values.

The position of the adjusted curves (Figs. 4, 5, 6, and 7), derived from the plot of the recorded values according to Eq. 1 and those according to Eq. 2, reveals the fact that the method of adjustment eliminates the differences due to plotting methods. The final results are essentially the same regardless of the plotting method, and whenever small differences occur they are caused by the fact that the plotted points do not define the position of the curves adequately.

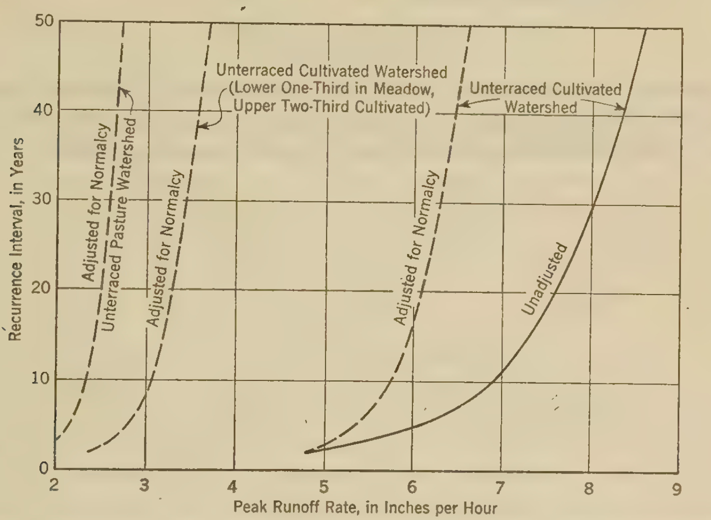

FIG. 7.—PEAK RUNOFF VALUES FOR VARIOUS RECURRENCE INTERVALS DERIVED FROM PLOTTING EQ. 2

This procedure is presented in the expectation that constructive criticism and discussion will follow which will provide an adequate procedure or method for the treatment of similar data.

CONCLUSION

In estimating a peak runoff value for a particular drainage area it has been a common practice in the past (and still is in some hydrologic and hydraulic fields) to apply a selected coefficient to a Yarnell rainfall value for the time of concentration of the area and a given recurrence interval. Usually the selected coefficient has been rather high, as it was assumed that the occurrence of that condition of soil and cover which would yield most runoff would be coincident with that of maximum rainfall intensity for the given recurrence interval. Actually this does not always happen, and the runoff values thus determined are probably too high when compared with those based on a long-term record of runoff.

It is recognized that nothing can take the place of long-term runoff records for this type of runoff-frequency study. Additional years of record on the drainage areas used herein will either verify or revise the results shown in Figs. 4 and 5 or 6 and 7. In such 5-yr or 10-yr records as those used in this paper, a 25-yr rain may fall on the area when its soil and cover are most conducive to runoff, and the resulting peak may have a recurrence interval of 50, 100, or even a greater number of years. Such may be the case of the storm of July 21, 1938, on watersheds Nos. 2 and 3, the points for which (5.8 and 5.6 in. per hr) lie considerably higher than their respective curves (Fig. 4). About 6.5 in. of rain fell on the area during the 30 days preceding this storm. Pasture watershed No. 1 recorded a peak of 1.87 in. per hr which is more consistent with the other values for this area.

ACKNOWLEDGMENTS

DISCUSSION

SAMUEL ROBERTS,[11] JUN. AM. SOC. C. E.—The extension of short-term records for design purposes is a problem of frequent occurrence in flood control and drainage practice. Where long-term records are available, a straightforward procedure may be used to present the data in frequency form. The flood peaks are plotted in accordance with a suitable formula, such as Eq. 1, and a curve is drawn to fit all the plotted points, as in Fig. 4. For short-term records this procedure must be modified by an examination of the data to determine whether or not the record is a truly representative sample of the long-term record and, if not, what correction should be applied. The frequency curve finally drawn need not be the average of all the plotted points. If there is a sufficient scatter of points in a short record, such as ten years, it may be expected that one or more of the high peaks should have greater recurrence intervals than ten years, and that the other peaks will define the lower portion of the frequency curve. The final curve drawn with this premise in mind, therefore, may deviate considerably from the plotted positions of the higher peaks.

For plotting purposes, the writer prefers log-log paper instead of the probability paper used by the author and he prefers the plotting of the data by frequency in years, the reciprocal of F in Eq. 1. Peak discharge frequency curves plotted by this method usually are parabolic in shape, making extrapolation comparatively simple. Deviation from this shape occurs only in a watershed displaying material differences in characteristics between moderate and severe floods, such as would be caused by storage or by regulation.

The data given in Tables 2 and 3 have been replotted on log-log paper in Fig. 8, in accordance with the formula:

$$f = \frac{t}{N - 0.5} \qquad (3)$$

in which f equals the frequency of recurrence in years; t equals the number of years of record; and N equals the order number of the peak (highest equals 1, etc.). The Yarnell frequency curve, as given in Fig. 4, has also been replotted in Fig. 8. It may be noted that the plotted rainfall points agree reasonably well with the Yarnell curve and no adjustment in frequency is warranted. Furthermore, the plotted peak runoff points for the short records show a good scatter in magnitude, indicating a representative sample of the long record in each case.

It is singular to note that the curves thus drawn seem to support the common practice of using the rational method and the Yarnell rainfall frequecy curve. Judicious choice of the runoff coefficient based on such information as that given by the author and the frequency curves in Fig. 8 would result in a more balanced design. The coefficient of runoff for area A-5 varies from 0.25 to 0.3. For area 1 it is about 0.4; and for area 3 and area 2 (between 1938 and 1942), it varies from 0.45 to 0.6. The coefficient for area 2 (between

---

[11] Engr. (Hydrologic), U. S. Engr. Office, New York, N. Y.

1933 and 1937) is extraordinarily high and seems to indicate an inconsistency in the data, possibly caused by the changes in cultivation or plowing methods that may have reduced the concentration time; or perhaps the introduction of ground-water flow from other areas increased the flow measured at the gage. If the concentration time of area 2 had remained 5 min, it is improbable that the runoff rate would have exceeded the maximum 5-min rainfall rate for four out of five of the plotted values for the same period (see Fig. 8).

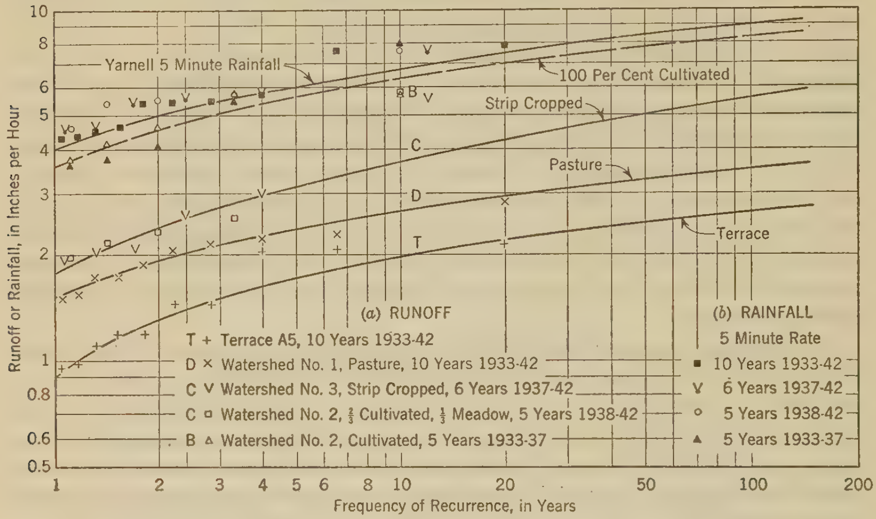

FIG. 8.—VALUES OF PEAK RUNOFF FOR VARIOUS RECURRENCE INTERVALS, EQ. 3

The areas studied by the author are so small that special cultivation methods may have an appreciable effect on the concentration time. From the descriptions given, the areas do not appear as dissimilar as the range in derived runoff coefficient indicates, and the assumption of a 5-min concentration time for each of the areas may not be valid. The data on hand are too inconsistent and variable to use for direct extrapolation to other watersheds. However, the paper can serve as a useful basis for further study, particularly if more information is published later for the same areas.

LLOYD L. HARROLD,[12] ASSOC. M. AM. SOC. C. E.—In view of the limited discussion of this paper, the writer could possibly infer that the procedures used therein have the sanction of the profession; but he will not. Although certain parts of the method received no comment—either confirmatory or refutatory—some phases of the procedure have been used for analyzing short-term watershed runoff for a number of locations. The writer has been reluctant, however, to adjust any of the runoff curves to normalcy. This hesitancy was in full view of the fact that almost without exception the observed rainfall rates for the periods of record have exceeded the normal expectancy. Long-term records at near-by U. S. Weather Bureau Stations, or Yarnell values, were used as normal in this comparison. The adjustment, if used, would lengthen the period of recurrence in each case; or, for the same recurrence interval, would reduce the flood peak. The unadjusted curves give flood-peak values that may be high. It appears better to have this factor of safety in the design flood peak rather than to apply an adjustment that may be questionable.

---

[12] Project Supervisor, SCS, North Appalachian Experimental Watershed, Coshocton, Ohio.

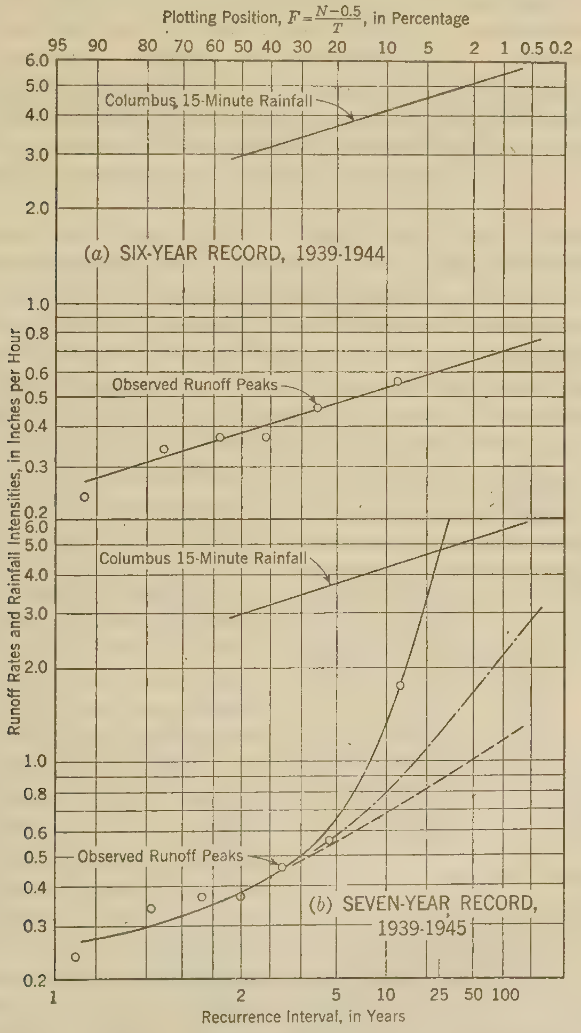

Fig. 9.—Record of Runoff on Watershed No. 10 (122 Acres) Coshocton, Ohio

Mr. Roberts' preference for log-log paper and the use of Eq. 3 (the reciprocal of Eq. 1) does not introduce any material change in the flood values for 25, 30, or 100 years. Data taken from the unadjusted curves in either Fig. 4 or Fig. 8 would be almost identical. Even the plotted rainfall points in both figures compare similarly with the Yarnell 5-min curves—Mr. Roberts' conclusion to the contrary. The plotting method does not eliminate the adjustment to normalcy, if such an adjustment is warranted in the first place.

Both the writer and Mr. Roberts feel the inadequancy of defining flood-frequency curves from short records. This has been brought out rather forcibly. A 6-yr record, 1939–1944, for a 122-acre watershed had been analyzed at the end of 1944 (Fig. 9(*a*)). The rainfall intensities and the soil moisture conditions recorded in this 6-yr period appeared to establish the fact that a normal period had been sampled. Press of other duties prevented the completion and publication of the report on this analysis. In view of the 1945 records this delay proved to be a blessing. It is necessary, frequently, to prepare preliminary reports which may be used until sufficient amount of additional data are obtained to warrant a revision on preparation of a final report. One cannot continue, indefinitely, to delay the analyses and publication of such reports.

In September, 1945, a flood peak of 1.72 in. per hr was recorded—three times as great as the highest flood in 6 years. The maximum 15-min rainfall for the storm was not exceedingly high—3.56 in. per hr. This is about a 5-yr storm according to the late David L. Yarnell, M. Am. Soc. C. E. Antecedent moisture, however, was very high, but not more than that occurring in 1941 (date of highest peak prior to 1945). Six inches of rain fell in the 3-week period prior to the date of the 1945 storm. There was no material change in the land use over the watershed throughout the entire 7-yr period. From an extension of the curve in Fig. 9, the recurrence interval of this 1945 peak would be somewhere above 1,000 years. This is unreasonable.

TABLE 4.—FLOOD PEAKS, WATERSHED NO. 10

Order	SIX-YEAR RECORD (1939–1944)		SEVEN-YEAR RECORD (1939–1945)

1	0.56	8.3	1.76	7.2
2	0.46	25	0.56	21
3	0.37	42	0.46	36
4	0.37	58	0.37	50
5	0.34	75	0.37	64
6	0.24	92	0.34	79
7	0.23	...	0.24	93
8	0.207	...	0.23	...
9	0.198	...	0.207	...
10	0.192	...	0.198	...
11	0.146	...	0.192	...

The peak values for the 7-yr period, 1939–1945, were replotted as shown in Fig. 9(*b*). The recorded peak values for the 6-yr and 7-yr periods are listed in Table 4. A line through the plotted points defines curve A, Fig. 9(*b*)). An extension of this curve crosses the rainfall curve. At a 50-yr recurrence the flood peak would be about twice as large as the rainfall rate. This is most unreasonable. Mr. Roberts' statement, that the frequency curve need not be the average of all the plotted points, certainly applies to this condition. All the points should not be used in defining this curve.

A curve (line C, Fig. 9(*b*)) through all but this highest value gives the 1945 peak as one occurring once in a little less than 1,000 years. This seems to be too great. Obviously, the probable recurrence of this peak value is somewhere between curves A and C—perhaps along curve B. Only a longer period of record will help to establish the true position of this flood-frequency curve.

Mr. Roberts' interest in this paper and his discussion are appreciated. The writer is subjecting the procedures to further study and may at some future date submit his findings to the profession.

Paper No. 2279

ELIMINATION OF CROSS CONNECTIONS IN LOS ANGELES, CALIF.

By Harry Hayes,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Roy O. Van Meter, Robert P. Lowe, and Harry Hayes.

Synopsis

The City of Los Angeles, Calif., has undertaken what is probably one of the most carefully planned and executed programs for the control and elimination of cross connections of any city in the United States. This is the outcome of development work started by the City Department of Water and Power, at first acting alone but gradually acquiring the cooperation of all governmental units having jurisdiction, which act in unison through a joint committee. The purpose of this paper is to describe briefly some of the factors which enter into the development of this program, the formation of the joint committee, and results accomplished.

History

When potable water delivered to a consumer from a source approved for domestic consumption may be polluted or contaminated by admission of polluting material through a connection to the consumers' water piping system, such connection is known as a cross connection. (By the term "cross connection" as used in these regulations is meant any connection between any part of a water system used or intended to supply water for drinking purposes, and any other source or kind of water that is not or cannot be approved as reasonably safe and potable for human consumption whereby water from said unapproved source may be forced or drawn into the drinking water system.[2]) The existence of dangerous cross connections inimical to the public health has been recognized for many years. Publications are replete with reports of epidemics of water-borne diseases resulting in sickness and death which have been attributed directly to dangerous cross connections. Investigations indicate that the number of instances of sickness caused by contaminated drinking

---

Note.—Published in March, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[2] "Cross Connection Regulations," adopted August 28, 1943, *Bulletin No. 64*, Dept. of Public Health, State of California.

water through backflow connections has been many times greater than the number actually reported in print. It is further apparent that, instead of diminishing, the number of instances where pollution has occurred is on the increase, due largely, it is believed, to the rapid increase and expansion of war industries. This is attested to by the reported incidents of salt-water pollution of drinking water lines in shipyards alone.

Many states have regulations governing cross connections, administered through public health authorities, some of which forbid the existence of cross connections even with secondary supplies that may be considered potable, whereas others allow such cross connections if the primary supply is protected by an approved double check-valve installation. As yet, no guaranteed procedure for backflow protection has been developed. Although some consider parallel piping systems with air-gap or broken connections as ideal, systems originally protected by such means have become cross connected by operators, which nullifies the supposed protection entirely. Others place reliance upon mechanical protective devices although such devices have not been fully developed to afford complete protection. It becomes a question of whether present mechanical deficiencies are more serious than the human element in making new cross connections. Current conditions in regard to cross-connection control by various state and local governmental bodies have been reported quite thoroughly by R. F. Goudey[3] and Robert E. Moore, Jr.[4]

The City of Los Angeles began conducting an increasingly vigorous campaign of cross-connection control and elimination in 1930, mostly through the Sanitary Engineering Division of the Department of Water and Power. Since that time most buildings in the downtown area, and many buildings in outlying areas, have been surveyed. Every new water-service sale is checked for use and all properties to which the services are sold, with the exception of dwellings with service connections less than 1.5 in. in diameter, are inspected for cross connections. In many cases properties or building plans are investigated before the service is sold, and, where it is found that backflow protection is required at the meter, the service is withheld until such protection is provided.

Until 1942, the control of cross connections on water piping systems connected to the municipal water supply mains was solely for the purpose of preventing backflow of polluted water into the street mains. That contamination of the water within a private water piping system might occur, with resulting danger to the health of occupants of the property, was not the primary concern of the Water Bureau so long as that contamination did not flow through the meter into the street main. Where contamination was known to have occurred, or was likely to occur, in a private water piping system, the matter was reported to the local health authorities for further action.

Right of entry on to private property for the purpose of investigating the water use, and for inspection for the existence of cross connections, was established by rules and regulations passed by the Board of Water and Power

[3] "Practical Aspects of Cross-Connection, Inter-Connection and Back-Flow Protection," by R. F. Goudey, *Journal*, A.W.W.A., March, 1941, p. 391.

[4] "Legal Aspects of Cross-Connection, Inter-Connection and Back-Flow Protection," by Robert E. Moore, Jr., *ibid.*, p. 495.

Commissioners[5] which have all the force and effect of general laws.[6] Other rules and regulations provide for the prohibition of cross connections on the consumers' property or protection of the water supply and the right to discontinue water service for violations.[7]

On a routine investigation of a water service for cross connections the inspector began at the meter and followed the water supply piping from the point of entry to the property, through all branches to the last foot of pipe, inspecting every connection, outlet, and water-using device and fixture found on the service. Every cross connection was listed and located, using sketches and drawings where required. When the survey was completed, the cross connections were listed (except cross connections to plumbing fixtures which were referred to the Department of Building and Safety) and presented to the owner or person in charge of the property with a legal order requiring their elimination from the potable water piping system.

Two alternates were allowed: The first was the complete severance of each individual cross connection on the system; and the second was the installation of a backflow protective device at the meter. By the use of the first method, the public water supply system was protected so long as no new cross connections were made. By the use of the second method, the mains were reasonably well protected so long as the checks were maintained in good condition. In either case, direct connections to the sewer were ordered severed.

ORGANIZATION AND FUNCTIONS OF THE COMMITTEE FOR CROSS-CONNECTION CONTROL

In 1942 the Cross-Connection Control Advisory Committee was founded to take over cross-connection control and elimination for the entire city. It was formed by a joint resolution passed by the Boards of Commissioners of the Building and Safety Department, the Health Department, the Water and Power Department, and the Board of Mechanical Engineers of the City of Los Angeles. Its membership is comprised of one representative from each of the departments and one attorney from the city attorney's office, plus certain advisory counselors who may be appointed from time to time. The sanitary engineer of the Department of Water and Power is the member from that department and is the permanent chairman of the committee.

The committee is a quasi-legal organization and is invested with all the police powers of the signatories to the joint resolution, in so far as they pertain to cross-connection control. The policy of the committee is to accomplish its objectives through education and cooperation rather than through enforcement, using its authority and the laws back of it only as a last resort. The committee has sponsored evening classes in Los Angeles at the University of Southern California and the Frank Wiggins Trade School for the purpose of educating the public on what constitute cross connections, the dangers of allowing their existence, and the methods for correcting or eliminating them, thus protecting the water supply system. These classes have been well attended by plant engineers, master plumbers and journeyman plumbers, plumbing and health inspectors, representatives of manufacturers of plumbing equipment, and many others who are concerned with the maintenance of the purity of the water supply system.

[6] *City Charter*, City of Los Angeles, Calif., Chapter I, Sections 82 and 220.

[7] *Rule and Regulation No. 59 to No. 62*, inclusive, Board of Water and Power Commrs., City of Los Angeles, Calif.

Field inspection forces were obtained by assigning to the committee inspectors from the various departments represented. A chief inspector and two assistants, with previous experience in this type of work, were selected from the engineering staff of the Sanitary Engineering Division of the Department of Water and Power to take charge of the inspection work. Most of the inspectors who have worked under the jurisdiction of the committee were obtained from the Plumbing Inspection Division of the Department of Building and Safety because the type of work involved is akin to plumbing inspection.

The procedure in making a survey under the authority of the committee is identical to that used by the Department of Water and Power before the committee was conceived. Great care is taken to see that each pipe line is traced to its end and every cross connection located. When the survey of a property is completed, the inspector writes a legal order requiring the elimination of all cross connections found having listed them in an attached appendix. In making up the list each cross connection is numbered consecutively, its location given, and the method of elimination stated. Thereafter it is referred to by number only. Wherever possible, cross connections of a like nature that can be eliminated by similar methods, such as the raising of low inlets into tanks, or installation of vacuum breakers on flush valves, are grouped together so that the order for elimination covers the entire group.

For many items on the list there is but one method of elimination. If such is the case, it is so ordered, but for others where the elimination may be accomplished by any of a number of methods, involving, perhaps, complete changes in piping systems, the owner is given the option of using the method that serves his purpose best.

In order to further unify the methods of elimination for all properties so that none will be discriminated against or given special advantages, a code of standard wording was devised for each type of cross connection, and in writing up his orders each inspector must follow this standard explicitly. The only time when deviation from the standard is allowed is when a new type of cross connection or an unusual condition is found that is not covered by the standard wording, and in that case it is referred to the engineers for codifying.

The legal order is dated as of the day it is served; and the person to whom it is served, or his agent or representative, is required to sign the order to acknowledge receipt of it. The order is then dated as to the time allowed for completion of the work ordered or provision made for its completion. The time limit given is usually two weeks. If the required work cannot be completed in this time, the owner is allowed to file biweekly progress reports and the limit placed on the time of completion is extended as long as evidence of good faith is shown. However, no order is allowed to be pigeonholed and forgotten.

Each inspector working on cross-connection control work, regardless of the department from which he is obtained, is deputized to act for each of the member departments in cross-connection control work. His duty is not only to insure the purity of the water supply in the city mains, but he is also interested in protecting the public health by the elimination of all cross connections and illegal plumbing installations on private premises that might adversely affect the purity of the water in the consumers' water piping system and endanger the health of any individual drinking from that system.

The three engineers from the Department of Water and Power and two plumbing inspectors from the Building and Safety Department who had had some experience in cross-connection inspection work formed the nucleus for the inspection. From time to time inspectors from other member departments were added. Each new man, when assigned to the field inspection force, was paired with an experienced man for a period of training until he was able to do the field work alone and perhaps train new men. The purpose of the committee was to allow every inspector working for a member department sufficient time on cross-connection inspections to become thoroughly familiar with the work so that he could recognize and order the elimination of any cross connections he might find when conducting his regular department inspection work. The time required to train regular plumbing inspectors in this work depends on the ability of the men assigned. Exceptional men will require from six to nine months; men who are slower to learn will require a year or more; and some will never be able to make a satisfactory survey. Overconfidence on the part of the trainee is the greatest stumbling block to overcome. It takes at least thirty days on the job before a conscientious inspector discovers how little he knows.

Inspections of water piping systems in buildings in the business district, food processing plants, hotels, hospitals and sanitariums, manufacturing plants, etc., that had previously been conducted by the Water Department engineers were undertaken by the committee's inspection force. With the outbreak of World War II and the necessity for a continuous flow of war materials, the committee confined its inspections more and more to plants and industries connected with the war effort. This safeguarded large concentrations of war workers and it was also found that preferential ratings could be used for obtaining the necessary critical materials. The inspection of residential, business, and other properties not connected with the war effort was abandoned for the duration, with the exception of special cases involving sickness.

Evidences of Pollution

Early in 1942, a series of incidents occurred which focused the attention of the committee on the Los Angeles Harbor area. The first of these was a report from the Sanitary Engineering Division of the Water Department that analyses of water samples collected at certain locations from the water distribution system in the harbor area showed evidences that pollution was getting into the mains from some source in the area. A sanitary survey indicated the possible sources of pollution as a shipbuilding yard and an army fort. The bacterial pollution appeared to be coincident with periods of heavy water use in the shipyard which caused low water-pressure conditions in the street mains and distribution systems serving both the yard and the fort. A quick check up showed both places to be replete with cross connections. An order was issued immediately that backflow protection be installed at the meters on all services entering the suspected properties. Thereafter there appeared to be less evidence of pollution in water samples collected from the city water mains in that area, but the water in the mains in the fort continued to show evidence of contamination and was quarantined for drinking purposes.

Systematic and complete cross-connection surveys of each of the properties revealed the existence of more than 350 cross connections in the shipyard and nearly a thousand at the fort.

Second in the series of incidents was the actual pollution of the fresh drinking water lines within the aforementioned shipyard. A ship's officer on board a ship tied to a wharf connected the fresh-water system in the yard to the salt-water system on board the ship, started the ship's pumps, and pumped sewage-polluted salt water throughout the yard's drinking water system. This was the first of five occurrences within six months where polluted water was forced back into drinking water systems in the harbor area, and although there are no official records of sickness resulting from these occurrences, it is known unofficially that there were many cases of illness due to these causes, and the loss of man-hours in the plants involved was high.

Such occurrences have not been confined to plants in Los Angeles or in California. Reports have been published of similar cases occurring in shipyards and industrial plants in various parts of the United States, indicating that hazardous conditions exist in all hastily built war production plants because, in most cases, it is impossible to get designers and engineers who have a practical as well as a theoretical knowledge of cross-connection control.

One of the most hazardous conditions found by the committee was the existence of many cross connections between the fresh-water domestic and fire-fighting systems and secondary piping systems carrying sewage-polluted salt water. Most of these were newly made and were intended to augment the supply of fresh water for fire-fighting purposes and many involved new installations of auxiliary salt-water pumps.

The committee notified the State Board of Public Health of the conditions found in the harbor area, with the request that action be taken to assist in removing the dangers. As a result, that Board called a meeting on June 22, 1942, of all city and county health officials of Southern California and other interested parties, for the purpose of considering this problem. As an outcome of this meeting the State Board of Health, on June 27, 1942, passed a resolution[8] condemning the use of cross connections and requiring their elimination or control. This same resolution was adopted by reference by the Los Angeles City Board of Health and became a law in the city on October 8, 1942.

THE SEVEN-POINT PROGRAM

In August a meeting was called by the committee and was attended by representatives of various federal, state, and local governmental agencies to discuss plans and procedures for cleaning up the cross-connection situation in war industry plants in Los Angeles, in general, and in the harbor area in particular. It was agreed that the committee should undertake this job and that ten inspectors from the Building and Safety Department would be assigned permanently to the committee for this work.

---

[8] *Resolution Relative to the Protection of Water Supplies Against Pollution Due to Cross-Connections with Auxiliary or Emergency or Firefighting Supplies*, State Board of Health, State of California, adopted June 27, 1942.

On September 15, 1942, a meeting of representatives from numerous shipyards and industrial plants, the U. S. Army, Navy, Coast Guard, Maritime Commission, the U. S. Public Health Service, State Department of Health, City Council, and other governmental departments concerned was called by the committee at the U. S. Naval Operating Base at Terminal Island (California) for the purpose of acquainting the representatives with the committee's proposed plan of survey and the policies to be followed by the committee in requiring cross-connection control and elimination and to discuss backflow protective installations.

The following seven-point program was presented to and adopted by the group:

1. Backflow protection at meter of all services to premises fronting on the harbor and to adjacent industrial and commercial plants.
2. Backflow protection at the wharf for all ship supplies.
3. Segregation of domestic and fire lines as far as possible so that no unprotected cross connections will endanger the domestic supply from pierhead, Siamese, or salt-water pump intakes.
4. Elimination of all dangerous plumbing cross connections.
5. Provision for the isolation of all pipe lines carrying processing water.
6. Adoption of color and sign scheme for designation of safe and unsafe water lines.
7. Organization of water foremen on each premise to supervise a unified plan.

These seven points represent the uniform policy established at the meeting of September 15 and followed by the committee.

On September 10, 1942, an office was opened in Wilmington, Calif., with ten inspectors and three engineers assigned to the survey. Work was started immediately on the waterfront properties. Preliminary contacts with plant managers were made by the engineers to arrange passes and entry for the inspectors, to obtain maps and drawings of the water piping system on the property if available, and to enlist the cooperation of the plant engineer in making the survey. In general, the cooperation of the management of the plants has been very satisfactory, but, as with individuals in a group, there are contrary ones who make it difficult for the inspectors. Although the inspectors carry sufficient legal authority to enter any of the plants for inspection purposes, it is the policy of the committee never to make use of such authority or to make any show of force in dealing with the plants unless compelled by a refusal of cooperation. That holds true also in the issuance of orders for the elimination of cross connections or any other required work for the protection of the drinking water system.

The survey proceeded with diligence, and the report to the committee (dated January 1, 1945) shows that the following had been accomplished as of that date:

Premises surveyed and legal orders issued	267
Cross connections found	12,500
Work completed on orders issued	99%
Survey of harbor area completed (industrial area only)	100%
Approximate cost of work ordered	$600,000

As the report shows, the survey of the harbor area is completed. Part of the inspector's duty is to be available on call to consult with plant managers in perfecting methods for the required elimination. As the work in the harbor is completed the inspectors are moved north into defense plants in the "shoestring" strip connecting the harbor area and the city and into the city area.

During 1943, the District Security Officers for the Army, Navy, Air Force, and other branches of the armed services were charged with the responsibility of securing the safety of the drinking water systems in all plants on war material production under their jurisdiction. As the Cross-Connection Control Advisory Committee was at the time proceeding with its program of cross-connection elimination in war production plants, it was requested by the District Security Officers to expand its activities to include water safety security.

The committee was supplied with master responsibility lists of war production plants, and surveys were made at these plants in accordance with their priority on the lists.

When the survey of a plant was completed, and an order for corrections was issued, a copy of the order was forwarded to the District Security Officer, who thereupon assumed responsibility for its enforcement. The committee, however, maintained a continuing inspection at the plant to see that the terms of the order were fulfilled.

(*1*) *Protection at the Meter*.—The requirement of backflow protection at the meter (point 1) is not confined to harbor-front properties alone, but to any plant or property having access to auxiliary water supplies and pressure producing equipment for utilizing such supplies. Fig. 1 comprises two reproductions of prints issued to property owners with orders for cross-connection elimination involving such necessary protection, showing various methods which have been approved by the committee, for installation at the meter, to protect against the pollution of the water supply in the street main.

The fundamental principle of backflow protection is the air-gap or broken connection. There is as yet no completely satisfactory substitute for a broken connection or a complete severance of a cross connection for permanent protection to a drinking water system. However, modern backflow protective equipment has been developed that will give a reasonable degree of protection if properly installed and maintained.

The first method of protection shown in Drawing No. A-1, Fig. 1, makes use of the air-gap principle by requiring the water supply to be discharged into a receiving tank through an overhead inlet which is sufficiently high above the overflow rim of the tank to prevent any siphoning back of water from the tank should a vacuum occur in the supply main. Furthermore, it is obvious that any pressure producing device in the consumer's water piping system could not force water back across this gap (as would be possible through a direct connection), either against the pressure in the main or into a vacuum that might occur in the main.

In general, the least air-gap distance required is twice the diameter of the inlet pipe, plus additional distances in special cases. As shown in Drawing No. A-1, the tank may be placed in an elevated position so as to provide gravity pressure in the consumer's water piping system, or the pressure may be produced by a pressure pump taking the suction out of the receiving tank. A device not shown in the drawings, which is the nearest equivalent to an air gap in protection, and which allows a solid connection to the water supply so that the main pressure can be utilized, is the siphon loop. This is a loop in the supply pipe which rises to a height of not less than 35 ft above the highest point from which back-siphonage of polluting material might occur. It can be used only on premises where there are no steam boilers, auxiliary water supply, or any pressure producing device connected into the water piping system except where the loop is raised to a height sufficient to compensate for the maximum pressure that may occur.

It is seldom practicable to use such a loop, as it requires a support that may extend a considerable distance above the roof of the building housing the piping system, although it has been recommended at times where conditions seem to warrant its use.

Where it is impossible or impracticable to require the use of the foregoing methods of protection on a water service, the committee allows the use of backflow protective devices of approved types, provided they are installed in an approved manner and maintained in good operative condition at all times. Such approved devices are shown in Drawing No. A-1, alternate method (Fig. 1) for services less than 6 in. in diameter, and Drawing No. A-2, Fig. 1, a typical double check-valve installation for 6-in. services and larger. Any device for such use must be submitted to the laboratory of the Building and Safety Department for tests and approval before its use is allowed in Los Angeles.

Although it is recognized that no mechanical device is the equivalent of a broken connection for backflow protection, great progress has been made in the development and the design of modern backflow protective devices. The trend is toward the perfection of the operating mechanism together with the use of devices which operate to destroy the negative and positive forces that cause backflow.

In general, the forces that tend to cause backflow through any cross connection are: (1) Reduced pressure or a vacuum in the water supply mains caused by main breaks, shutdowns for repairs, excessive water use, pumping connections for fire fighting, etc.; (2) gravity head of water in the consumer's piping system; (3) pressure producing equipment connected into the consumer's water piping system, or connections to a secondary water piping system having a higher (or occasionally higher) pressure than the primary system.

The fundamental principle of all backflow protective devices for installation at the meter has been the use of double check valves. Until recently they did

WITH ORDERS FOR THE ELIMINATION OF CROSS CONNECTIONS

authorities. The original recommendations were for check valves made entirely of bronze, but, as the cost is high for the larger sizes, the Department of Water and Power, in some of the early installations, allowed the use of a certain type of checks made of cast iron with galvanized body which has proved quite satisfactory. These checks were originally developed as detector checks on fire-sprinkler services and for compound meters where it was found desirable to check the main flow-through channel in order to force small flows through the by-pass meter. To accomplish this purpose the clapper of the check is weighted internally to cause positive closure of the valve under static or low-flow conditions and to require a substantial decrease in pressure on the property side to make it open. In addition, the valve contains other desirable features, such as bronze seat rings, hinge and hinge pins, rubber or composition bushed hinge-pin bearings, and rubber-faced clapper disk. This type of check valve is the first choice of the committee for use in double check-valve installations.

With the increased scarcity of strategic materials due to war conditions, it has become increasingly difficult to obtain valves meeting previous specifications and the committee has allowed the use of other types of valves, provided they are rebuilt to meet certain requirements. Practically any check valve that has a bronze seat ring and hinge-pin bearings in the body of the valve can be rebuilt to meet the requirements, which are as follows:

(*a*) The face of the clapper disk must be machined flat and fitted with a rubber face composed of fabric-reinforced medium soft rubber. Any valve already on the market which has a rubber face in the seat ring may be used without change; but the clapper disk must be bronze, or must have a bronze face.

(*b*) The bearing for the bolt that fastens the disk to the hinge arm must be rubber bushed and must be provided with rubber washers for each side of the hinge arm. These washers and bushing must provide a tight fit between the disk and hinge arm and yet be resilient enough to allow sufficient movement for proper seating of the disk when the valve closes. If the valve to be used is double-hinged with rubber bushings for the hinge pins, or, if it has an otherwise solid but resilient connection between the disk and hinge arm, the aforementioned change is not required.

(*c*) The hinge-pin bearing in the body of the valve must be drilled out and fitted with rubber or reinforced plastic bushings.

(*d*) The bearing on one side must be fitted with a packing gland and an extended hinge pin of bronze, stainless steel, or other rust-resisting material. The hinge pin must be keyed or pinned to the hinge arm. An outside lever must be fastened to the hinge pin with a key, or a substantial pin, in such a position that it is horizontal when the valve is closed.

(*e*) A weight must be attached to the arm lever and adjusted in a position that will require a differential pressure of approximately 1 lb per sq in. to open the valve. Check valves are available which are already fitted with a packing gland and outside weighted lever arms as required in items (*d*) and (*e*).

The committee made a study of double check-valve installations and recognized the fact that double check valves alone cannot be relied upon to provide adequate protection against backflow. Therefore, the installation of other devices was specified in conjunction with the check valves for the purpose of dissipating the forces that cause backflow. Referring to Drawing No. A-2, Fig. 1, it will be seen that there is a vacuum-relief valve inserted in the water supply line ahead of the first check valve. Whenever a vacuum occurs in the city's water supply line, this valve will open to supply air to satisfy the vacuum, thereby reducing the negative pressure on the inlet side of the check valve.

Again referring to Drawing No. A-2, it will be seen that a differential pressure-relief bleeder valve is connected into the spacer between the two check valves with a control line connected into the main supply line ahead of the first shutoff gate. This valve (which is power operated by water pressure) opens to atmosphere when the water pressure in the main drops below the pressure in the spacer between the checks, thus allowing the excess pressure to bleed off. This valve is set to operate on approximately a 1-lb differential but its action must be retarded so as not to be affected by water hammer.

The purpose of these two devices is to maintain an equalized pressure on both sides of the first check valve so that there will be no force to cause backflow through that valve if it leaks or is defective. Backflow protective devices for smaller services must incorporate these principles and in addition must have three checks, or their equivalents.

The latest development, in equipment for protection against backflow, is a device incorporating a zone of reduced pressure in the line of flow through the device. The chamber between the main barriers to backflow is maintained at a pressure lower than the inlet pressure for all conditions of flow, by means of weighted, spring-loaded, or power-operated check valves, and the differential pressure thus created is utilized to control the operation of a port opening to atmosphere from this central chamber.

The operation of this port has a dual purpose. It will operate to maintain a reduced pressure in the central chamber if leakage occurs into the chamber through failure of first barriers under normal conditions, or through the second barrier under backflow conditions. A small amount of bleeding from the central chamber occurring at intervals during extremes of fluctuation of pressures in the supply main is normal to its operation, and serves to maintain its automatic features in good operating condition. Excessive bleeding, however, indicates failure of the main barriers and the need for servicing.

(2) *Protection at the Wharf.*—All pierhead outlets, on wharves, for supplying fresh water to ships must be protected against backflow (point 2). In every case this means that a protective device must be installed on each individual outlet as it is possible for a ship, tied to a wharf with fresh-water lines from the pierhead outlet aboard, to pump sewage-polluted salt water not only into the supply mains but into the fresh-water tanks of all other ships taking on water at that wharf or into their own. The city is legally responsible for the delivery of fresh water to all ships taking their supplies from its mains and cannot tolerate the pollution of the water supply of one ship by another through water lines being fed from the city mains. These indicants are of common occurrence and have been the cause of much sickness, inconvenience, and loss of man-hours in shipyards all over the United States.

(3) *Pollution Through Fire Lines.*—Domestic water lines and fire-protection lines must be separated as far as possible where there are auxiliary pumps or intakes, or cross connections to a polluted secondary water supply (point 3).

In a large percentage of the plants in Los Angeles the domestic water lines and the fire-sprinkler lines are entirely separate systems using the same source of supply and are required to be maintained separately by the Rules and Regulations of the Department of Water and Power. Backflow protection is required on these fire-fighting lines only where there is equipment or conditions that may cause backflow of polluted water into the city water mains.

In many plants a single system is used for domestic and fire-fighting purposes and is supplied from the city water mains. Such arrangements have been called combined systems. Backflow protection on these systems is required only where local conditions show the necessity for it. In many large plants using a combined water system, and particularly in the Harbor area, auxiliary fire-fighting water pumps with polluted sources of supply (such as salt water) have been connected into the combined systems. These pumps in most cases are inoperative at all times except in case of fire and a dire need for water. In these plants the committee allows the cross connections to be maintained provided a permanent automatic chlorinator, delivering chlorine gas, is connected into the pump discharge or into the lines delivering the auxiliary water supply. The chlorinator must be maintained in a continuously operative condition so that, whenever the auxiliary pumps begin to operate and polluted water starts to flow into the combined water lines, it will open up full force and thoroughly chlorinate all water going into the system. At the end of the emergency operating period the combined system must be thoroughly flushed out with heavily chlorinated fresh water. A fire alarm must be in operation when the polluted water pump is operating; and a water foreman must be in constant attendance to report each instance.

(*4*) *Plumbing Cross Connections.*—The requirements that all plumbing cross connections must be eliminated (point 4) are covered by plumbing ordinances and include such specifications as low inlets to tanks and basins, toilet flush valves without vacuum breakers, and other items which can, and have, caused extremely hazardous conditions where the water piping system has been overloaded. The need for proper design of water piping systems and the elimination of plumbing hazards have been largely ignored by war plant contractors, under the erroneous idea that they were constructing a federal government operated or contractual plant and therefore were above all local ordinances and regulations. These items have been cleared up in the survey.

(*5*) *Pollution Through Processing Water.*—In many plants the drinking water lines are used for supplying water for industrial or processing purposes and are usually connected directly into the processing equipment so as to utilize the main pressure (point 5). In ordinary times when material is available the committee would require a separate system for carrying all industrial or processing water. With the present scarcity of material, however, it is the policy of the committee to allow the use of the domestic water for supplying industrial processes, provided the lines running to the processing equipment are "industrialized" or isolated from drinking water systems by the installation of backflow protective devices at the point of take off, so that, under all conditions of use, water cannot be forced or siphoned back into the drinking water lines.

Such corrections may require the running of a small-size line to supply drinking fountains, lavatories, etc., but, in general, such changes will call for the use of the minimum amount of material that will give the maximum amount of protection.

(6) Color Warnings.—Wherever there are two water systems in a plant, one carrying a safe, potable water used for drinking and other domestic purposes, and the other carrying a polluted, unsafe water (or water which is not protected and might at any time become polluted and unsafe), the committee requires that both systems be painted a distinctive color (point 6) so that plumbers or pipe fitters will not by accident make a cross connection between the two lines. In addition the committee requires that all outlets on the secondary system be posted with a reasonably large placard signifying that the water from that outlet is dangerous and should not be used for drinking purposes. The colors recommended by the committee for this use are solid blue, or blue stripes, for the drinking water lines, and red for the polluted lines. On the waterfront, maritime or naval standards may be used and are also recommended.

Proctorship Supervision.—An organization of water foremen for each premise, to supervise a unified plan of water protection, was started early in the program (point 7). The plan was to select, or have selected, from each plant or premise surveyed, one man or several men who would be thoroughly familiar with, or who would make themselves familiar with, the entire water piping system on the premises where they were employed. The plant engineer, or one of his pipe foremen, would be the logical man for the post. These men were to be made responsible for the purity of the water on the premises and were to see that no new cross connections were made on the premises, that all new installations of water piping systems were in accordance with existing laws and regulations, and that in those plants governed by point 3, where emergency fire-fighting connections are allowed to exist, all the precautions for maintaining the purity of the drinking water were observed. This organization has proved quite satisfactory, and has since been made a requirement in all plants by the State Board of Health.[2]

SUMMARY

Approximately 50,000 cross connections had been eliminated in Los Angeles by December 1, 1944, representing sizes from 1 in. to 12 in. in diameter at a total cost well over $3,000,000 to the consumer. Since the war this program has embraced practically all the defense plants and military establishments in the Harbor area and many such installations in other parts of the city. It is gratifying to note that all local Army, Navy, Coast Guard, and defense plant organizations are supporting this program. The War Production Board has approved the use of critical materials as required.

The committee is cognizant of the fact that the situation in Los Angeles is not unique but that conditions are duplicated in every war industry center. By adhering to its cross-connection control and elimination program, the committee hopes to make the city the safest place for industrial and other workers in the United States.

DISCUSSION

Roy O. Van Meter,[9] Esq.—The cross-connection control and elimination program in Los Angeles has been described by Mr. Hayes in a comprehensive manner. The subject is so broad that many interesting problems could be included. The City of Los Angeles did not embark on a survey to enumerate the cross connections but rather to eliminate all cross connections that were found. The surveys were started on a piecemeal basis. A certain critical area was laid out for surveys, a single property in the area was inspected, orders to eliminate the cross connections were issued, and the inspectors diligently prosecuted the case until every cross connection was eliminated or corrected. This procedure sounds easy, but in practice it resulted in many painful experiences.

Mr. Hayes has described the formation of the Los Angeles Cross-Connection Control Advisory Committee and also the problems confronting the committee prior to and after the outbreak of World War II. The permanent chairman of the committee had at his command just three trained engineers on cross-connection control work at the time the Los Angeles Harbor survey was started. The Department of Building and Safety provided six plumbing inspectors untrained in cross-connection control work and later increased the number to eleven, after the first group had become familiar with the work.

To complete the survey as soon as possible and to utilize the trained men to the fullest extent, the work, legal orders, and other features of the survey were standardized as much as possible. In general, the survey of a given area is conducted by the inspector in nine steps as follows: (1) A surface map is prepared; (2) file records are made on service cards; (3) the owner of the area is informed of the problem; (4) an underground location survey is made; (5) a legal order is prepared; (6) the legal order is presented to the owner; (7) any necessary steps are taken to enforce the legal order; (8) corrections having been made, the area is reinspected; and (9) final inspection having been approved, the case is closed.

(*1*) *The Map.*—A tracing of the area to be surveyed is made from a district sheet provided by the Department of Water and Power. The scale is 100 ft to the inch, and shows the location and size of the street mains; the locations, numbers, sizes, and serial numbers of the water services; the property lines; the street locations; and street names and numbers.

(*2*) *Service Cards.*—Information from service cards is then obtained. Each card (on which are listed meter number and size, owner's name and address, collection name and address, when the meter was set and turned on or off, and other pertinent data) is checked against information obtained in the field.

(*3*) *Informative Visit.*—Contact is made with the owner or manager of the premises and a full and complete detailed explanation is given of the historical background; the prevalence of cross connections, water-borne diseases, water-borne disease epidemics; the formation of the Cross-Connection Control

---

[9] Chf. San. Inspector, Bureau of Water Works and Supply, Los Angeles, Calif.

Advisory Committee and its powers and duties; federal, state, and local laws; rules and regulations; enforcement policies; the seven-point program of cross-connection control and elimination; types of cross connections normally found; methods of control and elimination; duties and liabilities of the owners or managers; the type of educational and cooperative campaign the committee is conducting; and the need for making an inspection of premises. After the introductory talk, permission to make the survey is requested; the manager is also asked to furnish a competent engineer or foreman who is familiar with the water system to help on the survey. Blueprints are sometimes found helpful; but, in every case, the information on them must be proved.

(4) *Underground Location Survey.*—A physical survey is made of every foot of exposed piping and the underground system is checked as accurately as possible. All lines are sketched on the tracing in the field. A water-use survey is then made to determine whether there are any cross connections or conditions that might tend to pollute the drinking water system.

(5) *Preparation of the Legal Order.*—In writing the legal order to eliminate the cross connection, the inspector must present to the assistant engineer in charge of the field work a summary of his findings together with sketches, blueprints, and piping layout. At this conference each cross connection is reviewed and classified as thoroughly as possible, and special cases are treated as independent problems. After deciding on the proper procedure to be followed in each case, the inspector writes his order using a standard wording form that has already been determined. Special wording may be used when existing wording forms do not apply. After the order is written, it is again checked by the assistant engineer. Then it is reviewed by the engineer in charge of field work; and finally the inspector must demonstrate the soundness of the order to the engineer while the two are reviewing the work together on the premises. If the order displays a good sound sanitary engineering basis, it will be approved for service.

(6) *Presenting the Legal Order.*—The legal order is then issued to the owner or manager instructing him to eliminate or correct the insanitary conditions. The legal order lists the cross connection or condition; location; proposed method of elimination; length of time for compliance; instructions as to what to do in case an extension of time is necessary; the laws, rules, or regulations that have been violated; complainants or enforcement agencies involved; and defendants and their duties and obligations during period of compliance.

(7) *Enforcing the Legal Order.*—Pressure is then brought to bear on the owner or operator to gain compliance as soon as possible. This may take the form of a recapitulation of the explanation given at the original conference (step (3)); the presentation of copies of the laws involved; conferences with keymen; letters from the city attorney regarding legal status; letters from the city health officer certifying the need for immediate compliance to help the management in efforts to gain priorities; orders from the Industrial Accident Commission, Naval and Army Security Officers, and other interested agencies; reinspections; etc.

(8) *Final Inspection.*—A final reinspection is made after all the work has been completed.

(9) *Closing the Case.*—The completed orders together with the maps, sketches, field notes, etc., are filed for future use as the War Department requires a continuing inspection of all defense plants.

The cross-connection problem was recognized as a health menace by public health officers several years prior to 1919. In that year, New Hampshire passed a law prohibiting the maintenance of such connections. Between 1920 and 1930, many similar laws were enacted. The problem received official national recognition in 1930, when the surgeon general of the United States issued a directive to all health officers, in which he ordered the outright elimination of cross connections or the installation of "* * * modern protective devices approved by the State Department of Health and installed and operated under the direct control of that Department." Cross connections are not effectively eliminated by the mere passage of laws or by surveys such as the $1,000,000 survey in Chicago, Ill., after the amebic dysentery outbreak in 1933; the $1,081,830 survey conducted in Cleveland, Ohio, in 1942; or the cross-connection survey made by the U. S. Public Health Service and the Works Progress Administration of all federal buildings located in Detroit, Mich., and New York, N. Y., in 1936 and 1937—unless such surveys are followed up by the issuance of individual orders to make necessary corrections; and, what is far more important, these orders must be enforced.

To those who have been endeavoring to control the cross-connection problem, it has become quite obvious that the situation has been growing worse instead of better. This is true for at least seven reasons, as follows: (*a*) Failure to pass control laws, (*b*) failure to enforce laws, (*c*) failure to publicize the problem, (*d*) failure to control the design of water supply systems, (*e*) failure to standardize and codify good practice, (*f*) failure of management to recognize the problem, and (*g*) failure of the engineer to promote good practice.

(*a*) *Control Laws.*—The failure of federal, state, and local lawmakers to pass cross-connection control laws—or rather cross-connection control laws that are uniform, specific, and at the same time understandable—is a contributing cause of the present situation. In most cases, engineers make the preliminary draft of the laws, after which the draft is referred to the attorneys for a redraft. When the engineers again see the draft, they often cannot recognize it as the product of their efforts. Therefore, they abandon the effort in disgust; the draft is approved by the lawmakers and codified. When the enforcement officer tries to enforce the provisions of the law, he is told by the attorneys that nothing can be done because the law contains too many loopholes and that a conviction could not be secured. In other words, the attorneys would have used the word, "may," where they should have used the word, "shall." Instead of being specific and describing the cross connection involved, the attorneys are vague to the point of ambiguity. Again, the attorneys fail to realize that the proper control of each cross connection is just as important in the problem of health and sanitation as is the determination of an individual stress in the design of a bridge truss.

(*b*) *Law Enforcement.*—The failure on the part of federal, state, and local law enforcement agencies to enforce such laws as are on the books—either because of negligence, ignorance, or fear of political pressure groups—is another contributing cause of present conditions.

(*c*) *Publicity.*—A third cause is the failure on the part of all concerned to publicize the cross-connection control problem. This results from the fear of enforcement officers that they will be criticized because such a condition was allowed to exist, the fear of political reprisals by financially interested pressure groups, and the fear of criminal and civil actions which might be filed against enforcement officers, cities, or utilities (both public and private) for past failure to perform duties and obligations properly. The cross-connection control problem is just as widespread and just as important as the syphilis problem, for example, and the sooner the public recognizes that fact and publicizes the cause and the cure, the sooner the situation can be controlled.

(*d*) *Design Controls.*—Federal, state, and local health authorities fail to recognize the need for specific regulations governing the design of water piping systems, the use of water in all its phases, and the continuing inspection of water systems and water uses. Little, if any, effort has been made to prevent either the improper design of water systems or the overloading of existing systems. The overloading of existing water systems presents one of the greatests hazards in cross-connection control. In one plant a sustained vacuum of 16 in. of mercury was recorded for a period of 5 min in the water system on the second floor. The operating head during the daytime was 5 lb per sq in. in the system on the first floor.

(*e*) *Good Standard Practice.*—Federal and state public health authorities fail to set up a "uniform practice code" for the elimination of cross connections, the testing of backflow protective devices, and the certifying of modern backflow protective devices. Everyone, without regard to authority or fitness, seems to have a voice in making decisions, and local health enforcement agencies are criticized and crucified if they propose any advanced ideas. In most cases the only approved method is the obsolete double check-valve assembly proposed about 1925. The principle of installing vacuum breakers and pressure differential releases on every pressure-operated backflow protective device should be universally adopted. Inventors, designers, manufacturers, and others are afraid to spend their money to develop new ideas for modern backflow protective devices because they know they will not be able to recover their money or because they fear that they will be accused of promoting a device on which they have a monopoly. If the standards were made high enough, and were enforced, many devices would be developed. There is a growing demand for dependable equipment.

(*f*) *Responsibility of Management.*—Management fails to give due consideration to the cross-connection control problem, and is often willing to expend large sums of money for the installation of water systems without consulting local authorities regarding sanitary engineering requirements. The fault for this condition lies with the enforcement authorities rather than with the plant management. The authorities have assumed that the management has as much knowledge of the subject as experts. This is especially evident in the large industrial plants where extensive changes have been ordered. After the reasons for the required changes have been explained, the management has usually concurred and has cheerfully ordered the work completed. In several cases the work order has involved the expenditure of more than $50,000 for a single area.

(*g*) *Responsibility of Engineers.*—Engineers, individually and collectively in their associations, fail to give more than lip service toward solving the problem. The individual plant engineer tries to establish a record for economy. Either consulting and designing engineers are not familiar with water piping and cross-connection problems, or they deliberately fail to incorporate in designs the necessary safety factors required to insure a safe and potable water supply. The associations have made studies and recommendations; but, as yet, they have not made insistent efforts to see that the results of their studies are incorporated in a "Uniform Water Piping and Cross-Connection Control Code."

Summary.—So far as cross-connection control is concerned, enforcement officers have conspicuously failed in carrying out their sworn duty—that is, the safeguarding of public health; the formulation of equitable laws; and, what is far more important, the enforcement of all laws in a uniform manner without fear of political pressure groups and without favor to minority groups.

ROBERT P. LOWE,[10] ASSOC. M. AM. SOC. C. E.—The difficulties that must be surmounted to produce an effective program for elimination of cross connections are given in this paper. The formation of the Cross-Connection Control Advisory Committee is one solution to the diversity of interested jurisdictions which have hindered vigorous action against this recognized danger to the public health. Therefore, the ability of the City of Los Angeles to combine the jurisdictions of the Building and Safety Department, the Health Department, the Water and Power Department, and the Board of Mechanical Engineers for this specific purpose is commendable. A number of cities have made extensive surveys, but nearly all have resulted in very little actual elimination on a large scale, because of complications in authority which were not entirely overcome. This condition will continue to exist unless more authority can be granted under one jurisdiction, as the Los Angeles solution is not always possible.

It is obvious that considerable educational work is necessary to indicate the urgency for the elimination of the cross-connection menace which is often not realized by the layman nor even by the average civil engineer who is not associated with the sanitation field. This was quite evident on a cross-connection elimination survey prosecuted by the War Relocation Authority at its Centers in 1943 and 1944. In many cases plumbers were found to be most aware of the conditions, but they could not control the allocation of time and funds for the changes. Action by the sanitary engineer in the Health Section finally overcame most of this difficulty. Removal was obtained in practically all cases by persistent check ups with renewed emphasis of importance to every one in direct authority.

The condition at the Army fort in the Los Angeles Harbor area was no doubt an extreme case for army installations. As the Centers for the War Relocation

---

[10] San Engr., War Relocation Authority, Washington, D. C.

Authority are built on army camp style, they can be compared very easily with the usual cantonment type of installation for troops. This consists of central block latrines and mess halls that centralize and simplify plumbing installations. Very little trouble was found with these installations. In contrast, the Center hospitals were found to be the source of about 90% of cross connections of all types. A few were found at sewage treatment plants and in repair shops. Strict control of hospital plumbing can eliminate the largest source of possible water supply contamination at most army installations of the cantonment type.

The Public Health Service Drinking Water Standards that were adopted on September 25, 1942, raised the requirements for drinking (and culinary) water provided by common carriers for the use of passengers carried in interstate traffic. These standards recognize the seriousness of the cross-connection menace and emphasize responsibility for potable water throughout the distribution system. In the past, great stress has been placed on the source of supply and purification plant control; therefore it appears that modern water purification has become inconsistent with distribution system control. This fault does not lie with any one group. Instead, it is a jurisdictional problem that is clearly indicated by the formation of the Los Angeles Cross-Connection Control Advisory Committee.

Conclusion.—All indications point to the fact that improved distribution control is necessary before present water-purification standards will be consistently beneficial. War, with its necessity for speed and temporary installations, has focused more importance on the seriousness of the cross-connection problem, and there seems to be little doubt that the postwar period will see action on a larger scale. However, it appears that legislation and educational methods on a state-wide basis will be necessary for uniform control, as the jurisdictional difficulty has proved to be slow and almost insurmountable in most instances.

Harry Hayes,[11] Assoc. M. Am. Soc. C. E.—Mr. Van Meter's indictment of the apathy of public officials in prosecuting cross-connection control is no longer applicable to the City of Los Angeles. There has been such apathy in the past, however; but, after a change in personnel and an intensive program of education, an active spirit of cooperation has become evident among all city officials concerned with the elimination of cross connections. Several of these officials have undertaken aggressive programs in their respective spheres of influence.

The Army post mentioned by Mr. Lowe is not a new installation, but a permanent post constructed many years ago. Almost all the plumbing fixtures were old in style and constituted dangerous cross connections. The water system was heavily overloaded and partial vacuums were a common occurrence. These conditions, together with many cross connections of long standing, created a hazardous health problem.

Since 1945, there has been a notable addition to the cross-connection control program in the City of Los Angeles—the establishment of a $50,000

---

[11] Asst. San. Engr., Dept. of Water & Power, Los Angeles, Calif

Foundation for Cross-Connection Control and Research by the University of Southern California, conducted under the direction of the dean of engineering. A separate laboratory building has been constructed and equipped under the auspices of this foundation for the complete testing of all backflow-prevention devices, from the smallest size, to and including 12-in. pipe sizes. This Foundation began its work by conducting rigorous research into all conditions of cross-connection control and backflow-prevention devices, and it is anticipated that the findings of this body will constitute a source of impartial and authoritative information on all such matters. In addition, a plumbing laboratory has been established to determine standards for backflow devices used in connection with standard plumbing.

COMPUTING COAGULANT REQUIREMENTS IN SLUDGE CONDITIONING

BY A. L. GENTER,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. PAUL D. MCNAMEE, D. L. MCLEAN, K. FRASCHINA, WALTER H. BROWN, JR., AND A. L. GENTER.

SYNOPSIS

The practice of partly dewatering sewage sludges in continuous vacuum filters is relatively recent. The procedure for estimating the initial cost of such an installation for different types of sludges is comparatively simple. It involves estimating the tons of sludge solids to be disposed of during each operating day and the capacity and dimensions of the component mechanical elements of the filtration equipment. The mathematical basis for the latter factors has been supplied by rather extensive experience with such equipment.

However, when it comes to the more important item of predicting the annual operating charges involved in using this equipment, a logical mathematical basis is lacking. This is due to the fact that experience with such filters has demonstrated the necessity of using chemical reagents to render all typical sludges sufficiently curdled or coagulated to permit their rapid draining under suction. This experience has shown that the sludge demand for such reagents varies greatly with various types of sludges in different plants; and, even in the same plant, filter yields are largely a function of the amount of coagulant added to the sludge, providing the drum speed of the continuous filter is adapted to certain ranges of coagulant dosage.

Empirical knowledge of these items relating to chemical requirements has been gained by methods of trial and error and involves assumptions that need clarification by mathematical analysis. At times these assumptions have been disappointing from the standpoint of annual operating costs. In quite a number of plants the cost of chemicals per ton of sludge solids treated is an extremely expensive item. Instances are also known in which such filters have been installed and then either abandoned or partly substituted by less expensive methods of sludge lagooning, sand-bed dewatering, or trucking of liquid sludge

---

NOTE.—Published in March, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr., Baltimore, Md.

to neighboring farm areas because the annual operating charges for chemicals and incidental filter upkeep were unexpectedly high.

The objective of this paper is to present some evidence of a mathematical relationship between the quantities of chemical reagents demanded by various sludges and certain basic sludge assays. Such a relationship should accomplish several useful purposes:

(*a*) It should supply an explanation of where chemical coagulants go in dosing typical sludges;
(*b*) It should enable a designing engineer to select the most economical method of sludge processing and disposal for given local conditions;
(*c*) It should enable the plant superintendent to determine what may be done to improve the economics of sludge conditioning and filtration in his plant; and
(*d*) It should stimulate further investigation of the factor presented herein relating to the influence of volatile matter on coagulant demand.

As ferric chloride remains the most effective coagulant—that is, produces the best sludge floc with the least amount of chemical—the following studies relate particularly to this compound. Other coagulating aids and substitutes, such as lime, chlorinated copperas, and ferric and aluminum sulfate, are also considered.

Review of Established Pertinent Facts

Experience has already taught the following pertinent facts about sludges and their liquid requirements for chemical coagulants:

(*a*) The major fraction of all sludges is the water that must be strained from the solids by coagulation and filtration;

(*b*) The minor fraction of sludge solids consists of organic and inorganic matter, which are expressed approximately in terms of volatile matter and ash by the combustion of the dried sludge;

(*c*) The volume of the major fraction of water depends primarily on the specific gravity of the solids, which in turn depends on the ratio of organic to mineral matter in the sludge solids;

(*d*) The organic fraction of sludge solids is destroyed partly by bacterial action during storage of freshly collected raw solids, and it is destroyed materially in controlled sludge digestion. This action not only reduces the ratio of organic to mineral matter, but it also increases both the water fraction and the solute concentration of such decomposition products as the bicarbonates of ammonium and calcium, in the water fraction. Instances are known in which the bicarbonates present in fresh raw sludges increase almost one hundred times through digestion. Measured in terms of percentage on solids present, an increase of ten to twenty times is not uncommon.

SLUDGE-WATER DEMAND FOR FERRIC CHLORIDE

Studies of the effects of elutriating decomposing sludges by the writer,[2] C. E. Keefer, M. Am. Soc. C. E., and Herman Kratz, Jr.,[3] at Baltimore, Md., and P. D. McNamee[4] at Washington, D. C., have disclosed and confirmed the fact that the water associated with the solids in a sludge has a specific chemical demand of its own which may be regarded as distinct from that of the solids. This water or "liquid demand" is largely a function of items (*c*) and (*d*).

The addition of ferric and aluminum salt solutions to solutions of ammonium and calcium bicarbonates causes definite chemical reactions; that is, the liberation of carbon dioxide gas and the formation of precipitates of ferric and aluminum hydroxide. According to the combining weight relations of this reaction for ferric chloride:

$$\underset{(162.21)}{FeCl_3} + \underset{(3 \times 79.06)}{3NH_4HCO_3} \rightleftharpoons \underset{(106.86)}{Fe(OH)_3} + \underset{(3 \times 53.5)}{3NH_4Cl} + \underset{(3 \times 44.01)}{3CO_2} \quad \ldots(A)$$

and

$$\underset{(2 \times 162.21)}{2FeCl_3} + \underset{(3 \times 162.12)}{3Ca(HCO_3)_2} \rightleftharpoons \underset{(2 \times 106.86)}{2Fe(OH)_3} + \underset{(3 \times 111)}{3CaCl_2} + \underset{(6 \times 44.01)}{6CO_2} \quad \ldots(B)$$

In these reactions one need be concerned only with the numerical weight relation of the reaction between the ferric chloride and bicarbonate ion. As the standard method of measuring bicarbonate alkalinity (HCO_3^-) is in parts per million of calcium carbonate, $CaCO_3$, the weight relationship between $FeCl_3$ and HCO_3^- shifts to that between parts per million of calcium carbonate, and parts per million of ferric chloride. In reactions *A* and *B*, $2FeCl_3 = 6HCO_3^- = 3CaCO_3$. Therefore, 1 ppm $CaCO_3 = \frac{2}{3} \times \frac{162.21}{100}$ $FeCl_3$ $= 1.08$ ppm $FeCl_3$.

As it is common practice in sludge conditioning to measure the chemicals used in terms of sludge solids—namely, as the percentage of sludge solids—the alkalinity should be measured in the same manner. The percentage alkalinity should then be multiplied by the foregoing constant 1.08 to arrive at the liquid demand for ferric chloride in terms of the solids.

Let Y_1 = alkalinity expressed as percentage of solids, then

$$Y_1 = \frac{\text{Percentage of sludge water} \times \text{ppm alkalinity} \times 0.0001}{\text{Percentage of sludge solids}} \quad \ldots\ldots(1)$$

Let X_1 = percentage of ferric chloride required on sludge solids to complete the chemical reactions with this alkalinity. Then,

$$X_1 = 1.08\ Y_1 \quad \ldots\ldots(2a)$$

or

$$Y_1 = 0.926\ X_1 \quad \ldots\ldots(2b)$$

---

[3] "The Vacuum Filtration of Elutriated Sludge," by C. E. Keefer and Herman Kratz, Jr., *ibid.*, September, 1934, p. 845.

[4] "Filtration Tests with Elutriated and Unelutriated Digested Solids," by Paul D. McNamee, *ibid.*, September, 1939, p. 764.

Eqs. 2 are the simplest possible formulas of a straight line, expressing the fact that the sludge liquid demand for ferric chloride is a straight-line function of the percentage of alkalinity present on sludge solids.

Solids Demand for Ferric Chloride

As some of the bicarbonates and other solute reagents are undoubtedly trapped within the spongy or capillary porous structure of the wetted sludge solids it is logical to assume that this solid water complex likewise has a chemical affinity or demand for ferric chloride.[5] This is conveniently termed the "solids demand" in order to distinguish it from that of the large fraction of free water in which the solids are suspended. The latter liquid demand must be satisfied largely before additional ferric chloride can reach the solid complexes.

In view of what has already been stated about the influence of the organic-to-mineral ratio of the sludge solids on sludge moisture, the solids demand for ferric chloride should be subject, in some manner, to the same influence. If the solids were entirely mineral, they would require little or no coagulation for vacuum filtration.

Basic Data Used in Determining Solids Demand

If the foregoing statements are fundamentally reliable, it should be possible to estimate approximately the combined liquid and solids demands for ferric chloride with such simple plant data as percentages of solids, water, and volatile matter in a sludge and the parts per million of alkalinity in the sludge water. In plant practice this involves not only reliable statistical averages in sampling and analytical methods but also careful vacuum filter operation. Careful filter operation infers: (*a*) Regulating the ferric chloride dosage so that this chemical is not wasted; (*b*) operating with a filter speed and drum submergence as required by the conditioned sludge; and (*c*) operating with a minimum of filtrate resistance in the filter cloth and in all drainage channels under this cloth. Items (*a*) and (*b*) are quite important in avoiding errors due to frequent faulty addition of any coagulant to a sludge, as well as overflowing sludge that has been conditioned either from a conditioning tank or from the filter itself. LeRoy W. Van Kleeck[6] has emphasized tersely the importance of item (*c*).

With these objectives and items in mind all data presented in Table 1 are purposely selected in order to establish a fairly reliable starting point for evolving a factor for the sludge solids demand. The other incidental objective was to choose data representing geographic variations in plant location, and variations in types of sludges, sludge moistures, alkalinities, volatile content, and ferric doses. The number of plants collecting sludge alkalinity data is not very large and in some plants the tabulation of such data does not extend over several years.

The largest raw sludge filtration plant publishing complete data in the United States is the Minneapolis-St. Paul (Minn.) plant (line 1, Table 1). It is also outstanding in careful filter operation. The essential assay figures for this plant are taken from analytical results for 1941 by George J. Schroepfer,[7] Assoc. M. Am. Soc. C. E. As both lime and ferric chloride are used at this plant, the equivalent ferric dose (Col. 9, Table 1) is determined by the method developed in this paper under the heading, "Other Coagulants: Lime and Ferric Chloride."

[a] Ratio by weight. [b] Percentage of alkalinity on solids. [c] Computed. [d] Minneapolis-St. Paul plant.

Whereas the Minneapolis-St. Paul data are outstanding in effecting coagulant economies resulting from careful operations in the filtration of primary raw sludge, the writer regards Springfield, Mass. (line 3, Table 1) as the pacemaker in formulating similar methods of filtering elutriated digested primary sludge for populations exceeding 100,000. Line 3, Table 1, gives data for the entire year of 1941 (the first year of operation at Springfield).

The data of line 2, Table 1, were selected primarily for comparison with the data in line 3 and do not represent the entire corresponding average for the year at Hartford, Conn. A particular time was selected during which the averages showed identical solids in the case of Hartford and the year's average at Springfield (Col. 4, Table 1), but showed lower alkalinity, volatile content, and ferric dose (Cols. 2, 5, and 9, Table 1) at Hartford. It was assumed that the lower values for alkalinity and volatile percentage with identical solids content at Hartford accounted for the lower ferric dose during the particular time and should, therefore, provide extreme low points for such values in plotting the graphic results for Fig. 1.

The averages in lines 4 and 5, Table 1, like lines 1 and 3, are the averages for the entire year of 1941 at Winnipeg, Manitoba, Canada, and the Richmond-Sunset treatment plant in San Francisco, Calif. Particular care is used in conditioning the sludge at Winnipeg, and K. Fraschina[8] has emphasized studies undertaken to improve careful operation at the Richmond-Sunset plant.

---

[7] *Transactions*, Am. Soc. C. E., Vol. 110 (1945), p. 194 (and private correspondence).

In a way the sludge filtered at Richmond-Sunset is remarkably different from the others. Operation of this plant involves mechanical preflocculation of the solids suspended in the sewage, single-stage digestion with about 62% destruction of 82% raw volatile matter, and elutriation of both supernatant and bottom solids from the digestion tank.

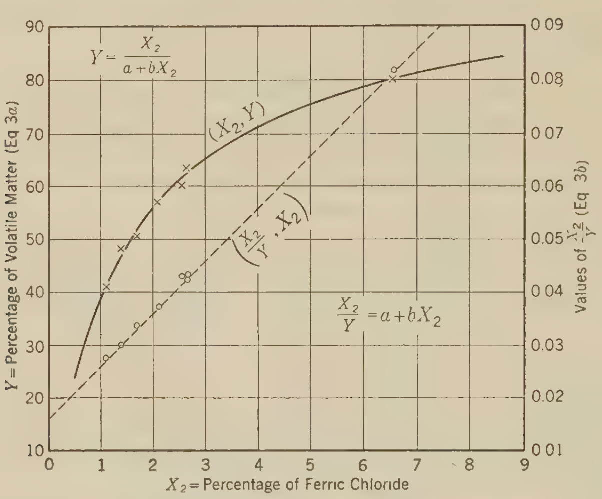

FIG. 1.—VOLATILE-FERRIC CHLORIDE DOSING CURVES

Line 6, Table 1, is chosen to represent about the most difficult type of sludge to coagulate and filter, either with ferric alone or ferric and lime combined—namely, digested mixed primary and waste activated sludge. Such sludges are usually low in solids and high in alkalinity. The sludge shown in line 6 was conditioned with lime and ferric chloride at Ann Arbor, Mich., in 1940 just prior to making some plant-scale elutriation tests. The combined price of the lime and ferric used amounted to the equivalent of about 13% ferric chloride alone, which sum is entered as Col. 9 for this sludge. A large quantity of this sludge was elutriated, conditioned, and filtered with the results shown in line 7, Table 1. Although the data shown are experimental, the writer regards them as characteristic.

Ferric chloride is used alone in conditioning waste activated sludges. However, in larger plants which condition and filter such sludges, alkalinity data are either entirely or largely missing because the ferric dose is primarily regulated by the hydrogen-ion concentration of the conditioned sludge. This is generally about pH 4.3. As such sludges are notably high in water content, considerably more ferric may be used in conditioning them to a pH 4.3 than to a pH 4.9 or pH 5, especially with automatic control of the dosing. Therefore, purely experimental data had to be used for such a sludge in line 8, Table 1. A sludge of high volatile content and low alkalinity was purposely selected to provide an extreme high point for graphic plotting of the influence of volatile matter on conditioning. The sludge was conditioned to about pH 4.9. Like waste activated sludge, the elutriated digested sludges in lines 2, 3, 4, 5, and 7, Table 1, are all conditioned with ferric chloride alone.

---

[8] "Laboratory Control of the Operation of the Richmond-Sunset Sewage Treatment Plant," by K. Fraschina, *Sewage Works Journal*, January, 1940, pp. 95–96.

In Table 1 it will be noted that the variations in volatile contents of the listed sludges are greater than 100%, the variations in solids and alkalinity are 600% and 2,400%, respectively, and the ferric doses vary from about 1.3 to 10.0 times as much—namely, 13%.

FACTOR FOR SOLIDS DEMAND EVOLVED

From the selected data in Table 1 the percentage of ferric chloride used for coagulation of the wetted sludge solids and incidental reactions should be determined with fair practical accuracy by deducting the percentage used for the alkalinity reaction, determined by Eq. 2*a* from the total ferric chloride used. In Table 1 this has been done in Cols. 9, 10, and 11. Col. 11 then shows the percentage ferric chloride on solids used for the volatile-solid complex, which may also be termed the ferric demand of the wetted solids themselves.

When the values of this demand in ferric chloride are plotted on the abscissa axis X_2 (see Fig. 1) against the percentages of volatile matter in the respective sludges listed as ordinate (Y-axis) values, a remarkably regular curve results. As shown in Fig. 1, this is a hyperbolic curve of the type

$$Y = \frac{X_2}{a + b\,X_2} \qquad (3a)$$

which converts to a straight-line equation

$$\frac{X_2}{Y} = a + b\,X_2 \qquad (3b)$$

Plotting the values for X_2 (Col. 11, Table 1) against these values divided by the respective volatile percentages Y (Col. 5, Table 1), as shown in the right-hand side of Fig. 1, results in a straight line. Using the simple method of averages on the six sludges dosed only with ferric chloride, the two constants calculate closely to $b = 0.01$ and $a = 0.016$.

Therefore the straight-line equation for solids demand is

$$\frac{X_2}{Y} = 0.016 + 0.01\,X_2 \qquad (4a)$$

which, multiplied by 100 to eliminate the constant 0.01, converts to $X_2 = \frac{1.6\,Y}{100 - Y}$. As Y is the percentage of volatile matter in the sludge, then $100 - Y$ is nothing but the percentage of ash, which simplifies Eq. 4*a* to

$$X_2 = 1.6\,\frac{\text{Percentage volatile}}{\text{Percentage ash}} \qquad (4b)$$

Eq. 4*b* is another straight-line equation for the solids demand.

The total ferric chloride dose, X, as percentage on solids is therefore the sum of the two straight-line equations (Eqs. 2*a* and 4*b*); that is,

$$X = 1.08\ Y_1 + 1.6\ Y_2 \qquad (5)$$

in which Y_1 is the percentage of alkalinity on sludge solids according to Eq. 1 and Y_2 is the ratio of volatile matter to ash in the sludge.

Col. 12, Table 1, shows the doses calculated according to this equation for the various sludges listed.

FACTS REVEALED BY EQ. 5

As a result of the reagents involved, Eq. 5 reveals a definite chemical influence in sludge conditioning. As it is primarily based on alkalinity assays and water-to-solids ratios this formula measures a definite reaction with ferric chloride and the alkalinity of the total water—namely, the free water and the residual within the sludge solid capillary structure. Such chemical reactions obviously involve basic and experimental constants.

In order to relate the ferric dose required for alkalinity to the sludge solids present in the first part of Eq. 5, it is necessary to use the ratio of water to solids. This ratio is evidently determined by the ratio of volatile matter to ash in the sludge solids in the second part of Eq. 5. This is thoroughly logical and may be regarded as a confirmation of the empirical law relating to the Mohlman sludge index, used for measuring the concentration of solids from mixed liquors, which states that this index correlates closely and varies inversely as the ash content of the sludge.[9] In reality all sludge solids complexes suspended in water may be said to have a sludge index.

Therefore it appears that, at present, the constant 1.6 is the only empirical factor or constant in the equation. It should be emphasized that the value of this constant may increase beyond 1.6 with dosing increments purposely used to increase filter yields or to produce minimum cake moistures for the heat drying of some sludges. Instances may be cited in which the constant is practically double the value herein evolved. Conversely there are instances of very low filter speeds (8 min per revolution), heavy sludge, and low dosage, for which this constant becomes practically the same as the first constant, 1.08.

For general mathematical purposes, Eq. 5, when ferric chloride and alkalinity assays are used, evidently becomes

$$X = 1.08\ Y_1 + K\ Y_2 \qquad (6)$$

in which K is an empirical constant which probably varies from the value of the first constant (1.08) to approximately three times this value. From the selected data for careful dosing it is about 1.5 times the minimum value—namely, 1.6.

The range of values for this constant, below 1.6, may be demonstrated to be representative of partial or incomplete ferric dosing of heavy sludges of relatively low alkalinity. The less complete the alkalinity and coagulation reactions are the slower will be the resulting filtration rates. This is quite evident from examination of the numerous filter yield graphs that have been published since 1933. Mr. Schroepfer[10] clearly shows this effect on raw sludge dosed with progressive increments of lime and ferric. From the data in Table 1, Item 1 (Cols. 5, 6, and 11), this constant for the 1941 Minneapolis-St. Paul data is computed to be about 1.35 when using the price equivalent of ferric alone. This certainly indicates partial, and therefore most careful, dosing.

---

[9] "Problems and Trends in Activated Sludge Practice," by Robert T. Regester, *Transactions*, Am. Soc. C. E., Vol. 106 (1941), p. 176.

Particle Size.—In revealing reactions largely of a chemical nature, Eqs. 5 and 6 ignore particle size—that is, the presence of finely dispersed colloids in any sludge. This is entirely logical. It would be unreasonable to assume that the various sludges listed in Table 1 contained particles or sludge aggregates of the same size.

Very finely divided solids in sewage will settle to a thin sludge having a high water-solid ratio. With bicarbonates present in the water this high ratio automatically increases ferric demand in terms of the solids. An outstanding example of this statement will be found in Mr. McNamee's filtration tests on the liquor associated with digested sludge.[4] Such supernatant liquor is rich in finely divided solids. In Mr. McNamee's paper[4] the total solid content was reported as 0.4% dispersed in a very high water-to-solid ratio (249 to 1) with a total alkalinity of 3,630 ppm in the water, and a volatile-ash ratio of 1.26. On the basis of Eq. 5, the liquid alkalinity demand for ferric chloride was 98% and the solids demand only about 2%, making a total of 100% ferric dose on solids present. This is remarkably close to the total optimum requirements (105%) for completed alkalinity and coagulation reactions established by properly analyzing the McNamee filtration data. With 0.38% actual sludge solids (which is practically the 0.4% total solids listed by Mr. McNamee), the calculated values total 105% ferric chloride. This is regarded as a rigid test for the validity of Eq. 5.

Floc Size.—This is an important factor in obtaining good filter yields at careful dosing rates and will be briefly dealt with hereinafter.

Eq. 5 Applied to Other Experimental Results Not Tabulated

Usually the best operating control for conditioning sludges is made by frequent laboratory checks with Buechner funnel filters and about 200 g sludge samples of the dosed sludge going to the filter. The laboratory-tested samples should dry to a vacuum break in less time than that required to complete a normal filter drum revolution. More informative, and therefore more reliable, checks are made on sludge samples dosed in the laboratory over various ranges of ferric chloride additions, and the Buechner filter rates in grams of dry solids per minute plotted against the percentages of ferric added are as shown in Fig. 2.

Sludges dosed for actual filter practice require more coagulant to produce sufficiently dry filter cake in a given time than do sludges tested in the laboratory. What may be a dose optimum in laboratory testing will be less than optimum in field practice. There are numerous logical reasons for this: Laboratory testing is essentially small batch filtration, usually done more carefully and at a higher vacuum than in field practice; sludge drainage is directly downward instead of upward against a revolving drum surface and therefore without cake scouring; and the dosed sample is not as long in reaching the filter with the consequence that there is no destruction of the coarsened drainable floc structure produced by either partial or complete coagulation. Therefore, laboratory filtration rates for 4 or 5 min of drying time may be pushed to considerably lower partial ferric doses than in the field, where coarse floc may be initially produced but cannot always be maintained for many reasons.[8,11,12,13]

---

[10] *Transactions*, Am. Soc. C. E., Vol. 110 (1945), Table 12, p. 201.

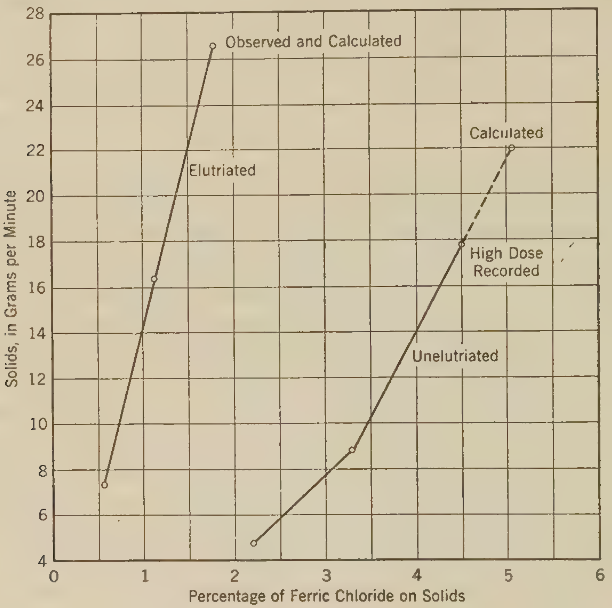

FIG. 2.—FILTER YIELD, FERRIC CHLORIDE DOSING CURVES (MCNAMEE TESTS)

As Eq. 5 accounts for complete alkalinity reaction and probably complete volatile coagulation, the confirmation of this equation by Buechner filter tests has two requirements—the calculated dose should be somewhere near the upper end of the plotted graphs (that is, near the optimum dry solid yield rate), and it should fall directly on such graphs. Obviously reliable sampling, sludge assays, testing technique, and the average of a number of tests are best for this purpose.

Mr. McNamee's laboratory studies of digested supernatant were adopted as the initial test of the validity of Eq. 5. In his published work,[4] the course of alkalinity removal from digested sludge through elutriation and the effects of this removal on sludge conditioning were followed for the first time. His tables showing seventy-two coagulation and filtration tests on unelutriated and elutriated sludges were next used in preparing graphical data for Fig. 2 and as a test of the validity of Eq. 5. Here the graph points of average low, medium,

and high doses used are plotted against average solids yields for the thirty-six filtration tests on straight digested sludge and the thirty-six tests on the elutriated sludges. At practically completed alkalinity and coagulation reactions the equation was found valid, and the dose calculated from the average assays of the unelutriated and elutriated sludges fell on the respective graphs near the maximum recorded yield points.

The essential analyses for the digested sludge at Cranston, R. I., before and after elutriation and comparisons of the computed doses are presented in Table 2. This new plant[14,15] produces digested mixed primary and waste activated sludge, which for obvious reasons has a high ferric chloride demand. In Fig. 3 and Table 2 the optimum graphed doses are remarkably close to the calculated doses.

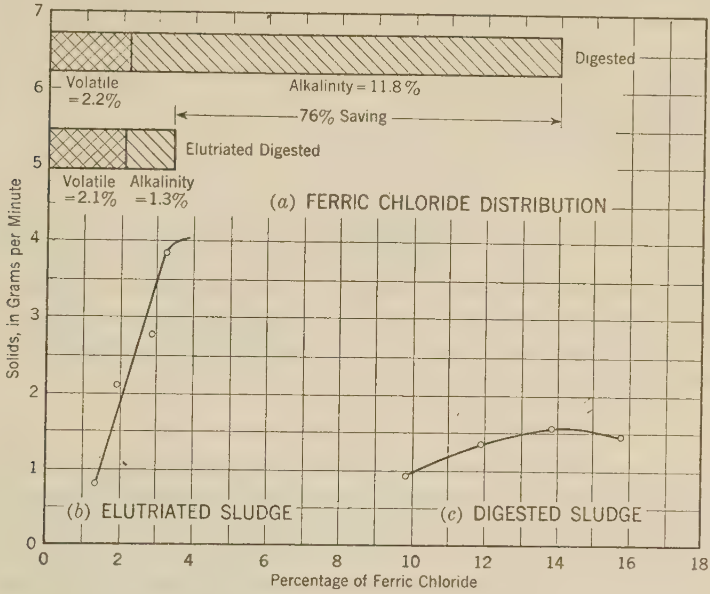

FIG. 3.—FILTER YIELD, FERRIC CHLORIDE DOSING CURVES, CRANSTON, R. I.

Instances of laboratory tests on other sludges may be cited. In some of these the calculated dose is somewhat less than the recorded optimum, indicating a somewhat higher optimum constant than 1.6. However, in all cases thus far recorded the calculated doses fall on the recorded graphs and are therefore regarded as distinct point indexes of near optimal doses in laboratory testing and a reasonable pacemaking low dose in actual practice.

Similarly, in the exhaustive field tests made and recorded by Messrs. Keefer and Kratz,[3] Eq. 5 demonstrates clearly, through point indexes, the relative positions of the various graphs (similar to Figs. 2 and 3) for all sludges dosed

with ferric chloride. These field tests, made in 1933 and 1934, were run in a manner very similar to laboratory tests—that is, on different batches of large samples of various sludges within various dosing ranges. Here the effects of various concentrations of dissolved ammoniacal nitrogen in parts per million on coagulant requirements were followed. Through the known ratio of ammonium to total bicarbonates the recorded parts per million of ammoniacal nitrogen produced values for Eq. 5. The various graphs were then located at points near the dose optima recorded.

TABLE 2.—COMPUTATION OF FERRIC CHLORIDE DISTRIBUTION IN ELUTRIATED AND DIGESTED SLUDGE; CRANSTON, R. I.

Description	Elutriated (Fig. 3(*b*))	Digested (Fig. 3(*c*))
Alkalinity (parts per million)	300	2,700
Analysis (Percentage by Weight[a])—		
Volatile matter	57	58
Mineral matter	43	42
Computed Values of $FeCl_3$—		
X_1 (by Eq. 2*a*)	1.3	11.8
X_2 (ratio of volatile to mineral, multiplied by 1.6) (Eq. 4*b*)	2.1	2.2
Total, by computation	3.4	14.0
Total, recorded	3.3	13.9

[a] Water 97.6% and solids 2.4% in both sludges.

EQS. 5 AND 6 AS AN OPERATOR'S GUIDE

From the foregoing observations it is evident that Eq. 5 establishes more of a point than a line on such ferric dosing and yield graphs. Other K-values in Eq. 6 may be established from proper laboratory and field testing. In practice, if the actual average ferric dose is materially in excess of values calculated by Eq. 5, careful Buechner filter tests should be run in the laboratory. Here this equation will be an indicating guide to the approximate dose optimum necessary.

If such laboratory tests indicate the approximate validity of the equation and if plant practice on the same sludge does not, the operator has good evidence that chemical is being wasted somewhere in processing the conditioned sludge. The chief sources of this trouble have been cited.[5,8,12,13]

If laboratory tests denote that much higher doses are required than are indicated by Eq. 5, this should necessitate the graphical plotting of the average of several laboratory tests to determine if the constant K in Eq. 6 should be changed to a value materially higher than 1.6.

Exceptions to Eq. 5.—Such a change in the value of K may be due to the logical exceptions found in sludges containing undue amounts of ferric reducing agents or other coagulant-consuming compounds resulting from industrial wastes. In some cases such waste products may be beneficial and in others distinctly inimical to good coagulant economy. In sludges containing mineral oil wastes, cutting oil with soaps, etc., various emulsions and ferric consuming smears (ferric soaps) can result, thus increasing the ferric demand while adversely influencing dry cake yields. Such atypical conditions do not invalidate

Eq. 5. Some of these complexes may be accounted for through proper laboratory tests and the constant K changed to fit local conditions; or the complexes can be largely eliminated by other methods.

DISTRIBUTION OF COAGULANT REQUIREMENTS IN VARIOUS TYPES OF SLUDGES

In Fig. 3(*a*) the distribution of the portions of the total ferric dose for liquid and solids demand is shown graphically for the sludges tested in the laboratory at Cranston. With the unelutriated sludge, 84.3% of the total dose is used to offset alkalinity alone, leaving only about 16% for the actual coagulation intended. As elutriation displaced most of the alkalinity factor and a small portion of the volatile matter, most of the ferric dose remained for solids demand.

A similar graphical method could be used on the various sludges listed in Table 1. However, such a procedure would not depict the quantity of ferric chloride related to the various quantities of sludge collected and processed in different types of plants.

A more illuminating comparison results when the data are limited to various types of sludges collected from average domestic sewage only. For this purpose the writer has used the amounts of average fresh sludge solids removed by the different treatment methods. Tables of data presented by Karl Imhoff and Gordon M. Fair,[16] Members, Am. Soc. C. E., were extended to coagulation and vacuum filtration and the results are given in Table 3, the ferric chloride distribution for the liquid and solids demand being shown in pounds per 1,000 persons daily.

In calculating the pounds of digested solids on this basis, the writer has assumed in all cases a reduction of 65% of the fresh solid volatile in digestion, and 66% in digestion followed by elutriation, as the latter process removes some volatile and further concentrates the sludge. There is always a loss of some solids through digester supernatant withdrawals, elutriation, and vacuum filtration. Consequently, in Table 3 the average digested and elutriated solids reaching the filters will be found to be somewhat higher than in practice. A good example of this statement is to be found in the 1942 results for Springfield. About 130 lb per 1,000 persons daily of primary solids, of 74% volatile matter, were collected. The percentages of volatile matter reduction in digestion, and through digestion and elutriation, were 65% and 66.3%. The removal efficiency of suspended solids was about 60%. The digested sludge contained 8.5%, and the elutriated sludge 12%, solids compared to 8% and 10% shown in Table 3. The percentage of ferric chloride consumption was identical with that computed in Table 3. However, due to loss of solids in processing digester supernatant, elutriate, and filtrate, the actual ferric consumption was about 0.7 lb per 1,000 persons daily instead of 1 lb shown in Table 3.

The percentage solids (Col. 6, Table 3) and alkalinities (Col. 5, Table 3) in the various sludges are taken from conservative averages collected by the writer. In storing and concentrating primary sludge comprising 72% volatile

[a] In pounds per thousand persons daily. [b] Elutriated with water of 100 ppm alkalinity at an elutriation ratio R of 4 to 1 (countercurrent). [c] Elutriated with plant effluent of 200 ppm alkalinity at an elutriation ratio R of 4 to 1 (countercurrent).

matter and its mixtures with secondary sludges for filtration, the alkalinity (Col. 5, Table 3) can easily exceed the listed values, especially in warm weather. Obviously such sludges of high alkalinity can be benefited by proper elutriation. However, such treatment has not been included in Table 3, since it is not typical practice in the United States.

Mechanically flocculated sludges like those involved at Richmond-Sunset and the new San Diego, Calif., plant are quite light and will probably be found to be somewhat like the graph for Table 3(*c*), with activated sludge when properly digested and thoroughly elutriated.

Although sludges collected from combined sewerage systems may double in quantity the amounts shown in Col. 2, Table 3, the total coagulant and its distribution will not double. In fact for fresh plain sedimentation the Col. 9, Item 1 value may be but little more. This is due to the increase of mineral and decrease in volatile matter in such sludges. This is quite evident at Minneapolis-St. Paul where the percentage of volatile matter in the concentrated raw sludge is actually less than that of the digested sludge at Richmond-Sunset (see Table 1) with the result that the primary sludge at the former plant is very heavy and very easy to condition. The 1941 Minneapolis-St. Paul figure for Col. 2, Item 1 of Table 3, was about double the listed value, that is, 246 lb. As a result of the low dose requirements (see Table 1) the value in Col. 9, Item 1 of Table 3, is 6.15 lb, which is only 8% more than the 5.7 lb listed. If this particular sludge were digested and elutriated the values in Col. 9 for Items 2 and 3 would increase about 60% and become more like the Col. 9 values for Items 5 and 6.

The bar graphs in Table 3 supply illuminating evidence of where ferric chloride goes for the various types of sludges. Where the percentage of alkalinity on solids is relatively low as in the primary sludge, its mixtures, and the elutriated sludges, most of the ferric is used for the solid demand. The reverse is the case with the unelutriated digested sludges in which, despite good mineralization of the solids and lowered volatile-to-ash ratio, the high percentage of alkalinity makes this factor predominant in coagulant requirements.

The graph in Table 3(*c*) certainly indicates that there is little if anything gained in using vacuum filters on digested mixed primary and waste activated sludges of relatively high volatile content without the benefits of elutriation. Due to the light solid content of such sludges it can be demonstrated in several instances known to the writer that more ferric chloride or equivalent ferric chloride and lime per 1,000 persons is used on the digested mixture than would be used on the fresh undigested mixture. For example, by changing the percentage of solids in this digested sludge (Col. 6, Item 8, Table 3) to 2.5, the alkalinity factor (Col. 7) becomes 12.6 lb, which, together with the same volatile factor, totals more than 14 lb of ferric chloride (Col. 9) per 1,000 persons daily. This is 27% greater than the chemical demand shown for the fresh sludge mixture. In this example of digested sludge, the alkalinity demand is almost 90% of the total requirements. It is certainly faulty practice to coagulate such sludges and dewater them in vacuum filters without elutriation. If elutriation is not to be used, it is far better engineering to provide sand-bed filtration.

Volatile Matter Destruction as a Measure of Chemical Saving

The percentage of volatile matter destroyed is identical with the percentage reduction in the volatile-ash ratio through the digestion of any sludge. Although the true significance of this statement has been overlooked, Eqs. 5 and 6 now lend it importance. As the reduction in the volatile-ash ratio of a sludge means a corresponding reduction in ferric chloride demand for this ratio, the reduction in volatile matter through digestion is a direct measure of ferric chloride saved per pound of original volatile matter, providing the resulting alkalinity gain is removed by elutriation. However, as the reduction in ferric demand through this procedure also leaves less solids to be conditioned, the final ferric chloride demand is used on the percentage of original raw solids left. This makes the over-all percentage of ferric reduction, for the remaining volatile-ash ratio, equal to

$$R = 100 - \frac{1}{100} \times \text{Percentage of original raw solids remaining} \\ \times \text{percentage of original volatile content remaining} \quad \text{(7)}$$

For example, in the case of Springfield, the 1941 averages (in either pounds or percentages) showed:

No.	Description	Quantity
1	Raw volatile content (69.5% of which is removed in digestion and 30.5% of which remains)	73.6
2	Ash	26.4
3	Total	100.0
4	Remainder of original volatile content (30.5% × 73.6)	22.4
5	Plus original ash	26.4
6	Total original solids remaining	48.8

Therefore, $R = 100 - \frac{48.8 \times 30.5}{100} = 85\%$ saving in ferric chloride through digestion and elutriation. This can be checked readily through methods previously shown in Eq. 4*b*. Thus, neglecting the original and final alkalinity factors, the volatile-ash, ferric chloride requirements are:

$$\text{Original, } \frac{73.6}{26.4} \times 1.6 = 4.46\%$$

$$\text{Final, } \frac{22.4}{26.4} \times 1.6 = 1.36\%$$

The original ferric chloride requirements are intended for 100 lb of raw solids, whereas the final 1.36% is used on 48.8 lb of solids remaining; namely, 0.66 lb of ferric chloride. This is 3.8 lb less than the original 4.46 lb of ferric chloride required, or 85% saving. This saving is based on keeping the alkalinity factor constant in both instances. As a matter of fact proper elutriation may add to this saving by further reducing this factor.

One particularly interesting feature to be noted about Eq. 7 is the fact that, regardless of the ultimate value assigned to the constant, K (1.6 in this example), Eq. 7 will not be changed.

Calculations for Sludge Elutriation.—Eqs. 5, 6, and 7 reveal the genuine advantages gained by reducing the volatile-ash ratio through digesting the sludge as much as economically possible and then removing the inimical alkalinity factor by sludge elutriation. These two procedures combine to reduce the amount of sludge solids to be handled, size of equipment required for filtration and drying or incineration, annual operating charges for chemicals, power for filter hours, and maintenance, at the same time increasing filter yields and the uniformity of sludge characteristics, and eliminating odor nuisance.

The alkalinity (in parts per million) remaining in the sludge moisture after single-stage, multi-stage, and countercurrent elutriation in two tanks may be computed from the following equations, wherein D is the alkalinity in the digested or stale raw sludge water before elutriation, E is the alkalinity of the elutriated sludge, W is the alkalinity of the elutriating water, and R is the ratio of volumes of elutriating water to the volume of moisture in the sludge: For single-stage elutriation—

$$E = \frac{D + R\,W}{R + 1} \qquad (8a)$$

for n-stage elutriation—that is, repeating the elutriation with fresh water n times at the same ratio R—

$$E = \frac{D + W\,[(R + 1)^n - 1]}{(R + 1)^n} \qquad (8b)$$

and for countercurrent elutriation in two mixing and settling tanks—

$$E = \frac{D + (R^2 + R)\,W}{R^2 + R + 1} \qquad (8c)$$

If the water and sludge are both metered, to obtain the true value of R (the ratio of water to sludge moisture by volume), the metered ratio is divided by the fraction of water present in the sludge.

With the alkalinities D, E, and W determined before and after elutriation, the elutriation ratios, R, used to obtain the alkalinities, E, may be computed by solving for R in Eqs. 8: For single-stage elutriation—

$$R = \frac{D - E}{E - W} \qquad (9a)$$

for n-stage elutriation (each wash)—

$$R = \sqrt[n]{\frac{D - W}{E - W}} - 1 \qquad (9b)$$

and for countercurrent (two tanks)—

$$R = \sqrt{\frac{D - E}{E - W} + 0.25} - 0.5 \qquad (9c)$$

In Eqs. 9, to convert R to the ratio of water to sludge, multiply the estimated values of R by the fraction of water present in the sludge.

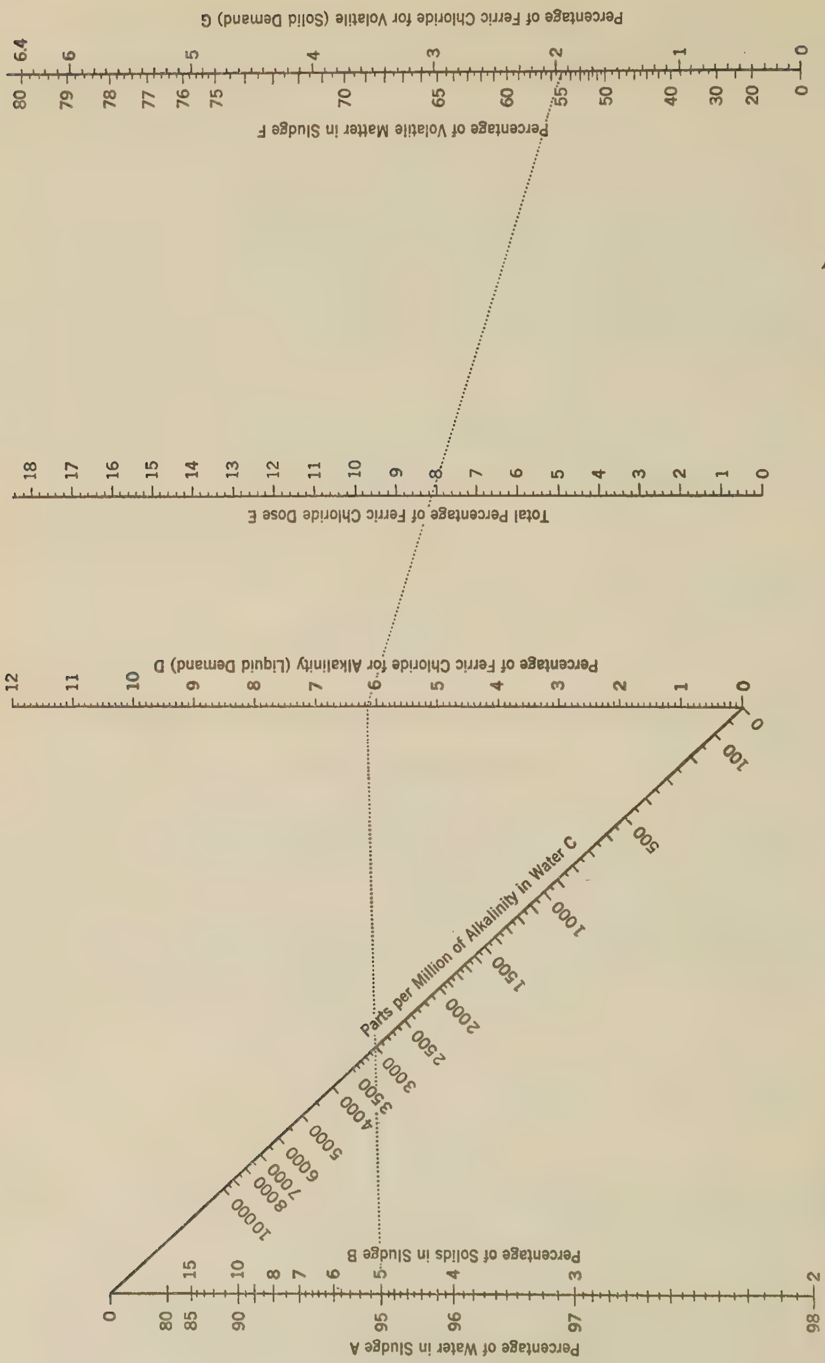

Fig. 4.—Nomograph for Sludge Dosing; Eq. 5

Nomograph.—Fig. 4 presents a useful nomograph of Eq. 5. The N-shaped part of this graph for the alkalinity factor is scientific and therefore relatively exact, with proper sludge sampling and basic analyses.

As an example, consider a digested sludge with 5% solids, 95% water, 3,000 ppm of alkalinity, and 55% volatile content. Connect 95% on scale A, through 3,000 ppm on scale C to 6.15% on scale D. Next connect 6.15% on scale D with 55% volatile on scale F. The total ferric chloride dose (8.1%) is read at scale E. Thus, the actual alkalinity demand in this typical example is more than 6% $FeCl_3$, which is easily 75% of the total requirements. By elutriating this sludge to 300 ppm alkalinity and thickening to 8% solids the alkalinity factor becomes negligible. Fig. 4 also shows that the alkalinity factor in waste activated sludges can play a definite rôle in consuming ferric chloride; for example, at 2% solids and 400 ppm alkalinity the liquid demand is more than 2% $FeCl_3$.

OTHER COAGULANTS

Chlorinated copperas, ferric sulfate, and aluminum sulfate are being used and have been tried extensively instead of ferric chloride. More of these chemicals than ferric chloride must be used for various reasons—heavier molecular weight relations in reacting with total bicarbonates, difference in the compressible hydroxide floc formed in the presence of the sulfate radical, less purity in case of the sulfates, and greater difficulty in effectively dissolving the ferric sulfate. Therefore, these substitutes for ferric chloride must be materially cheaper than the latter in order to find successful use. They also appear to be only of value on well mineralized sludges of low alkalinity.

Chlorinated Copperas (Chemical Symbol, $FeSO_4Cl$; and Molecular Weight, 187.36).—Theoretically it takes 1.16 times more of this pure coagulant than ferric chloride to complete the reactions of Eq. 5. This chemical has been used extensively at Baltimore. The indications are that the dosage approximates this ratio of about 1.2 of chlorinated copperas to 1 of ferric chloride.

Ferric Sulfate (Chemical Symbol, $Fe_2(SO_4)_3$; and Molecular Weight, 399.87).—Theoretically 1 mol of this compound reacts the same as 2 mols of ferric chloride with bicarbonates. This means that 1.233 times more of the pure sulfate salt than ferric chloride is required to complete the reactions of Eq. 5. Although this chemical is delivered in an anhydrous state and is easy to handle, as marketed commercially it is far from being as pure as ferric chloride and is much less soluble in the cold. Consequently the quantity of the commercial salt used will exceed the theoretical weight ratio to ferric chloride.

This salt as ferri-floc is being used successfully on elutriated digested sludge at Annapolis, Md., due to its price of $36.10 per ton in 1941 compared with about $99.00 per ton for anhydrous ferric chloride. Since 1941 about 2.7% ferri-floc on sludge solids was used. This is about 1.6 times as much ferri-floc as ferric chloride previously used.

Aluminum Sulfate.—The chemical symbol of pure crystal sulfate of aluminum is $Al_2(SO_4)_3 \cdot 18H_2O$; and its molecular weight is 666.42. Most commercial sulfate, however, has less water of crystallization, and a molecular weight of about 595. Theoretically it takes about 1.84 times more of this commercial salt than of ferric chloride to complete the reactions of Eq. 5. In some parts of eastern United States this product, known as "paper maker's alum," is cheaper than any of the foregoing reagents. Its use on partly-elutriated and well-elutriated digested sludges presents some interesting disclosures relative to Eq. 5.

It was given extensive trials on elutriated digested sludges at Hartford in 1939, and in Winnipeg in 1940, with rather discouraging results. At Winnipeg the trials disclosed that this relatively pure alum was required in quantities 2.8 times larger than ferric chloride. Furthermore, the cake moistures were higher and the filter yields lower. These findings were confirmed at Hartford where the mineralization of the sludge was better than at Winnipeg. This was undoubtedly due to the precipitation of too much aluminum hydroxide by the bicarbonates left in the sludge. This hydroxide precipitate is exceedingly difficult to filter especially when present in excessive amounts in any sludge. What constitutes a beneficial amount of this precipitate was demonstrated in 1941 and 1942 at Springfield, where its use proved encouraging.

The same grade of alum as that used at Hartford and Winnipeg was tried at Springfield. However, in the Springfield tests the sludge was more thoroughly elutriated than at the other two plants. Therefore, the sludge alkalinity was lower. As a consequence these trials demonstrated the validity of Eq. 5 by the use of a chemical other than ferric chloride.

In 1942, during July and August, 8,023 lb of this chemical were used on 284,176 lb of sludge solids producing an average cake solid yield of 7.4 lb per sq ft hourly. The average sludge assays were 14.2% solids, 45% volatile content, and 212 ppm alkalinity. The average dose was about 2.8% alum on sludge solids. On this basis the calculated ferric chloride dose is 0.14% for alkalinity and 1.31% for the volatile factor, or a total of 1.45%. For aluminum sulfate this calculated dose would be about $1.84 \times 1.5 = 2.8\%$.

Aluminum hydroxide floc is evidently more compressible and fragile than the sludge floc produced when using ferric chloride. J. D. McDonald, engineer in charge of sewage treatment at Springfield, informs the writer that when alum was used, flash coagulation was necessary—that is, running the alum solution into the sludge stream being discharged from the bucket elevator and through baffles in the mixing chamber and then directly to the filter without any further stirring. Ferric sulfate solution is added in a similar manner at Annapolis.

Evidently, under proper conditions, crystal alum can compete with ferric salts when its pound price is less than half that of anhydrous ferric chloride, the sludge is well mineralized through digestion and then elutriated to a low alkalinity. A similar statement applies to the use of chlorinated copperas and ferric sulfate.

Lime and Ferric Chloride.—This combination is used extensively on raw and digested sludges but not on waste activated and elutriated sludges.

Eq. 5 and its nomograph, Fig. 4, are of material help in using lime and ferric chloride on those sludges where the combination may be advantageous. Lime is used with the intention of saving ferric chloride and reducing the total chemical cost per ton of sludge solids.

The combined lime and ferric requirements are just as much a function of the liquid and solids demands of any sludge as are the requirements for ferric chloride, or any of the other ferric or aluminum salts used alone. In this combination lime functions as calcium hydroxide and cannot entirely replace ferric chloride except with some sludges containing relatively large amounts of certain industrial wastes.

In a strict sense, calcium hydrate is not a sludge coagulant. Added to sludges relatively rich in bicarbonate alkalinity before ferric chloride is added, calcium hydrate precipitates the bicarbonates as calcium carbonate. The latter is an inert filter aid which prevents the liberation of carbon dioxide gas as bothersome foam when ferric chloride is added. As calcium hydroxide is only slightly soluble in water, an excess is always needed. On fairly heavy sludges, lime as CaO displaces about one half the ferric chloride dose that would be necessary if no lime were used.

Ratio of Lime to Ferric Chloride.—The importance of this ratio depends largely on the local market price of the two chemicals. This fact seems to have been overlooked in a number of installations.

The saving in the amount and cost of ferric chloride by the addition of lime depends on four essential factors: (1) The ratio of the price of ferric chloride to lime or available CaO per pound; (2) the actual ratio of the two chemicals used; (3) the minimum percentage of ferric chloride permissible with lime; and (4) the actual ferric chloride demand of the sludge. The amount of ferric chloride displaced by using lime equals the percentage of lime (L) used on sludge solids divided by the ratio (R) of the cost of ferric chloride to the cost of available CaO per pound; that is, equal to L/R. Furthermore, if the total percentage of ferric chloride used alone to produce an economic filter yield is equal to C, and the minimum percentage of ferric chloride used with lime to produce the same yield is equal to F, the economic limit to which the engineer may go in using lime is

$$C = F + \frac{L}{R} \qquad (10a)$$

$$R = \frac{L}{C - F} \qquad (10b)$$

Obviously $(C - F)$ is the weight or percentage, on sludge solids, of ferric chloride displaced by using lime. Therefore, the moment the ratio of percentage of lime used to maximum percentage of ferric displaced exceeds the price ratio (R), money is definitely being wasted. Nothing is gained when the two ratios are equal. In fact, it may be argued that money is being lost due to the added expense of removing lime incrustation. Consequently money can be saved only when $R > \dfrac{L}{C - F}$.

Increasing the value of R in Eq. 10b increases the range within which lime (L) can be of value in displacing ferric chloride $(C - F)$. Thus two plants in different localities may produce digested sludges having about the same total chemical demand but with ferric chloride and available lime costing $30 and

$10 per ton respectively in one plant ($R = 3$), and $72 and $12 respectively in the other plant ($R = 6$). With experimentally determined values of $C = 6$ and $F = 3$ in both plants, the lime dosage (L) in the former plant will have to be less than 9% to save money, whereas in the latter plant money may be saved at all lime doses less than 18%.

As a result of these observations, Table 4 has been compiled from the records of four of the largest and best known plants using lime and ferric chloride. The data for all plants are averages from 1941 records. Table 4 indicates that the first plant (Item 1) is the only one that definitely saved ferric chloride and money by using ferric and lime. Aside from the emphasis placed on filtration economies at the former plant, it must be remembered that the low ferric demand of the sludge and the higher price ratio (R) combine to produce most of this result.

TABLE 4.—TYPICAL FERRIC CHLORIDE EQUIVALENTS TO FERRIC CHLORIDE AND LIME COMBINATIONS (PERCENTAGES)

No.	Plant	Price ratio R	CaO used L	$FeCl_3$ used F	$\frac{L}{F}$	TOTAL $FeCl_3$		$FeCl_3$ on cake	CaO on cake	TOTAL $FeCl_3$	
						C[a]	$R = 4.1$[b]			Observed	Computed
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)

5	Averages..................	3.3	10.0	2.9		6.0	5.3			5.0	5.0

[a] Total percentage of ferric chloride, equivalent (symbol C). [b] Total percentage of ferric chloride equivalent with R (Col. 2) the same in all plants as in plant No. 1.

The use of lime and ferric chloride on the digested sludges in the remaining plants, with their higher alkalinity and lower cost ratios, is further complicated by both higher ratios of lime to ferric chloride necessary to meet the higher liquid demand and lower price ratios. Consequently the economy of this procedure becomes more difficult and somewhat questionable. The low lime to ferric chloride ratio (Col. 5, Table 4) for the Southerly plant at Cleveland (Item 4) is not quite typical. On a few occasions during 1941 it was necessary to increase the ferric dose to make up for the absence and scarcity of lime supply. In 1940 the average was 3.5 as compared with 2.8 in Col. 5, Table 4.

The values in Col. 6 are determined by Eq. 10*a*; those in Col. 10 are determined in the same manner when computing lime and ferric chloride percentages on dry cake weight. The values in Col. 7 are computed by the same equation when R is 4.1 in all cases. This places all plants on the same price ratio basis as Minneapolis-St. Paul and removes this particular advantage this plant has over the others in determining Col. 6 values.

Eq. 5 was used on the yearly average sludge assays for the values in Col. 11 and decimals were eliminated in the tabulation; for example, the Westerly and

Southerly plants were computed as 5.7% and 4.8% of ferric chloride, respectively. On this basis the average calculated doses show a rather close approximation to the average of Col. 7 and a closer agreement with the average values in Col. 10, Table 4.

In a way this should be expected. In most cases of Table 1, where ferric chloride alone was used in developing Eq. 5, the ferric chloride doses have been determined on dry cake solids. This chemical increases the weight of cake solids very little. In using lime and ferric chloride this is not the case. In this practice the cake solids are increased sufficiently to account for the differences between Cols. 6, 10, and 11, Table 4. Furthermore, in such installations using ferric chloride and lime, the actual sludge solids handled are estimated both from weighed cake and gallons of sludge sent to the filters. In some instances this procedure may result in an error. The error should be less when calculations are made on cake solids actually weighed and determined through accurate sampling and moisture determinations despite the fact that integrated weightometer readings are frequently light.

In this case, Cols. 10 and 11, Table 4, indicate that Eq. 5 is approximately valid for sludges dosed with lime and ferric chloride when the combined percentages of these chemicals on cake solids are converted to the equivalent percentage of ferric chloride according to Eq. 10*b*. Furthermore, at price ratios of 5 and 6, common to smaller plants using crystal ferric chloride, Eq. 5 will be found relatively accurate.

Therefore, if Eq. 5 or its nomograph, Fig. 4, is to be used as a guide for careful dosing of lime and ferric chloride with essential assays known, Eq. 10*b* also will be of value, for then the percentage addition of lime (L) will be:

$$L = R\,(C - F) \qquad \text{(10c)}$$

with C determined either by the nomograph or careful tests, and R from local prices.

SUMMARY

Eq. 5 has been developed with the purpose of increasing current knowledge of the basic factors that influence coagulant requirements in sludge conditioning. Research indicates that these factors are broadly two in number: (*a*) The liquid demand of the chemically and biochemically contaminated water associated with the sludge solids; and (*b*) the demand of the wetted sludge solids themselves. In this paper, the former is based on the scientific weight relationship of bicarbonate alkalinity to ferric chloride, whereas the latter is based on an empirical relationship of ferric chloride to the volatile or organic portion of the sludge solids.

In determining both of these demands experimentally, the writer has purposely chosen only those plant records and experimental results that are pacemaking in their efforts to save conditioning chemical. Such a choice of statistical averages does not involve dosing sludges to produce the best filter yields and driest cakes in actual practice. With these facts in mind it is believed that the second part of Eq. 5 clearly indicates that the solid demand for ferric chloride and its chemical substitutes is a function of a constant times the ratio of volatile matter to ash in the sludge solids. Undoubtedly the ratio of water to sludge solids in the first part of the equation is likewise determined by this same ratio. As the volatile-ash ratio only approximates the true ratio of organic to mineral matter the true ratio may disclose more meaning to the constant evolved. For general mathematical purposes the formula for total ferric chloride requirements (X) when using alkalinity assays is as expressed by Eq. 6, in which K is the only empirical constant. According to the degree to which the liquid and solid demand of a sludge is combined with ferric chloride prior to filtration, constant K probably varies from the value of the first constant (1.08) to some multiple of this value. For careful vacuum filter practice it is approximately 1.6 (see Eq. 5).

Such careful practice primarily depends on constancy of sludge characteristics and operating averages. To designers of vacuum filter installations either Eq. 5 or 6 should be of definite aid in choosing the best type of sludge processing to produce the lowest values for both liquid and solids demands and to gain constancy of operating averages. However, the operator's chief aid in taking economic advantage of the constancy of sludge characteristics through careful filter operation is the installation of coagulation and filtration equipment that does not tend to destroy the coagulated sludge floc and keep the conditioned sludge unduly long in process before reaching the filter cloth.

DISCUSSION

PAUL D. McNAMEE,[17] Esq.—The question, "How much coagulant is necessary to condition a sewage sludge for filtration?" would rate $64 on any quiz program. As a rule, fresh solids require less coagulant than do digested solids, whereas activated sludges require the highest dose. Without running actual filter tests, it is hazardous even to venture a guess as to the actual amount of coagulant required by a particular sludge. The common procedure is to add varying amounts of coagulant and then to compare filter yields or filtration times. Mr. Genter has presented a simple method for calculating coagulant requirements which should prove helpful to all persons engaged in the filtration of sludge. Eq. 6 appears to hold for all types of sludge; but, as Mr. Genter has stated, it may have to be modified somewhat when more results are available for comparison. To date, Eq. 6 has had limited application and it will be necessary to apply it to many other sludges before its true worth can be evaluated.

An equation of this type establishes the optimum dose required and gives the operator a definite value at which to aim. In actual practice it is often difficult to attain theoretical values; but, as Mr. Genter has stated, the use of such an equation does show when something is wrong. Mr. Genter's basic data showed that the Washington, D. C., plant used more coagulant than is indicated by Eq. 6. Laboratory tests at the plant verify this conclusion. At the Washington, D. C., plant, there has been some difficulty in maintaining a constant flow of elutriated solids to the sludge meter, which in turn controls the ferric chloride doser. In other words, the ferric chloride is discharged every time the sludge meter makes a certain number of revolutions, and the sludge meter will revolve with a full or a partial load. If the operator regulates the discharge for a partial load and then receives a full load, the sludge will be underconditioned, which causes the filters to become clogged with slime. This necessitates shutting down the filter and washing the cloth. To keep the filters running, it is necessary for the operator to set the dose for a full load, with the result that the sludge is overconditioned when a partial load is received. The trouble is caused by small pieces of wood and trash that find their way to the plant. The plant itself has no screens; the sewage is screened at the main sewage pumping station. The bottleneck in the plant for this material occurs at the sludge pumps that handle digested and elutriated sludge. A single stick will become lodged in a pump and a mat of fine material is built up which eventually clogs the pump. An extremely small amount of trash can cause considerable trouble. For example, if just one sizable stick escapes in every 4,000,000 gal of sewage treated, sufficient interference has been created to require thirty pump cleanings per day. Various steps have been taken to remedy this condition, such as increasing the size of the pumps and lines, but the condition, although relieved, still exists. A different type of coagulant doser would eliminate the overdosing, but additional screening facilities are needed for final solution of the problem.

---

[17] Chief Chemist, District of Columbia Sewage Treatment Plant, Blue Plains, Washington, D. C.

With the present setup, it is necessary to overcondition the sludge by a definite percentage even if straight digested sludge is being filtered. Thus, the saving in coagulant by elutriation under present conditions is higher than the theoretical saving since the same percentage increase is three times more for the digested, than for the elutriated, sludge in terms of ferric chloride.

Eq. 6 is divided into two parts: One part determines the ferric chloride required to satisfy the alkalinity of the solution, and the other part determines the amount of coagulant actually needed to coagulate the sludge. The first part is based on well-known and established facts. Although there are many theories in chemistry, there are but a few fundamental laws. The first part of Eq. 6 is based on the law of combining weights, which is well established. If any fault is found with Eq. 6, it will probably involve the second part where Mr. Genter was limited to eight sewage sludges for the derivation. The ferric chloride requirements are shown to be a function of the ratio of volatile matter to mineral matter in the sludge. This condition is somewhat difficult to explain since the determination of volatile matter complicates the picture. The volatile matter is generally taken as a measure of organic matter, although this assumption is only approximately true. Considerable inorganic material is changed by ignition into other forms—with corresponding changes in respective weights. Compounds such as sulfates break down with the loss of sulfur dioxide; carbonates lose carbon dioxide; and other compounds may sublime. The true organic content of a sample, therefore, would probably be lower than the volatile content. This fact does not invalidate Eq. 6, but it does make the use of Eq. 6 more difficult since the operator does not know just how much true organic matter is measured or to what extent the volatile loss may have included inorganic substances capable of reacting with coagulant. The fact that Mr. Genter's ratio of volatile matter to mineral matter does show such remarkable agreement with coagulant requirements must mean that the mineral-matter conversion factor measured by the volatile test is fairly constant for the different sewage sludges.

Breaking down the coagulant requirements of a sludge into two components as Mr. Genter has done affords a clear-cut picture of the value of elutriation. Not only can it be seen at a glance which sludges lend themselves to elutriation but also it is possible to calculate the exact savings of coagulant that can be realized. Eq. 6 should prove helpful to any person estimating the value of elutriation.

In the case of partial dosing to produce partial coagulation, the writer believes that it is a question either of the mixing or of the contact of the ferric chloride itself with the sludge, rather than a question of the precipitation of ferric hydroxide by partial alkalinity neutralization. In running batch samples, the stirring is usually fairly constant. When a strong solution of ferric chloride is added to a sample, there will be a zone where all the alkalinity is satisfied and the local sludge particles are in contact with more ferric chloride than is necessary to condition them. The resulting sample contains conditioned and unconditioned sludge. In the case of sludges with high alkalinity, more ferric chloride is precipitated before it can come in contact with a sludge particle and the percentage of sludge conditioned is not directly proportional to the percentage increase in dosing.

Mr. Genter's paper certainly supplies "food for thought." It is probably the first attempt to correlate the coagulant requirements of all types of sewage sludges with certain sludge characteristics. It was known that, with well-digested sludges, where the volatiles are low and more or less constant, the coagulant requirements vary almost directly with the alkalinity; but this relationship did not hold when other types of sludge were considered. By introducing the ratio of volatile matter to mineral matter, Mr. Genter has correlated the other sludges. A study of Eq. 6 will prove worth while. For instance, if the operator is interested in discovering how the thickness of the sludge will change coagulant requirements, it is only necessary for him to select a given alkalinity value and plot the X-values for different sludge concentrations. About ten times as much coagulant is required for a 1% sludge as for a 10% sludge to satisfy the first or X-part of the equation. If for no other reason than curiosity, all operators who filter sludge should try to apply Eq. 6 to the particular sludge with which they are dealing.

D. L. McLEAN,[18] Esq.—The liquid wastes from a modern community vary from day to day and from season to season to such an extent that any mathematical analysis of the amount of coagulant required to condition the sludge from these wastes for partial dewatering by vacuum filters would appear to be a most difficult, if not impossible, task. However, Mr. Genter simply divided the constituents of the sewage sludge into its liquid and solid parts and used the alkalinity of the liquid portion and the volatile matter of the solid portion as his fundamentals. In this most ingenious manner he has reduced the whole intricate problem to the simple mathematical relationship of Eq. 6, which can be applied to all types of sludge and adapted to meet any set of conditions.

Eq. 5, and particularly the nomograph of this equation (Fig. 4), are of particular value and use in the operation of a treatment plant where vacuum filters are used for the partial dewatering of sludge. To check the application of the use of this nomograph and equation, and to show the relationship between the amounts of coagulant determined from them as compared with the actual amount used in practice, the writer offers some data from the treatment plant records of the Greater Winnipeg Sanitary District at Winnipeg. In this plant vacuum filters are used to partly dewater the elutriated digested sludge with ferric chloride as the coagulant. First, a check will be made on the yearly quantities of ferric chloride used for conditioning elutriated sludge; next, a special run will be checked where digested sludge was filtered without elutriation; and finally the filtering runs for a month will be compared, run by run, as well as the monthly average. If the actual results and the nomograph check within reasonable limits, then the value of the nomograph for checking this plant's coagulant requirements will be demonstrated.

The results of applying Eq. 5 can be compared with the actual average values for 1944. In that year, 1,906,255 lb of dry filter cake solids were conditioned with 53,739 lb of ferric chloride. This gave an average of 2.8% of ferric chloride used. Properties of the elutriated sludge were as follows:

---

[18] Superintendent, Greater Winnipeg San. Dist., Winnipeg, Man., Canada.

Average alkalinity, 940 ppm; sludge solids, 9%; sludge moisture, 91%; volatile matter, 52%; and ash, 48%. With these values, Eq. 5 yields the following values for the percentage of ferric chloride required: For the alkalinity demand, $\frac{91}{9} \times 0.094 \times 1.08 = 1.03\%$; and, for the solids demand, $\frac{52}{48} \times 1.6 = 1.73\%$. The ferric chloride required for the total dose is the sum of the two, or $1.03 + 1.73 = 2.76\%$. For all practical purposes, this calculated dose is the same as the 2.8% actually used.

Using 940 ppm for alkalinity, as the average for the past three years of operations and combining this with the tabulated averages of 90.5% water, 9.5% solids, 50.7% volatile matter, and 49.3% ash, the calculated dose of ferric chloride is found to be 2.7%, which checks with the 2.7% actually used.

To compare the results by Eq. 5 with those obtained from a special filtering of digested sludge that was not elutriated, the following data may be used:

On an isolated special plant run of digested sludge which was not elutriated, more than 9% of ferric chloride was required to render the sludge filterable. This sludge had an alkalinity of 4,430 ppm, a water content of 93.8%, a solid content of 6.2%, and a volatile content of 57%, with 43% ash. The ferric chloride requirement calculated by Eq. 5 is: For liquid demand, $\frac{93.8 \times 0.443 \times 1.08}{6.2} = 7.2\%$; and, for the solid demand, $\frac{57}{43} \times 1.6 = 2.1\%$. The ferric chloride total requirement is $7.2 + 2.1 = 9.3\%$, which checks with that actually found by the test.

TABLE 5.—COMPARISON OF ACTUAL AND PREDICTED FERRIC CHLORIDE REQUIREMENTS

September, 1944	Alkalinity (ppm)	Water (%)	Volatile (%)	FERRIC CHLORIDE (%)	
				Actual	Fig. 4
2	920	88.1	51.7	2.3	2.4
5	730	90.9	52.7	2.7	2.8
9	830	90.8	53.8	2.7	2.8
11	860	88.1	52.9	2.5	2.5
13	850	88.5	49.3	2.5	2.3
16	940	88.4	48.2	2.1	2.2
18	850	88.3	51.5	2.6	2.4
20	860	90.8	51.5	2.8	2.6
23	930	89.9	51.7	2.9	2.6
26	890	90.9	57.1	2.8	3.0
29	920	91.7	56.2	2.9	3.1
Average	....	....	....	....	2.59

The results of filter runs for one month, compared run by run with the quantities of ferric chloride taken from Fig. 4, are given in Table 5. The nomograph average for the month (2.59%) compares with the actual percentage (2.54%) computed from the 5,101 lb of ferric chloride used in conditioning 200,912 lb of dry filter cake solids.

These examples of the use of Eq. 5 or Fig. 4 show that for a wide range of conditions it is a most valuable and rapid method to give a check of the ferric chloride used in conditioning sludge in treatment plant operation. A wide divergence between the value given by Fig. 4 and the ferric chloride actually used indicates the probability of inefficiency in some part of the filtering process and should lead to a remedy for any such condition.

As an aid to plant operation Mr. Genter's work is of great value. It should be of equal value to the designing engineer in the selection of the most economical method of sludge disposal. In research it suggests economies to be effected in sewage treatment by concentrating sludges and selecting sources of wash water for efficient elutriation, and emphasizes the value of thorough digestion.

K. FRASCHINA,[19] ESQ.—The problem of calculating coagulant requirements in sludge conditioning has been reduced by Mr. Genter to a simple mathematical process of apparently wide application which should prove to be very useful to all persons engaged in sludge filtration. In applying his equations to plant practice, however, Mr. Genter warns of the necessity of reliable statistical averages in sampling and analytical methods, and of careful vacuum filter operation.

This discussion will be confined to some theoretical aspects of the equations formulated, and to subsequent operational data for the Richmond-Sunset plant, with tentative explanations of conformity to, and departure from, Mr. Genter's equations.

In the first half of Eqs. 5 and 6 the amount of ferric chloride required to react with the chemically and biochemically contaminated water forming the major portion of the liquid sludge is determined by the reaction of the coagulant with dissolved bicarbonates, as shown in Eqs. (*A*) and (*B*) (see heading, "Sludge-Water Demand for Ferric Chloride"). Any possible effects of phosphates, borates, or silicates, if present, are not considered. It is entirely logical that the reactions given should go practically to completion because the solubility of hydrous ferric oxide is extremely small in water, the reaction proceeding quantitatively even in weakly acid solution.[20] The solubility product of hydrous ferric oxide is not exactly known; it depends somewhat upon the manner of precipitation but is of the order of 10^{-36}. It follows, therefore, that the amount of iron left in solution at a pH-value of about 4 will be in the order of 0.05 mg per liter. Since alkalinity is also determined, by titration with acid, to a definite pH-value of about 4, it can be inferred, if the foregoing is correct, that the pH-value of the conditioned sludge should be about 4 at the completion of the reactions expressed by Eqs. (*A*) and (*B*), and before any coagulant is available for the "solids demand" of the second part of Eqs. 5 and 6. This is not necessarily the case, at least with elutriated digested sludge. At the Richmond-Sunset plant, for instance, some residual titratable alkalinity remains, for sludge need not be conditioned with ferric chloride to a lower pH-value than about 6 for successful filtration. The effect of this on Eq. 6 would be to decrease the coefficient of Y_1 and increase the value of K.

The second part of Eq. 6 measures the coagulant required for the "solids demand." The fact that the solids-water complex does have a ferric chloride demand can be demonstrated by the presence of considerable amounts of reduced iron in the ferrous state in the filtrate. This "solids demand" is measured in the equation by an empirical constant K and the ratio of percentage volatile matter to percentage ash. Mr. Genter has emphasized the fundamental importance of this ratio in estimating the loss of volatile matter during the digestion of any sludge and the economies that can be realized in digestion and elutriation. These relationships are neatly expressed in Eq. 7. In sludge ignition, organic matter is destroyed and considerable inorganic matter is converted to a variable extent into other forms depending on the temperature of ignition and the particular salts present. The volatile content determined by ignition probably exceeds, and at best only approximates, the actual organic content. The latter presumably determines the proportion of coagulant required; little or no coagulant is required for the mineral matter, as stated by Mr. Genter.

[19] Supt., Richmond-Sunset Sewage Treatment Plant, San Francisco, Calif.

[20] "Textbook of Quantitative Analysis," by I. M. Kolthoff and E. B. Sandell, The Macmillan Co., New York, N. Y., 1936, p. 294.

The determination of volatile matter and ash is further complicated by the fact that both are based on the weight of dried solids in the sludge; volatile matter is the percentage loss of solids on ignition, and ash is the percentage remaining. The weight of dry solids is not susceptible of absolute determination. In the standard method,[21] the sample is evaporated overnight in a 103° C oven, cooled in a desiccator, and weighed; or evaporated on a water bath, dried at 103° C, cooled, and weighed to constant weight. At the Richmond-Sunset plant it has been found that a continuous apparent decrease in solids percentage occurs on continued heating at 103° C, probably due to loss of the more volatile organic fractions or to the decomposition of the more unstable organic materials. A limiting or constant weight is approached only after prolonged heating. Furthermore, the dried solids are very hygroscopic; they absorb water very rapidly. Unless weighings are made under such conditions that absorption of water is reduced to negligible proportions, solids and calculated volatile percentages in general will be too high, and computed ash percentage too low. The net effect on the volatile-to-ash ratio depends on the relative loss in weight on heating and gain in weight from moisture absorption, and may either increase or decrease the apparent ratio with corresponding changes in the value of K in Eq. 6. For example, if ash weight remains constant and solids are reported too high by 5%, the apparent volatile-to-ash ratio of a 3% solids sludge of 65% volatile matter will be increased 7.7%; with the same error in a 3% sludge of 50% volatile, the increase will be 10%.

Another factor which may affect the percentage of coagulant required is the rate of flocculation. Hydrous ferric oxide, when first formed, is a positively charged colloid in the acid region to a pH-value of about 6 to 7.5, negatively charged in the alkaline region.[22] In the first case, hydrogen ion and probably some ferric ion are adsorbed from solution; in the second case, hydroxide ion and probably some ferric ion are adsorbed. Flocculation is promoted in the acid region by anions and in the alkaline region by cations, the most effective in either case being those of higher valence. The rate of flocculation and, therefore, the amount of coagulant required for any given sludge may depend to a certain extent, then, on the particular dissolved salts present. The rate of flocculation may also be influenced by the presence of certain impurities in the ferric chloride itself, such as calcium, zinc, copper, ferrous iron, hydrogen, sulfate, and phosphate ions.

[21] "Standard Methods for Examination of Water and Sewage," published jointly by the A.P.H.A. and the A.W.W.A., New York, N. Y., 8th Ed., 1936, p. 173.

[22] "Handbook of Applied Hydraulics," by C. V. Davis, Editor-in-Chf., McGraw-Hill Book Co., Inc., New York, N. Y., 1942, p. 802.

None of the foregoing invalidates the use of Eq. 6 but some factors have been presented that may serve to explain anomalous behavior in applying Eq. 6 and to indicate modifications in sampling and analytical methods that may be required.

[a] In Table 6(*b*) the values in Col. 6 were computed for each month from the actual accumulated pounds of solids, volatile matter, and ash. The percentages in Cols. 4 and 5 are rounded values computed from these same monthly totals. In some months, therefore, the values in Col. 6 will not coincide with the ratio, Col. 4 : Col. 5. [b] No data available; the value 470 was assumed for purposes of computation.

In Mr. Genter's paper the data presented for the Richmond-Sunset plant are for 1941. Subsequent data computed as weighted averages by fiscal years are given in Table 6(*a*). The data for 1944–1945 are the most reliable statistically because improvements have been made in the measurement of volumes of sludge filtered and in methods of sludge sampling and analyses. In Table 6(*b*), monthly weighted averages during 1944–1945 are given to show the deviations not apparent when weighted averages over the year are considered as in Table 6(*a*).

The data in Table 6 can be considered as valid tests of Eqs. 5 and 6 with the following qualifications: Wartime dislocations in personnel were felt since early in 1942 but were most acute during the fiscal year 1943–1944. The technique of sludge filtration has conformed in most respects with Mr. Genter's criteria of careful operation, although it has been necessary to operate the single filter at practically maximum speed at all times to treat the sludge produced. If more filter area were available, filter speed could be reduced and somewhat greater economy in the use of ferric chloride would be attained.

In Table 6(*a*), except in 1943–1944, fairly close agreement is shown between computed ferric chloride doses by Eq. 5 and actual doses (Cols. 7 and 8); and computed values of K by Eq. 6 (Col. 9) are approximately 1.6, the tentative value set for careful filter operation. The higher values for 1943–1944 can be attributed in part to new and inexperienced operators. This confirms the necessity for competent and experienced personnel if most effective filter operation and maximum operating economy are to be attained.

When the data for 1944–1945 (which, in Table 6(*a*), line 4, show excellent agreement when compared with computed values by Eqs. 5 and 6 on a weighted yearly average basis) are compared by months, rather wide discrepancies appear. In Table 6(*b*), K-values computed from Eq. 6 vary from 0.70 to 2.18. The high K-value in September may be attributed in part again to changes in personnel, and the high value in February to errors in measurement arising from the small quantity of sludge filtered. The low doses in November, December, and January (Col. 7, Table 6(*b*)) with respective K-values of 1.33, 0.70, and 1.12 (Col. 9) are more difficult to explain. At this plant single-stage digestion is employed followed by elutriation of both supernatant and bottom solids from the digester. It is not possible to obtain a supernatant of much less than 1.5% solids with the limited capacity of this single digester. The major portion of elutriated sludge filtered usually consists of solids from the supernatant. From the middle of November to the middle of January the digester was in an abnormal state of activity with most of the sludge accumulated in an actively digesting mass at the top and with only a small amount of partly digested sludge at the bottom. The solids content of the intervening layer decreased to less than 1%. Relatively greater proportions of bottom sludge were withdrawn to elutriation during this period than usual and at the same time there occurred the greatest dilution of elutriating water with storm water. Several possible explanations of the apparently anomalous behavior of this sludge on filtration—that is, less coagulant required than computed—suggest themselves. First, digestion had not proceeded as far as usual and, in the sludge solids, intermediate digestion products including more than usual quantities of scum solids containing such excellent aids as disintegrated hair, paper, etc., were present whose coagulant demand no longer could be evaluated properly by the volatile-to-ash ratio; and, second, the flocculating effect of dissolved salts in the associated water phase was changed by the presence of unusual soluble decomposition products.

The plant was shut down for mechanical repairs from the middle of January to the end of February; the digester then reverted to normal activity. The aforementioned atypical behavior in sludge filtration has not recurred since.

Walter H. Brown, Jr.,[23] Esq.—The purpose of this discussion is to show that, through the use of the equation recommended by Mr. Genter, material savings were made in the use of ferric chloride at the Cranston sewage treatment works. The writer is not a chemist and will therefore limit his remarks to the mechanical results obtained.

---

[23] Supt. Sewage Treatment, Dept. of Public Works, City of Cranston, Cranston, R. I.

By substituting Eqs. 2*a* and 4*b* into Eq. 5 in place of Y_1 and Y_2, an equation for the total dose of ferric chloride for elutriated sludge is evolved, as follows—

$$\text{Total dose } FeCl_3\ (\%) = \frac{H_2O\ (\%)}{\text{Solids}\ (\%)} \times 0.0001 \times \text{alkalinity (ppm)} \times 1.08 + \frac{\text{Volatile matter}\ (\%)}{\text{Ash}\ (\%)} \times 1.6 \quad \text{(11)}$$

By using Eq. 11, Buechner funnel tests were performed in the laboratory at Cranston, the results of which checked closely the dosage as determined theoretically. However, when such dosage was applied to the elutriated sludge in actual practice, the sludge was absolutely unmanageable. It was found that almost an 80% increase above the theoretical was required. This fact led to a suspicion that the ferric feeders or mixing tank, or both, were not functioning as efficiently as possible.

[a] Parts per million. [b] Total dry solids, in pounds. [c] Percentage excess (Col. 12 − Col. 13)/Col. 13.

Examination proved that the ferric feeders were very erratic in their operation. They were subsequently discarded and a volumetric type feeder was designed by the writer. After a period of adjustment and refinement, the actual dose was found to be approaching the theoretical. Further investigation showed that the mixing tank at Cranston was short-circuited; and, after that was remedied, Eq. 11 yielded the actual as well as the theoretical dosage.

Table 7 contains the data that led to a check of the equipment at the Cranston works. In the period reported a fairly wet filter cake (77.8% H_2O) was being produced with an average excess ferric dose of approximately 74%. For the months of May through September, 1945, the overdose was only about 8% and the filter cake had been reduced to about 76.5% H_2O. This resulted in a substantial saving in the use of ferric chloride. Furthermore, the digested sludge at the Cranston works now contains, on the average, less volatile matter and much more alkalinity than shown in Table 2. Due to the relatively large quantities of brewery waste discharged into the sewers and treated at the Cranston plant, sludge digestion is particularly turbulent (gas production, 1.7 cu ft per capita per day) and the resulting alkalinity of the digested sludge is notably high. As will be seen from comparison of Cols. 2, 4, and 7, showing the volatile contents of the digested and elutriated sludges, the latter is frequently higher than the former. This is due to the accumulation of top, or less completely digested, solids sent to elutriation.

In view of the effects of such industrial wastes on the treatment at Cranston, for some time the writer doubted the applicability of Mr. Genter's equation to the sludge treated at Cranston; but subsequent tests and investigations have demonstrated that this basic equation undoubtedly holds.

A. L. GENTER,[24] M. AM. SOC. C. E.—The discussions of this paper on the mathematical analysis of a practical and theoretical problem have originated in widely separated localities. In all efforts to understand natural phenomena, and to control them, both the practical and the theoretical are equally important. From the standpoints of presenting more statistical evidence of the validity and usefulness of Eqs. 5 and 6 to the designing engineer and operator and of critically examining the component parts of these equations—the discussions have been valuable contributions to the subject and are gratefully acknowledged.

Reply to them will be confined chiefly to the practical and theoretical phases of that part of Eqs. 5 and 6 which cannot be understood immediately in an intellectual manipulation of either equation. This difficulty refers to Eq. 4*b* which states mathematically that in addition to including the liquid alkalinity requirements of a sludge, measured in terms of water per unit weight of dry solids, the chemical requirement is a function of a constant multiplied by the weight of volatile matter per unit weight of ash present in the sludge.

Mr. McNamee agrees that the first part of Eqs. 5 and 6 (that part determined by Eq. 4*a*) is scientifically valid. He is logically cautious, however, about deriving equivalent validity from Eq. 4*b* and from the second part of Eqs. 5 and 6 without further evidence of supporting data. This caution arises chiefly from the difficulty of explaining the ratio of volatile to mineral matter in terms of the ratio of true organic matter to mineral matter. Mr. Fraschina agrees with this observation. As the writer has previously indicated (see heading, "Facts Revealed by Eq. 5") and will presently attempt to demonstrate, the volatile-ash ratio in these equations takes in considerably more territory in sewage treatment in general, and in sludge disposal in particular, than has been generally contemplated in the examination of the effect of this ratio on coagulant consumption.

---

[24] Cons. Engr., Baltimore, Md.

The mathematical language involved in the use of this ratio in Eqs. 4*b*, 5, and 6 does not necessarily imply measurement of organic matter itself. It does, however, measure the amount of sludge water present in a sludge per unit weight of sludge solids, and this is most important. The amount of volatile matter in a sludge evidently contains mostly organic and possibly some inorganic matter essential to the organic capillary structures—both of which ingredients are responsible for the polar-surface activities of the solid and its water-imbibing properties acting as capillary structures and colloidal aggregates. The ratio of volatile to ash, times some constant, therefore, measures these water-imbibing capacities instead of presenting any picture of the amount of true organic matter present in a sludge.

There is nothing novel in the idea that the amount of water in a sludge is some function of the volatile matter present. There is something new, however, in evolving mathematical tools for measuring this function. In discovering such tools, it seems to the writer that it is not so essential that the mineral-matter conversion factor in the volatile test be fairly constant, as it is that the analytical methods and data be kept on an "even keel" by closely following "standard-method" procedures. In fact, the data presented from all parts of North America, and the equations evolved therefrom, are a composite tribute to the reliable uniformity of standard scientific analytical procedure and the competence of analysts and observers.

Such equations cannot be derived without an ample supply of supporting data. The writer feels that this condition was met in the data presented in Table 1. He also feels that it is not so important that data be collected from seven or eight sludges as it is that they cover a wide range of treatment practices, reliable essential assays, and careful dosing operations. Nevertheless, the greater the number of data collected and correlated, the more reliable will be the average data used in deriving such equations. If a scientific hypothesis is sufficiently important, additional evidence of its truth should be sought. This is undoubtedly the meaning of Mr. McNamee's comment on this point and the writer thoroughly agrees with it. Therefore, he will attempt presently to supply ample additional evidence.

In addition to these observations, it should be noted that, unless the hypothesis geared into the mathematical machinery of such pioneering investigations is capable of confirming experimental averages already recorded and unless it becomes a guide in the investigation of new data and consequently becomes equally capable of predictions which observations later verify, the hypothesis is a museum piece instead of a useful scientific instrument.

At the time the data presented in Table 1 were subjected to the impartial machinery of mathematical correlation, the writer offered Eq. 5 and its more generalized expression Eq. 6 as instruments of prediction. The statistical data involved approximately 7,000,000 lb of sludge solids, 191,000 lb of ferric chloride, and 8,000 lb of alum.

In the succeeding five years, notwithstanding the influence of war emergencies on the nature of sewage treated, plant overloading, operation, changes in volatile and alkalinity contents of the sludges, and additional recorded data, together with data from other plants where careful dosing is practiced, expanded the statistical data to considerably more than ten times the sludge solids and ferric chloride involved in Table 1. These additional data demonstrate that Eqs. 5 and 6 have served certain plants as reliable instruments of prediction and promise to continue to do so. This is made evident not only by the new data generously contributed and discussed by Messrs. McLean, Fraschina, and Brown but by considerable additional data collected from plants in Springfield, Mass., Hartford, Conn., and other places not tabulated and discussed.

All these data could be tabulated and summarized to indicate the validity of that part of the equations involving the so-called solids demand—that is, the constant 1.6 times the pounds of volatile matter per pound of ash—notwithstanding the great differences in the volatile and alkalinity contents listed in Tables 1, 2, 5, 6, and 7 and in the recent unpublished records from other plants. What could be demonstrated by such a comprehensive comparative tabulation can be made equally evident from the data relative to the Richmond-Sunset plant in San Francisco, Calif., in Tables 1 and 6.

Since the publication of the 1940–1941 data for that plant in Table 1 (line 5, Cols. 5 and 6), the volatile-ash ratio of the elutriated sludge has gradually increased from 1.74 to the 2.23 average of Table 6 (line 4, Col. 6). This material increase of more than 28% has taken place without any significant change in the yearly average value of the constant 1.6. Notwithstanding the causes of the increase in the volatile-ash ratio, incidental to the use of an overloaded single-stage digestion tank, occasional variations in the K-values of Table 6, and Mr. Fraschina's logical explanation of them, the 1940–1941 and 1944–1945 statistical averages for this plant have the same average value of 1.6 for K as do those listed for Winnipeg, Man., Canada, Hartford, Conn., Springfield, Mass., etc., and ultimately for Cranston, R. I. Since the publication of Table 7 relative to the Cranston plant, a private communication from Mr. Brown regarding the improved ferric feeder shows that the average K-value for the months of from June to December, 1945, also settled down to 1.6. That the value remained near this average all over North America can scarcely be thought mere coincidence.

Volatile-Ash Ratio and Sewage Treatment.—The writer has elsewhere emphasized[25] that sewage treatment, from plain sedimentation to final dewatering, is a system of correlated, progressive steps in removing undesired suspended and settleable solids from a large quantity of water. Everything in the system is connected in some definite manner with the amount of volatile matter in the solids being dewatered. This definite correlation may be traced from the effects of the volatile matter on the specific gravity of the solids in plain sedimentation (where gravity alone frequently accomplishes 99.96% of solids dewatering) to all the ever-increasing economic difficulties incidental to further dewatering.

---

[25] "Principles and Factors Influencing Vacuum Filtration of Sludge," by A. L. Genter, *Sewage Works Journal*, November, 1941, pp. 1164 and 1165.

In one of these final dewatering steps, investigations have disclosed the fact that the amount of solute-carrying water per pound of sludge solids is a function of a constant times the amount of volatile matter per pound of ash in the sludge—the inevitable result of conditions associated with this ratio in previous steps of the dewatering system. Therefore, the validity of the statement can be extended to: "Every step in this system is mathematically related to the volatile-ash ratio and some constant value."

The causes associated with this ratio will be found in the surface energy or polar nature of water related to polar groups and ions in the wetted solids. Water is the best solvent and ionizing agent and constitutes 99.9+% of sewage and from 90% to 98% of most sludges. Its solvent and hydration properties are due to the free surface energy of water which results from the polar character of its molecules (H – OH), "* * * because of which water acts as though it contains positive and negative electrical charges slightly separated from each other."[26] The polar nature of most solids submerged in water manifests itself by the presence of polar groups of molecules in the wetted solid surfaces (interfaces) having a strong solution tension or attraction for the polar-water molecules, as a result of which the molecules orient themselves toward the water:

> "The theory that molecules are oriented in surfaces and interfaces has a profound effect upon the development of surface chemistry, of colloid science and upon the theories of the internal structure of liquids,* * *."[26]

This theory also accounts for the surface charges of the wetted solids, for coagulation phenomena, and for all the water-imbibing properties of capillary gelatinous structures containing volatile matter and ash—namely, starches, agars, albumin, gelatin, pectins, zoogloeal masses, activated sludge floc, and all organic solids found in sewage which are subject to bacterial decomposition. Even hydrated mineral structures of a gelatinous nature that show volatile and ash contents by decompsoing at red heat owe their powers of hydration to the same polar forces—silicic acid gels and the flocculent precipitates of iron and aluminum hydroxide. Furthermore, most of the finely divided mineral solids found in sewage are attracted to water by polar groups such as silica, clays, oxides, and sulfides.

In capillary-active solid and semisolid structures common to most suspended and settleable sewage solids, the volatile and mineral ingredients are primarily responsible for the polar activities, hydration properties, and surface chemistry pertinent to the subject. In these structures the ingredients are related in some definite manner to other definite properties, such as:

(1) Specific gravity of sludge solids;
(2) Hydraulic subsiding rates or settleable solids;
(3) Capacity of sludge solids for imbibing and retaining large amounts of enmeshed water;
(4) Concentration of polar solutes in the imbibed and enmeshed water which necessarily has an influence on item (5);

---

[26] "Surfaces of Solids in Science and Industry," by William Draper Harkins, *Science*, Vol. 102, September 21, 1945, pp. 293–294.

(5) The chemical coagulant requirements; and
(6) Elastic properties of solids aggregates (compressibility of solids).

Item (6) concerns deformation under filtration pressure and has been fully discussed elsewhere.[27] Like solids, aqueous gels are characterized by definite elastic properties.[28] Although the influence of volatile matter on sludge compressibility in filtration is quite pronounced and remains to be mathematically investigated, it is altered advantageously by chemical coagulation, which, in items (4) and (5), has been mathematically related to the volatile-ash ratio.

In pushing the causes associated with this ratio in items (4) and (5) back a step to item (3), one encounters some fresh evidence of a most convincing nature on the general validity of this basic ratio. This evidence primarily involves referring to another field of organic colloids in order to relate the water-carrying power of solid gels to the amounts of volatile matter and ash in such gels.

Most gelatinous or amorphous aggregates of sludge solids are similar to gels, zoogloeal and otherwise. This fact becomes quite evident in relating hydration properties to the volatile matter and ash present. C. K. Tseng,[29] in his article on seaweed colloids (phycocolloids), shows that the various types of agars, in natural conditions, are calcium, magnesium, potassium, and sodium salts of various agar acids. The gel-forming properties of the various agars, and their allied phycocolloids, are functions of the ash contents, which is equivalent to stating that they are functions of the volatile and ash contents. The dried amorphous agar which scientists use (the standard agar of the bacteriologist) is prepared from seaweed species Gelidium, has an ash content of less than 5%, and contains 95% or more volatile matter. Such agars are:

> "* * * insoluble in cold but soluble in hot water, a one per cent neutral solution of which sets at 35° to 50° C to a firm gel melting at 80° to 100° C."

In other words, the solid gel of 19 to 1 volatile-ash ratio imbibes ninety-nine times its own weight in water to set to a solid gel that has a melting point near the boiling point of water.

Another seaweed colloid is carrageenin, which resembles agar in a general way, but has a much higher ash content (about 20%, or a volatile-ash ratio of 4 to 1) and requires concentrations of 3% or more to form solid gels containing about thirty times its own weight in imbibed water. These gels also melt at lower temperatures.

In any case, the Tseng article[29] clearly demonstrates that the power to imbibe water and to form firm gels, at ordinary temperatures, by different seaweed colloids is definitely a function of the volatile and ash contents of the different types listed. These colloids are believed to be chiefly cell-wall constituents of various seaweeds, comparable to the pectins of the land plants.

These pertinent facts were emphasized because the hydration and water-imbibing properties of such gels are remarkably similar to the disclosures relative to the water-imbibing and enmeshing properties of activated sludges made by Gail P. Edwards,[30] M. Am. Soc. C. E., as will become more evident through mathematical analysis of Mr. Edwards' disclosures. His pioneer studies relating to the effects of volatile matter on solids concentration in sedimentation tanks have deserved much more attention from the research engineer and scientific investigator than has heretofore been evidenced. They have been particularly valuable to the writer in the present investigation, not only because of the ample supply of statistical evidence on the influence of volatile matter on the water content of the sludges investigated, but also because of the wide range of volatile contents in the sludges. The percentages of volatile matter in the sludges investigated at the sewage treatment plants at Wards Island and Tallmans Island in New York, N. Y., ranged from 38 to 85.5, thus the volatile-to-ash ratios varied from 0.61 to 5.9.

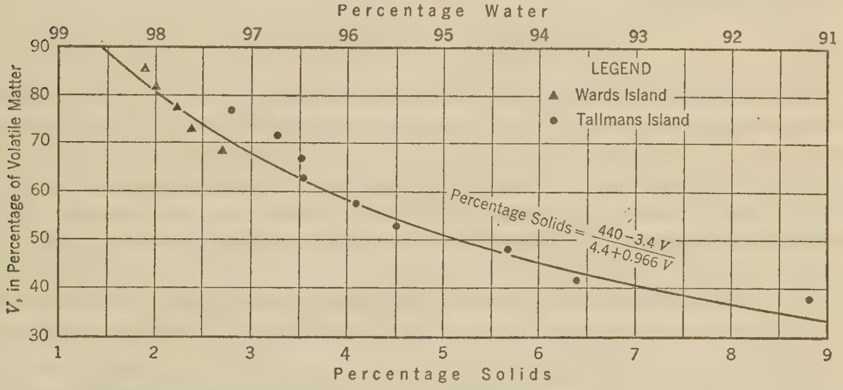

FIG. 5.—RELATION BETWEEN PERCENTAGES OF VOLATILE MATTER AND SOLIDS (ILLUSTRATING EQ. 13)

Fig. 5 illustrates the graph of the mathematical equation evolved by the writer from the original data published by Mr. Edwards.[31] Separate graphs are shown by Mr. Edwards for Wards Island and Tallmans Island sludges.[32] In Fig. 5, the full line is plotted from the writer's equation and accounts for both sludges. The various data-point averages for the two New York plants are indicated in Fig. 5 by black circles for Tallmans Island and by black triangles for Wards Island. The percentages of volatile matter are plotted as ordinate (y-axis) values, and the percentages of solids are plotted in ascending order, with the corresponding percentages of water in descending order as abscissa (x-axis) values.

Mr. Edwards' published data and graph averages for Tallmans Island indicate a curve of a hyperbolic type which (when the different y-axis and x-axis values are symbolized as V equals percentage of volatile matter, W equals percentage of water, and S equals percentage of solids in sludge) the writer evolves as:

---

[30] "New Developments in Activated Sludge Plant Operation," by Gail P. Edwards, *Sewage Works Journal*, November, 1940, p. 1080.

[31] *Ibid.*, p. 1080, Tables I and II.

[32] *Ibid.*, p. 1081, Fig. 3.

$$W = \frac{100\ V}{4.4 + 0.966\ V} \quad \text{.......................(12)}$$

and

$$S = \frac{440 - 3.4\ V}{4.4 + 0.966\ V} \quad \text{.......................(13)}$$

Dividing Eq. 12 by Eq. 13 to determine the quantity of water per unit weight of solids (Eq. 1), a fact of major importance to this discussion is developed:

$$\frac{W}{S} = \frac{29.4\ V}{29.4 + 100 - V} \quad \text{.......................(14)}$$

Because the value 100 − V, as formerly stated in developing Eq. 4*b*, is nothing but the percentage of ash in the sludge, Eq. 14 clearly states that in these particular sludges:

$$\frac{\text{Water (\%)}}{\text{Solids (\%)}} = K' \frac{\text{Volatile (\%)}}{K' + \text{Ash (\%)}} \quad \text{................(15)}$$

Eq. 15 is undoubtedly the general law expressing the amount of evaporable water per unit weight of dry solids in sludges containing volatile matter. It establishes the measurable influence of the volatile-ash ratio and some constant value on the water-carrying power per unit weight of sludge solids in the first stage of solids dewatering in sewage treatment (that is, in sedimentation) and confirms the validity of this influence in sludge dewatering by vacuum filtration.

Eq. 15 also clarifies the subject of the capacity of sludges to imbibe water. In the presence of the total water included in this equation, the ratio of volatile percentage to a constant plus the ash percentage is somewhat greater than the volatile-to-ash ratio itself. Since the ratios in the equation were determined from the sedimentation of wetted solids and include enmeshed water freely associated with the settled solid flocs, this additional constant amount indicates a water-imbibing or enmeshing factor (see sludge property item (3)). This factor will vary greatly with the polar or water-binding properties of the sludge solid structures—it will be highest with the water-enclosing, gelatinous structures of activated sludge floc, before and after digestion (also with other hydrated gel structures) and lowest with denser and less hydrated sludge solids. Processing suspended solids through activation and primary solids through digestion increases their value.

The average of several of the most prominent treatment plants shows K'-values of about 7 for primary raw sludges, 16 for digested primary, and 27 for waste activated and digested waste activated in plants having primary sedimentation with sludge activation. The actual observed K'-values for Tallmans Island average 26.2; and, for Wards Island, 31.5. The average values at the Southerly and Easterly plants at Cleveland, Ohio, for concentrated waste activated sludge fed to digestion and after digestion agree fairly well with the Tallmans Island values.

As the K'-value includes enmeshed water freely associated with the flocculent or hydrated structures of various sludge solids, the value will obviously vary somewhat with the detention time in sedimentation and with sedimentation tank design. Without standards for these factors, the K'-value is best determined by evaporation. In any case it indicates the existence of water-imbibing and enmeshing properties resulting from the sludge-solid structure associated with the amount of volatile matter per unit weight of mineral matter present.

It must be noted that Eqs. 5 and 6 really express the sum of two conveniently separated coagulant-consuming reactions occurring in the same total amount of water per unit weight of solids as shown by Eq. 15. The quantity $\frac{K' V}{K' + 100 - V}$ in Eq. 15 could be used to represent the water-solids ratio in Eq. 6 and would then be related to the quantity $K \frac{V}{100 - V}$ of the solids demand in Eq. 6. When multiplied by the ferric chloride constant 1.08, the constant K' in Eq. 15 would be some multiple ($n\ K$) of the basic K in the solids demand. Notwithstanding the magnitude assigned to the values K and $n\ K$ by practice and theory, the volatile-to-ash ratio in the sludge remains the essential factor in determining, in terms of sludge solids, the total water containing the solutes reacting with the added coagulants in free solution and in the wetted solid surfaces.

There is ample theoretical background for the foregoing disclosures provided by the buoyant effect of the lighter volatile fraction on the specific gravity of the sludge solids. The general statement found in the literature that the volume of a sludge (that is, the ratio of water to solids) depends mainly on water content and only slightly on the character of the solid matter can be quite misleading. The simple truth lies in reversing this statement; thus:

> "It is the capillary and polar characters of the wetted sludge particles and gelatinous aggregates of the sludge submerged in water that determine both the specific gravity of the sludge solids and the water content of a sludge."

Sufficient evidence has been supplied to demonstrate that the amount of water per unit weight of solids in a sludge is a function of the amount of volatile matter per unit weight of ash.

The influence of this important ratio on the specific gravity of sludge solids and their consequent gain or loss in hydraulic subsiding values are of prime importance to the general subjects of sedimentation and further sludge dewatering.

Among the factors controlling free settling rates of solids in water—particle size and structure and the frictional or viscous resistance of water to the falling solid—the gravitational pull on the solid is of prime importance. This is measured in terms of the gravity constant times the difference in the specific gravities of the solid and water. In centimeter-gram units, the difference indicates the apparent weight of the submerged solid. The apparent weight loss in water occurs because of the buoyant force of the water on the solid; and, in the plain sedimentation of sewage solids, the apparent weight loss depends on the volatile-ash ratio. This loss increases as the specific gravity of the sludge solids (G_s) decreases. Since the specific gravity of the volatile matter (G_v) is so near that of water, it has a material influence on this loss or on the resulting buoyant force of the water on the sludge solids.

The weight loss of sludge solids in water is the sum of the losses of the volatile and mineral fractions or percentages in the solids—namely, with 100 grams of solids in water the sum of the cubic centimeters of water displaced and the apparent total weight loss in grams is $\frac{V}{G_v} + \frac{100 - V}{G_m}$, in which V is the percentage or grams of volatile matter; $100 - V$, the percentage or grams of ash present; and G_v and G_m, the respective specific gravities of the volatile and mineral matter.

In this sum of apparent losses that of the lighter volatile part is always $\frac{G_m V}{G_v (100 - V)}$ times greater than that of the mineral part; that is: $\frac{V}{G_v} \div \frac{100 - V}{G_m} = \frac{G_m V}{G_v (100 - V)}$. As the average values for G_m and G_v will be fairly constant in most plants, this ratio (R) of the weight loss of the volatile part to that of the mineral part of sludge solids may be expressed as:

$$R = K_2 \frac{\text{Volatile (\%)}}{\text{Ash (\%)}} \qquad \text{(16)}$$

in which K_2 is the ratio of the specific gravity of the mineral part of the solids to that of the volatile part.

With this constant in mind Eq. 16 simply measures the gain or loss in the buoyant power of water on the submerged sludge solids through the increase or decrease in the volatile-ash ratio of the sludge.

The ratio R of the buoyant force of water on the volatile part to that of the mineral part of a sludge is a straight-line function of the specific gravity constant K_2 times the volatile-ash ratio of the sludge. For example, with $G_m = 2.5$ and $G_v = 1$, K_2 equals 2.5 and the buoyant power of water on the volatile part of a sludge averaging 50% volatile matter (volatile-ash ratio 1 : 1) is 2.5 times greater than that on the mineral part. The buoyancy ratio doubles in a sludge having a 2 : 1 volatile-ash ratio (66.7% volatile : 33.3% ash) and quadruples in a sludge having a 4 : 1 volatile-ash ratio (80% volatile : 20% ash).

The buoyancy ratio therefore is one of the fundamental causes of the gain or loss in hydraulic subsiding rates of settleable solids and of the consequent gain or loss in the quantity of water with its solute per unit weight of sludge solids in the progressive dewatering steps involving Eqs. 5, 6, and 15.

Adding the imbibed and adsorbed water, previously associated with the polar nature of the volatile solids, will change the effective displacement volume of the volatile and mineral parts of a sludge and the buoyancy ratios expressed by Eq. 16. Thus, both the free and impeded settling rates and the final water content of the sludge will be changed. The final effect has already been accounted for in Eqs. 13, 14, and 15 and the discussion concerning them.

The plot of percentages of volatile matter against the specific gravity of sludge solids (G_s) determined by the usual equation $G_s = \frac{100}{\frac{V}{G_v} + \frac{100 - V}{G_m}}$ results in a graph similar to Fig. 5 for the same volatile and solids range. However, the latter experimental graph shows the buoyant effects of imbibed and enclosed water in the settled sludge floc. Furthermore, experimental Eq. 13, when extended to a sludge containing solids of a hypothetical 100% volatile content, shows 1% solids and 99% water content. Although such an extension may lead to erroneous conclusions, the graphed values taken within the experimental range do indicate that at Tallmans Island the specific gravity of the volatile matter is slightly greater than that of water—probably 1.02 or 1.04—which denotes that some hydrated mineral matter later appearing in the ash is probably a part of the wetted volatile structure.

Although the analytical determination of volatile matter and ash in sewage treatment is not as scientifically exact as chemical determination of solutes in the sludge water, it is quite as exact and reliable as the current method of determining the amount of water and dry solids by evaporation. The measurements involving weighted average percentages of moisture and solids, volatile matter, and ash in all the dewatering steps are sufficiently accurate and informative when computed to the first decimal place. Therefore, further precision is not warranted in measuring weighted average percentages of solute and coagulant on solids that have been determined by evaporation. With this in mind, measurements of amounts of water per unit weight of sludge solids and of volatile matter per unit weight of ash are just as reliable yardsticks in Eqs. 5, 6, 15, and 16 as is the law of combining weights in Eqs. 5 and 6; and they have quite a reliable scientific background.

In these equations and those from which they are derived, the separation of a sludge into volatile and ash components is analytically convenient in relating and measuring the various properties of polar water and wetted polar volatile solids to successive solids dewatering steps. As noted before in discussing Eq. 15, the separation of sludge requirements for coagulating chemicals into an alkalinity demand, and added solids demand, is also expedient. The solids demand is altered by digestion and the alkalinity demand may be altered by elutriation previous to chemical conditioning. Nevertheless, both reactions involve the same solute ions in the same sludge water. In addition to the alkalinity reactions, there are the rather widely known oxidation-reduction reactions associated with the use of ferric chloride, which are conveniently associated with the carbon compounds, sulfides, etc., in the wetted solids demand. Probably other minor reactions are associated with this demand. However, because of the presence of calcium and magnesium in sludges, it is doubtful whether borates, silicates, and phosphates will be found in sufficient quantities as true solute ions to affect the coagulant consumption in average sludges significantly. The chief polar ions involved in the surface chemistry of coagulation will be the various bicarbonates.

Aside from the polar compounds found in the chemically and biochemically fouled water associated with wetted sludge solids, the surface chemistry of the polar solids holding this water and its solutes is active in coagulation. As described elsewhere,[33] the process of coagulating water-logged sludge solids is similar, in principle, to the curdling of milk and depends on the chemical transformation of polar groups in the water-imbibing structures, with the result that these structures clump into solid aggregates having far less attraction for water.

---

[33] "Principles and Factors Influencing Vacuum Filtration of Sludge," by A. L. Genter, *Sewage Works Journal*, November, 1941, p. 1179.

Such clumping may also be termed a coarse flocculation process, but the rate of obtaining properly clumped solid aggregates in coagulating sewage sludges has only a limited likeness to the rate of flocculation common to the colloid chemical practice of coagulating rather pure sols dispersed in relatively pure water. The writer, therefore, doubts if the clumping rate in current vacuum filtration practice has any measurable effect on ferric chloride consumption. He does agree, however, that both the method of mixing coagulant with a sludge, and the duration of the mixing, are of material importance to coagulant economy. This has been emphasized elsewhere,[8,34] including the last paragraph of the "Summary."

In any case, the research involved in this paper and in its discussions should leave little doubt that the coagulant requirements of various sludges are functions of the solutes in the sludge water; and, what is most important, the amount of this water per unit weight of sludge solids is a function of the amount of volatile matter per unit weight of ash in the sludge. In presenting the foregoing investigations of the causes and consequences of this relationship from the initial stages of solids concentration in plain sedimentation to the final stages of the disposal of the solids, it is felt that the amount of evidence has left the problem less baffling.

DETERMINATION OF PRESSURES WITHIN A SIPHON SPILLWAY

By I. M. Nelidov,[1] M. Am. Soc. C. E.

With Discussion by Messrs. A. Shukry, and I. M. Nelidov.

Synopsis

A correct determination of the internal pressures in closed conduits is an important factor in their design. In ordinary pipes with a straight alinement the computation of internal pressures is rather simple. It is limited to determination of the height of the piezometric line above the center line of the pipe after which a multiplication of this piezometer height by the unit weight of water gives the average value of the internal pressure within the pipe. This pressure is normally called "positive"—that is, in regard to the pressures exerted by air it is greater than the latter and their difference is positive. However, there are cases in which pressures become "negative," or smaller than the pressure exerted by air. Such cases occur (*a*) in closed conduits when the vertical alinement is above the piezometric line, (*b*) in conduits behind valves or gates; and (*c*) in siphons in which the effect of the curvature of the flow filaments is revealed by a distribution of internal pressures different from hydrostatic pressures. In the siphons the pressures may become either positive or negative. Expressions for the pressures within a siphon are derived in this paper.

Introduction

In designing a true siphon the strength of the walls should be based on pressures within the siphon, because they may become smaller or greater than atmospheric pressure. The unbalanced pressures resulting from the curvilinear flow will produce forces which will be especially noticeable at the summit and at the outlet, provided the latter has the usual reverse curves.

Notation.—The letter symbols used in this paper are defined where they first appear in the paper, and are assembled for reference in the Appendix.

Note.—Published in March, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] With U. S. Engr. Dept., Sacramento, Calif.

THEORY

The theory upon which the derivations were based is that of the free vortex or irrotational flow with a velocity potential.[2] With this assumption the energy content E for each filament is the same, independent of the location of the filament within the flow. By inspection in Fig. 1, the atmospheric vacuum head h_a is equal to

or

$$\frac{p}{\gamma} = h_a + h - y - h_v + h_{vo} \ldots\ldots\ldots\ldots\ldots\ldots (1b)$$

in which h = the distance from the invert to the mean water gradient (positive when the mean water gradient is above the invert); y = the height above the invert to a filament where a value of pressure is to be determined; p = pressure intensity at the filament, distant y above the invert; h_v = velocity head at the filament distant y above the invert; h_{vo} = mean velocity head corresponding to pressure energy $\frac{p_o}{\gamma}$ and distance above the invert y_o; and γ = the unit weight of water = 62.5 lb per cu ft.

---

[2] Discussion by B. A. Bakhmeteff of "Tests of Broad-Crested Weirs," by J. G. Woodburn, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 430.

Likewise, by inspection in Fig. 1,

$$\frac{p'}{\gamma} = h_{vi} + \frac{p_i}{\gamma} - h_v - y \qquad (2)$$

in which h_{vi} = velocity head at the filament along the invert. Combining Eqs. 1b and 2:

$$\frac{p_i}{\gamma} = h_a + h - h_{vi} + h_{vo} \qquad (3)$$

Once $\frac{p_i}{\gamma}$ is found, $\frac{p_c}{\gamma}$, $\frac{p_o}{\gamma}$, $\frac{p_i}{\gamma}$ and $\frac{p}{\gamma}$ can be determined from the following expression (see Fig. 1):

$$h_{vc} + \frac{p_c}{\gamma} + d = h_{vo} + \frac{p_o}{\gamma} + y_o = h_v + \frac{p}{\gamma} + y = h_{vi} + \frac{p_i}{\gamma} = E \qquad (4)$$

from which

$$\frac{p_c}{\gamma} = E - h_{vc} - d \qquad (5a)$$

$$\frac{p_o}{\gamma} = E - h_{vo} - y_o \qquad (5b)$$

$$\frac{p_i}{\gamma} = E - h_{vi} \qquad (5c)$$

and

$$\frac{p}{\gamma} = E - h_v - y \qquad (5d)$$

In Eqs. 3, 4, and 5, p_c (at the crown), p_o (at y_o), and p (at any point y) are absolute pressures; that is, the atmospheric pressure has been added in each case. The pressures relative to the atmospheric pressure p_r can be obtained by deducting h_a from the absolute pressures p_a as shown in Fig. 1(b), or:

$$p_r = p_a - h_a\gamma \qquad (6)$$

These relative pressures (p_r) are the ones to be used in structural computations. (In this paper, a minus sign indicates that the resulting pressure is directed toward the inside of the conduit, and a plus sign means the reverse.)

For a complete solution it is necessary to determine h_a, h, h_{vi}, h_{vc} (velocity head at the crown), h_{vo}, and the dimensions of the siphon cross sections—such as the width b, the depth or height d of a cross section normal to the direction of flow, and one of the radii. Let h_a = 24 ft to 28 ft as reduced from its theoretical value of 33.9 ft due to vapor pressure. Other values of head —h, h_{vi}, h_{vc}, and h_{vo}—are determined from flow computations.

Assume that the mean velocity V_m (equal to the velocity at distance y_m

above the invert) and the cross section area A are given. First, the flow will be referred to mean hydraulic gradient and mean energy gradient, thus:

$$h = h_o - (1 + \sum K)\, h_{vo} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

in which h_o = the head necessary for priming the siphon or in general the head above the invert of the summit of a siphon; and K = the coefficient of loss from the inlet to the point under consideration. Usually the value of h or the position of the mean hydraulic gradient is fixed by the conditions at the outlet, whether free or submerged, and with the discharge defined by these conditions the mean velocity V_m can be found. Then the mean velocity head entering Eq. 7 must be expressed in terms of the mean velocity.

A coefficient $n = \dfrac{h_{vo}}{h_{vm}}$, representing the ratio of mean velocity head to that due to mean velocity, can be determined from the expression:

$$h_{vo} = n\, h_{vm} = \frac{\displaystyle\int_0^d \frac{V^2}{2\,g}\, dq}{\displaystyle\int_0^d V\, dy} = \frac{\displaystyle\int_0^d \frac{V^2}{2\,g}\, V\, dy}{\displaystyle\int_0^d V\, dy} = \frac{\displaystyle\int_0^d \frac{V^3}{2\,g}\, dy}{\displaystyle\int_0^d V\, dy} \ldots\ldots\ldots (8)$$

in which h_{vm} = the velocity head due to a mean velocity V_m; V = the velocity at any filament distant y from the invert; g = the gravity constant; and q = the discharge per unit width. For a flow convex upward, the velocity at any filament y is:

$$V = V_c \frac{r_i + d}{r_i + y} = V_c \frac{r_c}{r_i + y} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which V_c = the velocity at the filament at the crown; r_i = the radius of the siphon at the invert (Fig. 1); and r_c = the radius of the siphon at the crown. Substituting Eq. 9 in Eq. 8 and writing the solution for n:

$$n = \frac{h_{vo}}{h_{vm}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

that is:

$$n = \frac{\displaystyle\int_0^d \frac{V^3_c}{2\,g}\left(\frac{r_c}{r_i + y}\right)^3 dy}{\displaystyle\frac{V^2_m}{2\,g}\int_0^d V_c\left(\frac{r_c}{r_i + y}\right) dy} = \left(\frac{V_c}{V_m}\right)^2 \frac{\displaystyle\int_0^d \left(\frac{r_c}{r_i + y}\right)^3 dy}{\displaystyle\int_0^d \left(\frac{r_c}{r_i + y}\right) dy} \ldots (10b)$$

Let $\dfrac{V_c}{V_m} = \beta$ and $\dfrac{r_c}{r_i} = m > 1$; then Eq. 10b becomes

$$n = \beta^2\, r^2_c \frac{\displaystyle\int_0^d \frac{dy}{(r_i + y)^3}}{\displaystyle\int_0^d \frac{dy}{r_i + y}} = \beta^2\, r^2_c \frac{-\,0.5\,(r_i + y)^{-2}\Big|_0^d}{\log_e (r_i + y)\Big|_0^d}$$

$$= -\frac{\beta^2\, r_c^2}{2}\, \frac{r^{-2}_c - r^{-2}_i}{\log_e r_c - \log_e r_i} = \frac{\beta^2\,(m^2 - 1)}{2 \log_e m} \ldots\ldots\ldots\ldots (11)$$

For a flow concave upward, the velocity at any filament distant y above the invert is:

$$V = V_e \frac{r_i - d}{r_i - y} = V_e \frac{r_e}{r_i - y} \qquad (12)$$

Substituting Eq. 12 in Eq. 8 and again writing the solution for n:

$$n = \frac{h_{vo}}{h_{vm}} = \frac{\int_0^d \frac{V^3_e}{2\,g}\left(\frac{r_e}{r_i - y}\right)^3 dy}{\frac{V^2_m}{2\,g}\int_0^d V_e \frac{r_e}{r_i - y}\,dy} = \left(\frac{V_e}{V_m}\right)^2 \frac{\int_0^d \left(\frac{r_e}{r_i - y}\right)^3 dy}{\int_0^d \frac{r_e}{r_i - y}\,dy}$$

$$= \beta^2\, r^2_e \frac{\int_0^d \frac{dy}{(r_i - y)^3}}{\int_0^d \frac{dy}{r_i - y}} \qquad (13)$$

As with Eq. 10, when Eq. 13 is written in terms of β and m, the algebraic result is identical with Eq. 11. In applying this formula, however, a different numerical result is obtained for the case of flow convex upward (in which m is greater than unity) than for the case of flow concave upward (in which m is less than unity). Now to determine the expression for β: Since

$$V_m = \frac{q}{d} = \frac{\int V\,dy}{d} \qquad (14)$$

the value of $\beta = \frac{V_e}{V_m}$, for the case of flow convex upward, is determined from the following expression:

$$\beta = \frac{V_e}{V_m} = \frac{V_e\,d}{\int_0^d V\,dy} = \frac{V_e\,d}{\int_0^d V_e \frac{r_i + d}{r_i + y}\,dy}$$

$$= \frac{d}{r_e}\,\frac{1}{\log_e r_e - \log_e r_i} = \frac{d}{r_e \log_e \frac{r_e}{r_i}} = \frac{1}{\frac{r_e}{d}\log_e m} \qquad (15)$$

in which $m > 1$. For the case of flow concave upward it is:

$$\beta = \frac{V_e\,d}{\int_0^d V_e \frac{r_i - d}{r_i - y}\,dy} = -\,\frac{d}{(r_i - d)\log_e (r_i - y)\Big|_0^d}$$

$$= \frac{-\,d}{r_e \log_e \frac{r_i}{r_e}} = \frac{1}{\frac{r_e}{d}\log_e \frac{1}{m}} \qquad (16)$$

in which $m < 1$. Eqs. 15 and 16 are not identical, and they do not render identical numerical results.

The relationships between the various velocity heads are as follows. By definition (see Eq. 10a) $h_{vo} = n\, h_{vm}$. The corresponding relationship between h_{vc} and h_{vm} is defined as:

$$h_{vm} = \frac{V^2{}_m}{2\,g} \times \frac{V^2{}_c}{V^2{}_c} = \frac{V^2{}_c}{2\,g}\left(\frac{V_m}{V_c}\right)^2 = \frac{1}{\beta^2}\, h_{vc} \ldots\ldots\ldots\ldots \tag{17a}$$

Likewise,

$$h_{vc} = \frac{V^2{}_c}{2\,g} \times \frac{V^2{}_m}{V^2{}_m} = \frac{V^2{}_m}{2\,g}\left(\frac{V_c}{V_m}\right)^2 = \beta^2\, h_{vm} \ldots\ldots\ldots\ldots \tag{17b}$$

The relationship between h_{vi} and h_{vm} is defined as follows, since $\dfrac{V_i}{V_c} = \dfrac{r_c}{r_i} = m$,

$$h_{vi} = \frac{V^2{}_i}{2\,g} \times \frac{V^2{}_c}{V^2{}_c} = \frac{V^2{}_c}{2\,g}\left(\frac{V_i}{V_c}\right)^2 = h_{vc}\, m^2 = \beta^2\, m^2\, h_{vm} \ldots\ldots\ldots \tag{18}$$

The relationship between h_v, h_{vc}, h_{vm}, and h_{vi} for the flow convex upward is as follows: $\dfrac{V}{V_c} = \dfrac{r_c}{r_i + y}$ or

$$h_v = h_{vc}\left(\frac{r_c}{r_i + y}\right)^2 = \beta^2\, h_{vm}\left(\frac{r_c}{r_i + y}\right)^2 = \frac{h_{vi}}{\left(1 + \dfrac{y}{r_i}\right)^2} \ldots\ldots \tag{19a}$$

In the same way, for the case of flow concave upward:

$$h_v = h_{vc}\left(\frac{r_c}{r_i - y}\right)^2 = \beta^2\, h_{vm}\left(\frac{r_c}{r_i - y}\right)^2 = \frac{h_{vi}}{\left(1 - \dfrac{y}{r_i}\right)^2} \ldots\ldots \tag{19b}$$

The position of the filament at which the mean velocity head h_{vo} occurs is determined as follows: For the flow convex upward, since $h_{vo} = n\, h_{vm}$ (see Eq. 10a),

$$h_{vo} = n\, h_{vm} = h_{vc}\left(\frac{r_i + d}{r_i + y_o}\right)^2 \ldots\ldots\ldots\ldots\ldots\ldots \tag{20a}$$

or, since $h_{vc} = \beta^2\, h_{vm}$,

$$n = \frac{\beta^2\, r^2{}_c}{(r_i + y_o)^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{20b}$$

Therefore,

$$y_o = \frac{\beta\, r_c}{\sqrt{n}} - r_i = r_i\left(m\sqrt{\frac{2\log_e m}{m^2 - 1}} - 1\right) \ldots\ldots\ldots\ldots \tag{21}$$

For the flow concave upward:

$$h_{vo} = n\, h_{vm} = h_{vi}\,\frac{r^2{}_c}{(r_i - y_o)^2} \ldots\ldots\ldots\ldots\ldots\ldots \tag{22a}$$

or

$$n = \beta^2\left(\frac{r_i - d}{r_i - y_o}\right)^2 = \frac{\beta^2\, r^2{}_c}{(r_i - y_o)^2} \ldots\ldots\ldots\ldots\ldots \tag{22b}$$

and

$$y_o = -\left(\frac{r_c}{\sqrt{n}} - r_i\right) = r_i\left(1 - m\sqrt{\frac{2\log_e m}{m^2 - 1}}\right) \ldots\ldots\ldots\ldots \tag{23}$$

Example 1. Pressures at the Crown and Invert of the Summit Section (Convex Upward).—Consider a siphon for which the general conditions are as listed in Table 1(*a*). As shown in Table 1(*b*), other basic quantities are: $r_c = 20$ ft

TABLE 1.—COMPUTATIONS FOR PRESSURES AT THE CROWN AND INVERT OF A SIPHON

(*a*) GENERAL DATA

$Q = 100$ cu ft per sec, $A = 10$ sq ft, $b = 2.5$ ft, $d = 4$ ft, $r_i = 16$ ft, $q = 100/2.5 = 40$ cu ft per sec, $V_m = 40/4 = 10$ ft per sec, $h_{vm} = 1.55$ ft, and $h_a = 24$ ft

Equation	Symbol	Computation	Quantity	Unit
(*b*) EXAMPLE 1.—SUMMIT SECTION (CONVEX UPWARD, $h = -10$ FT)				
. . .	r_c	$16 + 4$	20	Ft
. . .	m	$r_c/r_i = 20/16$	1.25	. . .

5*c*	E	$1.96 + 13.63$	15.59	Ft
5*a*	p_c/γ	$15.59 - 1.26 - 4$	10.33	Ft
. . .	p_c	$10.33 \times 62.5 \times 1/144$	4.48	Lb per sq in.
21	y_o	$16\left(1.25\sqrt{\dfrac{2 \log_e 1.25}{1.25^2 - 1}} - 1\right)$	1.81	Ft
5*b*	p_o/γ	$15.59 - 1.59 - 1.81$	12.19	Ft
. . .	p_o	$12.19 \times 62.5 \times 1/144$	5.33	Lb per sq in.
. . .	p_a	$24 \times 62.5 \times 1/144$	10.42	Lb per sq in.
(*c*) EXAMPLE 2.—SECTION NEAR THE OUTLET (CONCAVE UPWARD, $h = +10$ FT)				
. . .	r_c	$16 - 4$	12	Ft
. . .	m	$r_c/r_i = 12/16$	0.75	. . .
16	β	$1/(3 \times 0.288)$	1.15	. . .
17	h_{vc}	$1.15^2 \times 1.55$	2.06	Ft
18	h_{vi}	$0.75^2 \times 2.06$	1.16	Ft
11	n	$\dfrac{1.15^2\,(0.75^2 - 1)}{2\,(\log_e 0.75)}$	1.01	. . .
10*a*	h_{vo}	1.01×1.55	1.58	Ft
3	p_i/γ	$24 + 10 - 1.16 + 1.58$	34.42	Ft
. . .	p_i	$34.42 \times 62.5 \times 1/144$	14.90	Lb per sq in.
5*c*	E	$1.16 + 34.42$	35.58	Ft
5*a*	p_c/γ	$35.58 - 2.06 - 4$	29.52	Ft
. . .	p_c	$29.52 \times 62.5 \times 1/144$	12.78	Lb per sq in.
23	y_o	$16\left(1 - 0.75\sqrt{\dfrac{2 \log_e 0.75}{0.75^2 - 1}}\right)$	2.19	Ft
5*b*	p_o/γ	$35.58 - 1.58 - 2.19$	31.81	Ft
. . .	p_o	$31.81 \times 62.5 \times 1/144$	13.78	Lb per sq in.
. . .	p_a	$24 \times 62.5 \times 1/144$	10.42	Lb per sq in.

and $m = 1.25$. The remaining steps of the solution follow in the sequence of steps in Table 1(*b*).

By Eq. 6 and Table 1(*b*) the pressures relative to atmospheric pressure, in pounds per square inch, are:

$$p_{cr} = 4.48 - 10.42 = -5.94$$
$$p_{or} = 5.33 - 10.42 = -5.09$$
$$p_{ir} = 5.93 - 10.42 = -4.49$$

The direction of action of these pressures is inward—that is, toward the inside of the conduit. The diagram of distribution of the absolute and relative pressures can be obtained from Eqs. 5*d* and 19*a*, thus:

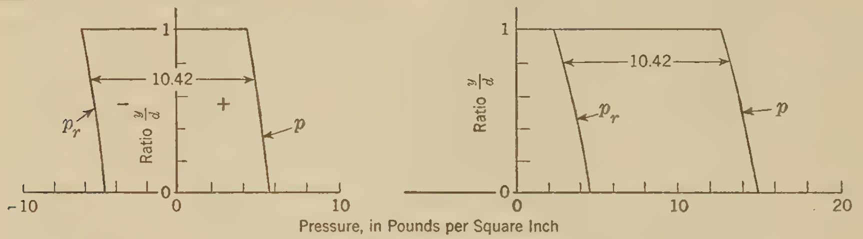
$$p = (E - h_v - y)\,\gamma = \frac{\gamma}{144}\left[E - \frac{h_{vi}}{\left(1 + \frac{y}{r_i}\right)^2} - y\right] \quad \text{........(24)}$$

or, substituting appropriate values,

$$p = \frac{62.5}{144}\left[15.59 - \frac{1.96}{\left(1 + \frac{y}{16}\right)^2} - y\right] = 1.74\left[3.90 - \frac{0.49}{\left(1 + \frac{y}{4d}\right)^2} - \frac{y}{d}\right] . \text{(25)}$$

in which $\frac{y}{d} = \frac{y}{4}$. The values of p are given in Table 2(*a*).

TABLE 2.—PRESSURES IN A SIPHON, IN POUNDS PER SQUARE INCH; ILLUSTRATIVE EXAMPLES



(*a*) EXAMPLE 1 (*b*) EXAMPLE 2

Item	Pressure	Ratios y/d					
		1.00	0.80	0.60	0.40	0.20	0.00
(*a*) Example 1.—Flow Through the Summit; Convex Upward							
1	p	4.48	4.80	5.10	5.40	5.66	5.93
2	p_r	−5.94	−5.62	−5.32	−5.02	−4.76	−4.49
(*b*) Example 2.—Flow Through the Section Near the Outlet; Concave Upward							
3	p	12.78	13.30	13.75	14.17	14.60	14.90
4	p_r	2.36	2.88	3.33	3.75	4.18	4.48

Example 2. Pressures at the Crown and Invert of a Siphon Section Near the Outlet.—The basic quantities, Q, A, b, k, r_i, q, V_m, h_m, and h_a, are the same as in Example 1. Other basic quantities (see Table 1(*c*)) are: $r_c = 12$ ft and $m = 0.75$. The remaining steps of the solution are listed in Table 1(*c*). By Eq. 6 the pressures relative to atmospheric pressure, in pounds per square inch, are:

$$p_{cr} = 12.78 - 10.42 = 2.36$$
$$p_{or} = 13.78 - 10.42 = 3.36$$
$$p_{ir} = 14.90 - 10.42 = 4.48$$

The direction of these pressures is outward—that is, toward the outside of the conduit. Similar to Example 1, the diagram of absolute and relative pressures is obtained from Eqs. 5*d* and 19*b*; thus (compare Eq. 24):

$$p = (E - h_v - y) = \frac{\gamma}{144}\left[E - \frac{h_{vi}}{\left(1 - \frac{y}{r_i}\right)^2} - y\right] \ldots\ldots\ldots (26)$$

Again, substituting appropriate values,

$$p = \frac{62.5}{144}\left[35.58 - \frac{1.16}{\left(1 - \frac{y}{16}\right)^2} - y\right] = 1.74\left[8.90 - \frac{0.29}{\left(1 - \frac{y}{4d}\right)^2} - \frac{y}{d}\right] . (27)$$

in which $\frac{y}{4} = \frac{y}{d}$. The values of p for Example 2 are given in Table 2(*b*).

SUMMARY

The derivations in this paper, which are based on the formulas for an idealized vortex flow in a siphon, and the subsequent numerical examples, illustrate that the pressures both at the summit and at the outlet of a siphon become unbalanced relative to the atmospheric pressures. Therefore, structural design should provide for these unbalanced pressures with due amount of steel reinforcement in the concrete if the siphon is a reinforced concrete structure or with an additional quantity of steel if it is of steel. Actual failures of siphons indicate the necessity for the provisions recommended.

The unbalanced pressures in the examples cited herein are about 5 lb per sq in. maximum, which is about 0.4 ton per sq ft or about 720 lb per sq ft. If it is remembered that a live load created by a crowd of people is usually assumed to be 100 lb per sq ft and in warehouses as much as 400 lb per sq ft, then it will be realized what magnitude of pressure is imposed on siphons and why some of them fail. It is therefore considered that a siphon (or as a matter of fact any closed conduit) with a curvilinear flow should be designed for the unbalanced pressures resulting from such flow.

APPENDIX

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942.

Without subscripts, the symbols refer to the summit, outlet, or anywhere along the line of the siphon. Subscripts c and i, respectively denote the crown point and invert at any section.

A = area of siphon cross section;
b = width of the siphon;
c = subscript denoting "crown";
d = height of the cross section under consideration, normal to the direction of flow;
E = energy content as shown in Fig. 1 (see Eq. 4);
g = gravity constant;
h = head = distance from the invert to the mean water gradient (positive when the mean water gradient is above the invert);
h_a = atmospheric vacuum head;
$h_{\blacksquare}$ = distance from the invert at the summit of a siphon to the water level in the reservoir;
h_v = velocity head at a filament distant y from the invert:
  h_{vc} = velocity head at the crown;
  h_{vi} = velocity head at the invert;
  h_{vm} = velocity head due to mean velocity;
  h_{vo} = mean velocity head;
i = subscript denoting "invert";
K = coefficient of energy loss from the inlet to the section under consideration;
m = ratio of the radius at the crown r_c to the radius at the invert r_i;
n = ratio of the mean velocity head h_{vo} to the velocity head h_{vm} created by the mean velocity V_m;
p = pressure intensity at a filament distant y above the invert:
  p_a = absolute pressure intensity;
  p_c = pressure at the crown;
  p_i = pressure at the invert;
  p_o = pressure intensity at a filament with mean kinetic energy, distant y_o above the invert;
  p_r = pressure relative to atmospheric pressure;
Q = rate of flow in a siphon;
q = rate of flow per unit width of siphon;
r = radius, with appropriate subscripts;
V = velocity of flow, with appropriate subscripts:
  V_m = velocity at a filament equal to the mean value of V, distant y_m from the invert;
y = distance to any filament measured upward from the invert:
  y_m = distance above the invert where the velocity of a filament is the same as the mean velocity of the section;
  y_o = distance above the inert where the kinetic energy of a filament is the same as the mean kinetic energy of the section;
β = ratio of the velocity of flow at the crown, V_c, to the mean velocity, V_m;
γ = unit weight of water, assumed equal to 62.5 lb per cu ft.

DISCUSSION

A. Shukry,[3] Esq.—The main assumptions on which the author has based the formulas for pressures within the sections at the summit and near the outlet of a siphon spillway are: (*a*) The flow around the siphon bends obeys the free vortex law; and (*b*) the elevation of the mean hydraulic and energy gradients at any point can be determined by adding the head losses of the individual elements from the inlet to the point under consideration.

As given by Eq. 7, the second assumption really was made because the given formulas must depend on a foreknowledge of the elevation of the mean water gradient at the point concerned.

The writer would like to discuss the foregoing two assumptions in the light of experiments conducted in 1942[4] on siphon models in the irrigation research laboratory of Fouad I University, Gîza, Egypt. Under the direction of Prof. H. Hefny, the writer measured the pressure and the velocity distribution across different sections of siphon models to study the behavior of the siphonic flow and to determine the extent to which the flow obeys the laws of pipe flow. Fig. 2(*a*) illustrates a view of one of the models; and Fig. 2(*b*), the arrangement of the laboratory. The identity of the various points marked by letters in Fig. 2(*b*) is as follows:

Point	Description
A	Adjustable copper gate shown in Fig. 2(*a*)
B	Side scales for the air vent
C	Lip of the siphon
D	Glass side for observing the action of priming
E	Pitometer tube for measuring velocity distribution
F	Differential gage for measuring velocity heads
G	Suction pump
H	Rubber tube connections with the pressure gages

Regarding assumption (*a*), the theoretical velocity distribution based on a free vortex flow at the summit and outlet bends of a siphon was derived by integrating a discharge element of depth dr. If the working head on the siphon is designated by H, then, according to Fig. 3,

$$Q = \int_{r_i}^{r_c} dQ = b \int_{r_i}^{r_c} V\,dr = b \int_{r_i}^{r_c} \frac{V_i\,r_i}{r}\,dr = b\,V_i\,r_i \int_{r_i}^{r_c} \frac{dr}{r}$$

$$= b\sqrt{2\,g\,H}\;r_i \log_e \frac{r_c}{r_i} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

The velocity at any point distant r from the center would then be:

$$V = \frac{V_i\,r_i}{r} = \frac{Q}{b\,r \log_e \frac{r_c}{r_i}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

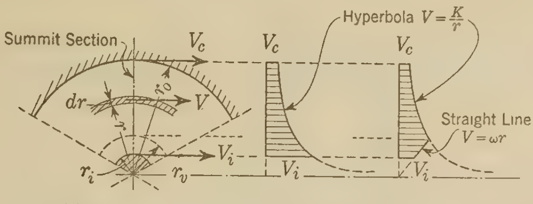
FIG. 2.—MODEL OF SIPHON, AND LABORATORY ARRANGEMENT

The working head H considered in Eq. 28 should not exceed 24.0 ft of water, which is the practical limit of partial vacuum, however high the working head may be.[5] The mean percentage difference (ΔV) between the theoretical and the actual velocity distribution curves was calculated at any section by the formula:



(a) (b) FREE VORTEX POTENTIAL (c) COMBINED VORTEX

FIG. 3.—VELOCITY DISTRIBUTION AT THE SUMMIT SECTION OF A SIPHON SPILLWAY

$$\Delta V = \frac{\int_{r_i}^{r_e} [V \text{ (theoretical)} - V \text{ (actual)}]\, dr}{\int_{r_i}^{r_e} V \text{ (actual)}\, dr} \times 100 \quad \ldots\ldots\ldots (30)$$

The following three types of sections were considered: (1) All sections at the bends of the siphon when operated under a constant working head (Fig. 4); (2) the summit section of the siphon when operated under different working heads (Table 3); and (3) the summit section of the siphon for various shapes of outlet, operated under the same working head (Fig. 5).

The results showed that similarity between the actual and the theoretical flow distribution was closer for smaller than for larger ratios of $r_c : r_i$, and that the velocity distribution at the summit bend did not appreciably change within the possible range of the working head or with different shapes of outlets.

To study the applicability of the free vortex law in predetermining the discharge passing through any siphon spillway, the theoretical and the actual discharges of seven different types of siphon spillways were compared. As seen in Table 4, the theoretical discharges are always less than the actual discharges. The percentage difference can thus be considered as a factor of safety; but, beyond a ratio of $r_c/r_i = 3.0$, the design, according to a free vortex assumption, may become uneconomic.

The reason for a departure of the actual flow from the ideal free vortex is explained by the fact that the free vortex law, when applied to bends of closed or open conduits, should be limited with respect to the pressure induced at the inner wall of the bend. According to this law the velocity at any point in the bend is inversely proportional to its radius. Consequently, as r_i approaches the value zero in very sharp curves, V_i approaches infinity and P_i/γ

radius r_v, the inner portion of the fluid behaves as a separate vortex filament, all particles of which have a constant rate of rotation ω, similar to conditions in a forced vortex where $V = \omega r$. The velocity distribution in this combined potential, generally known as the Rankine vortex, is shown diagrammatically in Fig. 3. It is obvious that the energy of flow in this vortex filament cannot be considered a constant because of its rotational motion. If r_i is greater than r_v, the flow in the bend will obey the free vortex law. On the other hand, if r_i is smaller than r_v the flow will obey the combined vortex potential. The value of r_v for any bend can be determined in terms of the dimensions and the flow conditions of the bend.

As regards the second assumption made by Mr. Nelidov, it should be mentioned that there has been considerable discussion as to whether the siphonic flow obeys the laws of flow in pipes—in other words, whether it is possible to divide the total length of the siphon into a number of bends and straight sections and to apply the existing coefficients and formulas for the individual parts so as to obtain the progressive net losses in friction and eddies. Most of this discussion[6,7,8,9,10] was based on pressure measurements at some sections of siphon models. The pressure head at any section was considered as the mean reading of the pressure gages, and the total head was calculated by adding to the pressure head the velocity head h_{vm}. Through the omission of the head-correction factors resulting from the nonuniform distribution of velocities and pressures, serious discrepancies in the energy lines were encountered, especially at the *vena contracta* downstream from the summit bend. Investi-

gators found the same phenomena when analyzing the energy losses from the recorded pressures in some existing siphon spillways.[11,12]

For the purpose of determining the correct analysis, the energy method was followed in deriving the mean values of the pressure, velocity, position, and total heads at any section. This was accomplished by integrating the energy curves (instead of the head curves) with respect to the area of the section, as given by the following: Mean pressure head,

$$h_{pm} = \frac{1}{V_m A} \int_0^A \frac{p}{\gamma} V \, dA \qquad \text{(31}a\text{)}$$

mean velocity head,

$$h_{vm} = \frac{1}{V_m A} \int_0^A \frac{V^3}{2 g} dA \qquad \text{(31}b\text{)}$$

mean position head,

$$h_{sm} = \frac{1}{V_m A} \int_0^A y \, V \, dA \qquad \text{(31}c\text{)}$$

and mean total head,

$$h_{tm} = \frac{1}{V_m A} \int_0^A \left(\frac{p}{\gamma} + \frac{V^2}{2 g} + y \right) V \, dA \qquad \text{(31}d\text{)}$$

In the writer's investigation, the aforementioned energy process eliminated the apparent discrepancies in the energy line of a siphon. The siphon was then divided into three parts—the summit bend, the straight leg, and the outlet bend. The coefficient K expressing the loss of head in terms of h_{vm} was obtained for each part and compared with the value given in the existing published data. The loss of head due to wall friction was calculated according to the modified Chézy formula (in foot-second units):

$$h_l = \frac{V^2{}_m \, n^2}{R^{1.333}} \qquad \text{(32)}$$

in which h_l is loss of head per unit length; n is Kutter's coefficient of roughness equal to 0.009 for the model walls; V_m is mean velocity in the section, and R is the hydraulic radius. The loss of head due to a bend, which is the head in excess of that which would occur in a straight conduit of equal length, has been obtained by at least two investigators: (*a*) William P. Creager and Joel D. Justin, Members, Am. Soc. C. E., determined coefficients based on the mean results of most of the tests which had been conducted on pipe bends;[13] and (*b*) James Williamson derived coefficients[10] in which the effect of the wall material of the bend was taken into consideration.

Comparison of the two revealed that the actual losses in the siphon elements were totally different from the losses of these elements when tested separately, as may be noted in Table 5. It was found, however, that the various elements of the siphon seemed to have a counterbalancing effect on

each other. A reduction of the loss at one part was offset by an increase of the loss at another, so that the total sum of the energy losses appeared to be practically unchanged. This may help to compute the rate of discharge passing through any type of siphon spillway with a reasonable degree of accuracy, as shown in Tables 4 and 5, but fails to give any correct indication for the pressures that may be induced at some sections of a siphon or the elevation of the energy line.

TABLE 5.—COMPARISON BETWEEN EXPERIMENTAL (K_a) AND COMPUTED (K_c) VALUES OF THE ENERGY LOSS COEFFICIENTS (BASED ON THE MEAN VELOCITY AT THE SUMMIT SECTION) AND THE RATE OF FLOW IN A SIPHON MODEL

[a] Computed value of the energy loss coefficient K_c, with bend losses as determined by the methods of W. P. Creager and J. D. Justin, and by J. Williamson, respectively.

Mr. Nelidov has shown clearly the relatively high pressures within the summit and near the outlet bends of a siphon, and the importance of providing good reinforcement for these unbalanced pressures, due to which failure of the siphon may occur. It may be added that a good factor of safety in the structural design should also be provided to withstand the intermittent violent shocks and serious vibrations during the actions of priming and de-priming, especially if the siphon is to be operated under high heads.

I. M. NELIDOV,[14] M. AM. SOC. C. E.—The discussion by Mr. Shukry is constructive and positive in its conclusions. On the basis of experiments, it is demonstrated that a similarity exists between the actual and the theoretical velocity, with variations on the safe side—that is, theoretical velocities are always smaller than actual velocities by various percentages ranging from 5% to 14% (see Table 3 and Figs. 4 and 5). Mr. Shukry makes a valuable comparison between the theoretical and actual discharges for seven existing siphons, which indicates that theoretical discharges are always smaller by various percentages, ranging from zero to 16%. On one occasion (for the Ferro siphon) the percentage variation was as high as 46%, which leads Mr. Shukry to conclude that for large ratios of $\frac{r_c}{r_i}$ (greater than 3.0) the discrepancy increases.

---

[14] Civ. and Structural Engr., El Cerrito, Calif.

With decreasing values of r_i a state may be reached such that the velocity V_i at the summit will be the limiting value based on the available atmospheric vacuum, after which the discharge will not be appreciably increased. The writer wishes to refer to his discussion of the article by Elmer Rock,[15] Assoc. M. Am. Soc. C. E., in which he indicated the possibility of a "limiting" discharge and a corresponding "limiting" head with the inference that further increase of the head will not produce increase in discharge. Similar results may be obtained with a constant head by decreasing the radius r_i. Referring to Example 1 and Table 1 of the paper, it may be found that by making $\frac{p_i}{\gamma} = 0$ in Eq. 3 and with $h_a = 24$ ft, $h = -10$ ft, and $h_{vm} = 1.55$ ft:

$$h_{vi} = h_a + h + n\, h_{vm} = 14 + n\, h_{vm} \ldots\ldots\ldots\ldots\ldots (33)$$

in which (see Eq. 11) $n = \frac{\beta^2 (m^2 - 1)}{2 \log_e m}$.

On the other hand, by Eq. 18, $h_{vi} = \beta^2 m^2 h_{vm}$. Equating Eqs. 18 and 33 and eliminating h_{vi}: $14 + n\, h_{vm} = \beta^2 m^2 h_{vm}$; or $-n + \beta^2 m^2 = \frac{14}{h_{vm}} = \frac{14}{1.55} = 9$.

By Eqs. 11 and 15 and with $m = \frac{r_c}{r_i}$:

$$\beta^2 \left[-\frac{m^2 - 1}{2 \log_e m} + m^2 \right] = 9 \ldots\ldots\ldots\ldots\ldots\ldots (34a)$$

and

$$\left(\frac{d}{r_c}\right)^2 \frac{1}{\log^2_e \frac{r_c}{r_i}} \left[-\frac{\left(\frac{r_c}{r_i}\right)^2 - 1}{2 \log_e \left(\frac{r_c}{r_i}\right)} + \left(\frac{r_c}{r_i}\right)^2 \right] = 9 \ldots\ldots\ldots (34b)$$

With $d = 4$ ft and $r_c = 20$ ft, Eq. 34b becomes

$$\frac{0.04}{\log^2_e \frac{20}{r_i}} \left[-\frac{\left(\frac{20}{r_i}\right)^2 - 1}{2 \log_e \left(\frac{20}{r_i}\right)} + \left(\frac{20}{r_i}\right)^2 \right] = 9 \ldots\ldots\ldots\ldots (34c)$$

By trial it is found that a value of $r_i = 0.3$ ft will be the limiting radius of the invert. It is true that the value of the ratio $\frac{r_c}{r_i} = \frac{20}{0.3} = 67$ is so great that the theoretical results may be questioned, but this example was used only as a numerical illustration of the process of obtaining r_i. At the same time the small value of r_i demonstrates that in this example the flow will agree with the assumed theory of irrotational vortex.

---

[15] Discussion by I. M. Nelidov of "Design of High-Head Siphon Spillway," by Elmer Rock, *Transactions*, Am. Soc. C. E., Vol. 105 (1940), p. 1069.

Another point of considerable interest was treated by Mr. Shukry in his discussion of the mean pressure, velocity, and position heads corresponding to the nonuniform distribution of velocities. As shown by Fig. 1, the writer has related his energy and hydraulic gradient lines to their mean values and not to those corresponding to the mean velocity.

The use of losses in the siphons computed with the coefficients selected from nonrelated tables should give quite divergent results. However, the main fault is the scarcity of information pertaining specifically to the siphon flow rather than defective experiments.

The writer wishes to thank Mr. Shukry for his exhaustive study of the problem.

DESIGN OF ROADBEDS

BY IRA B. MULLIS,[1] ESQ.

WITH DISCUSSION BY MESSRS. CHARLES W. BRITZIUS, J. T. L. McNEW, GUSTAVO PÉREZ GUERRA, JACOB FELD, JASPER L. STUCKEY, DELBERT L. LACEY, RENÉ S. PULIDO Y MORALES, K. B. WOODS, AND IRA B. MULLIS.

SYNOPSIS

The purpose of this paper is fourfold:

1. To review the fundamental properties of the three classes or phases of matter and to show that a roadbed material in particular is either strong or weak according to the phase in which it is found;

2. To offer experimental evidence showing the influence of gases, liquids, and solids on the stability of roadbeds;

3. To cite examples of roads and certain experience supporting the theory advanced; and

4. To outline a standard of procedure under which roads may be designed and built so they will remain stable under given conditions of traffic.

INTRODUCTION

The materials of roadbeds are of infinite variety. In size, the constituents range from boulders to finite particles of matter; in quality, from rigid and durable rocks to fluids. That all these materials are of equal structural value, no one would claim; but, unless the several relationships are controlled adequately, the essential balance cannot be established and maintained. However, before the relationships of these materials can be controlled wisely, their natures must be understood.

As in other matter, the constituents of roadbeds may be classified profitably into three distinct states or phases—gases, liquids, and solids. This approach is followed because it is the accepted method of classifying matter in general and provides an orderly approach to a clear understanding of roadbeds in particular.

Since matter may exist in any one of three states, no one state can be considered as being characteristic of a given substance at all times. Its state, therefore, depends upon conditions, such as temperature and pressure. Water,

---

NOTE.—Published in April, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr., Raleigh, N. C.

for example, at atmospheric pressure is a solid below 0° C and a gas above 100° C. Unqualified statements, such as "air is a gas," "water is a liquid," and "quartz is a solid," are inaccurate unless atmospheric conditions are specified, as each of these substances may occur in any one of these states.

Obviously, roadbeds should be constructed and maintained as rigid bodies and, to attain this condition, the properties of the component materials must be understood. Moreover, the proper balance of the components must be maintained at all times; otherwise, structural failure is certain. The ability to resist loads is a property of solid or rigid bodies; but, whenever fluids are present in critical amounts, the property of rigidity is lost. The several states of matter and their effects on the structural properties of roadbeds have been discussed by the writer elsewhere.[2] Although the effects of heat, pressure, and solvents on the structural properties of certain rigid bodies are commonly recognized, most specifications and professional papers indicate a lack of appreciation of how earthy substances may be protected against the weakening effect of air and water.

Of course, the temperature of roadbed materials never approaches the point of liquefaction, although under freezing temperatures the beds do become very rigid. These freezing conditions, however, do not have an adverse effect on roadbeds unless they are very wet. Therefore, the only condition remaining that can lower the measure of their rigidity to that of a plastic or fluid condition is the presence of critical amounts of fluid, such as air or water. The method of approach is a rational one, the principles of which have been long understood, although habitually overlooked.

States of Matter

Gases.—A gas consists of an aggregation of atoms or molecules in which the force of attraction is so overbalanced by the movement of the particles that it cannot act. In this condition there is no cohesion between the particles, therefore; they fly in all directions. If the attractive force between the particles is normally weak, the substance exists as a gas at ordinary temperatures; but any substance, whether normally a liquid or a solid, may be turned into a gas by heating it sufficiently. Temperature is a relative comparison of molecular or atomic vibration; therefore, if atoms and molecules are made to vibrate fast enough, the attractive forces between them become ineffective. The result is a gas.

Due to the foregoing properties, gases, unlike other forms of matter, have no constant volume but fill all parts of the container regardless of its size. Therefore, gases are highly compressible and, under sufficient pressure and loss of heat, may be converted into liquids and in certain cases directly into solids.

Liquids.—A liquid consists of a mass of molecules in which motion and the relative distance between the molecules are considerably less than in a gas; hence, the attractive forces are greater. In a liquid the molecules are free to move about but they cannot move very far apart. The result is that the liquid maintains a relatively constant volume, assumes the shape of its container, and unlike gases maintains a definite upper surface.

---

[2] "Principles Applying to Highway Road-Beds," by Ira B. Mullis, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), p. 1381.

In a liquid, the attractive forces are great enough to hold the molecules together; however, the attractive forces do not have absolute control. Occasionally, a molecule at the surface of the liquid moves fast enough to break away and fly off into space. This phenomenon is known as evaporation. Hence, liquids left in the open air long enough disappear by evaporation. A liquid may be turned into either a gas or a solid under appropriate changes of heat and pressure.

Substances in the liquid state have greater densities, greater internal friction, larger cohesive forces, and much smaller compressibility than in the gaseous state. However, loads can be supported by liquids only when confined or under conditions that permit the utilization of buoyancy and velocity.

Solids.—In contrast to gases and liquids, the attractive forces in solids have the upper hand. The molecules are no longer free to move as they do in fluids, each molecule being tied to a definite position in the solid. These ties, therefore, have varying strengths in different substances, and they are one reason, at least, why different solids have different melting points. If the forces holding the solid together are weak, the solid will have a low melting point; but, if the forces are strong, the solid will have a high melting point. The reason for this is apparent if one remembers that temperature is a measure of molecular vibration. When the attractive forces are weak, only a little vibration is required to separate the molecules. A weak solid, such as butter, begins to melt on a warm day; but a solid, such as tungsten, one of the strongest metals, requires a temperature of more than 3,000° C to melt it. In a similar manner, one may say that, since gumbo clay is one of the strongest sediments, much water is required to soften it; but kaolin being among the weakest, little water is required for softening. As solids are only slightly compressible, this is an indication that the atoms or molecules already are under very high compressive forces so that the application of more pressure does not largely increase the total volume change.

By dissolving a foreign substance in a metal, the resistance to plastic deformation may be changed greatly. Thus, the mechanical properties of steel in the iron-carbon system are determined by very small amounts of carbon; and minute quantities of gases such as hydrogen, nitrogen, or oxygen which may be dissolved in a steel have an influence on the yield point and also on the relation between stress and plastic deformation. Thus, it will be seen that substances are weakened by excessive heat and by admixtures tending to accelerate molecular vibration. Bodies of clay, for example, are weakened by absorbed water that accelerates the molecular vibration of the mixture. In a like manner, solid bitumen is weakened by the liquefying action of either heat or naptha.

INFLUENCE OF FLUIDS ON SOLIDS

Under normal conditions of the atmosphere, the component fluids and solids in a roadbed may be confined to air, water, and rock matter. Since the physical properties of each of these substances have been established, the effect of one on the other should be the better understood, through stress-strain measurements of an adequate number of combinations of these substances.

Air and Rock Matter.—The effect of air on the structural properties of masses of rock matter, coarser than fine sand, is so insignificant as to require little attention either during or following construction; but, in material of a smaller particle size, the effect of air is one of major importance. During construction, air becomes entrapped in the pore spaces of the material, tends to hold the particles apart, and thus prevents consolidation of the mass. This condition may be exemplified by the use of a recently sifted Portland cement in a partly filled bag. If pressure is applied, the mass of air and cement tends to flow away from the area under pressure and, upon removal of the pressure, recovery is not noticeable. In mixtures of this sort, solid particles aided by intervening films of air are free to slip; therefore, the body may be said to be a dry plastic mass. Even if it were possible to reduce the thickness of the air films to the minimum, and thereby obtain fair contact, there can be no consolidation when films of air intervene. (The word "consolidate" connotes more than compaction and includes a bonding together of the particles. It is here used only in this sense.)

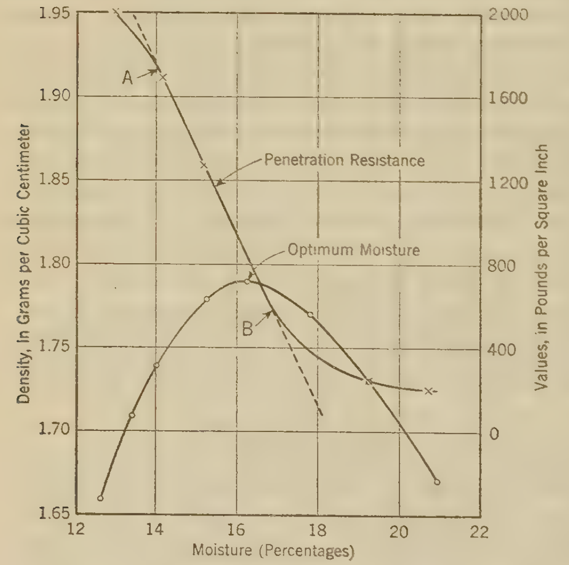

Fig. 1.—Relations of Density and Water Content to Penetration Resistance

The effect of air and water between particles of solid matter is exemplified in Fig. 1. This figure is based on data obtained through the use of an A.S.T.M. (American Society for Testing Materials) standard 5.5-lb hammer dropped 18 in., here referred to as the Modified Proctor method. On the dry side of the moisture-density curve, slipping begins under a moisture content of 14%. This manifestation is indicated by the break in the moisture-resistance curve at point A, Fig. 1. Corresponding to this point, the density approximates 1.74 g per cu cm and the moisture content 14%. Assuming an absolute density of 2.65, the voids occupy 34% of the volume. Of this volume 24% is water and the remaining 10% is air. Since slip is not indicated at the apex of the curve, corresponding to a density of 1.79 and a water content of 17%, slip starting at point A must be due to air content.

Although detailed information on the dry side of the moisture-density and stress-strain relations of the curve is meager, it is apparent that the presence of a critical amount of air in the pores of a solid produces a marked effect on the slip. For this and other reasons, the air permitted in a roadbed should be restricted to small quantities.

A good example of the adverse effect of occluded air in dry loessial sediments is found often during droughts on road construction projects on the Great Plains of the United States. Adequate compaction is impossible and slippage of the earthy material makes even moderate speed hazardous. Another well-known example is the slip experienced in attempting to travel over fine, dry, air-filled deposits of sand. Both of these examples are manifestations of voluminous pore space filled almost entirely with air.

Water and Rock Matter.—The effect of water on the structural properties of rock matter, coarser than fine sand, is of minor importance with the exception of the erosive action in streams during flood stages; therefore, no discussion will be given to this phase of the subject. However, the effect of water on the structural properties of sediments finer than coarse sand is one of major importance.

To assist in the elimination of air and to aid in the consolidation of sediments, the presence of water is essential. Without water, even clay particles cannot be made to stick together; however, when the compactive force is large, less water is necessary. This statement has been verified by J. W. Mellor[3] who found that, by increasing the pressure from 1 to 200 kg per sq cm, the water content for stickiness was reduced from 26.4% to 5.6%. Moreover, face brick is quite generally formed with moisture contents of 7% to 8%.

As water tends to weaken all hydrous materials, its use in fine sediments utilized in making roadbeds should be held to the minimum. Tough clays, such as the gumbos, can be consolidated more adequately by increasing the weight of the roller rather than by the addition of water. When excessive quantities of water are used, the body is thereby weakened and upon drying its shrinkage produces large cracks that aid in the perpetuation of cycles of excessive moisture change and cause much reduction in capacity to support loads.

If less water had been applied with a greater amount of compacting force, the density of the mass exemplified in Fig. 1 could have been increased greatly. This would have produced a consequent decrease in pore space and also would have increased the resistance to loads and the absorption of water. If the water content had been reduced to 14%, the density could have been increased to about 1.90; moreover, if the water content had been set at 10%, with an adequate method of compaction, the density could have been increased to 2.05. Since it is one of the purposes of this paper to develop a basis for an adequate standard of compaction for roadbeds, no specific numerical value of compaction will be proposed at this time.

By referring again to Fig. 1, it will be seen that slip due to water content starts at or near point B, representing a value very close to that of the optimum moisture as determined by the Modified Proctor method. With this moisture content, the mass is a plastic solid. Solid particles are at least partly surrounded by water and touch other particles only at certain points. As a result of this condition, the mass partakes of the properties of both solid and liquid.

---

[3] "On the Plasticity of Clays," by J. W. Mellor, *Transactions*, Ceramic Soc. (England), Vol. 21, 1921–1922, p. 95.

In this condition, solid particles under pressure slip over one another and, as the water itself is under pressure, the wet mass tends to flow in its characteristic manner. As the thickness of the films of water between solid particles is increased, the mass becomes more and more like a liquid; but, as the films are reduced in thickness, the mass becomes more and more viscous until the critical point is reached when the mass is a rigid body, a state essential in roadbeds at all times.

Although the late Mansfield Merriman,[4] M. Am. Soc. C. E., defined a material as plastic when it has no elasticity, so that the smallest forces cause permanent deformation, he was undoubtedly referring to a perfectly plastic material that does not actually exist. As in the case of viscous bodies, a certain amount of pressure must be applied before a plastic clay body can be made to flow through an orifice. In this statement research workers including W. D. Bancroft,[5] E. C. Bingham,[6] and Henry Green[7] are in agreement, although different clays in a plastic condition have different yield values.

The ideal state of a roadbed is that in which the elastic limit is high even when the pore spaces are saturated. To attain this state the moisture-density curve (Fig. 1) should be required to indicate a much higher density with an attendant decrease in water content. This change would leave point B, Fig. 1, on the penetration resistance curve little changed but point A would be raised to a higher value of resistance, provided the water content was not excessive.

Air-Water Relationship.—Obviously pore spaces will be filled with either air or water at all times. During dry weather, evaporation losses are to be expected. As water is lost, air takes its place; and in a similar manner, the pore spaces receive water and discharge air during wet weather.

The volume relationship of these fluids is of vast importance but detailed information in widespread areas is meager. From data developed in the State of Iowa by Bert Myers and the writer,[2] it would seem that in consolidated mixtures one should expect from 45% to 80% pore saturation during wet weather. In ordinary roadbeds, an average of from 70% to 80% is not unusual; in poorly compacted clay, 80% or more is found; and in silt, from 80% to 100%.

Since it has been shown that excessive volumes of either air or water are detrimental to roadbeds, the necessity of restricting these fluids is obvious. This can be done only through the restriction of pore space. If the pore space is small, the volume of air or water must likewise be small. Moreover, the smaller the pore space the more constant the water content—a fact explained by the enormous increase in molecular attraction of water to solids when the films are quite thin. In this condition, evaporation losses are indeed small and the entrance of additional water is made difficult by frictional resistance and the presence of occluded air.

[7] "Further Development of the Plastometer and Its Practical Application to Research and Routine Problems," by Henry Green, *Proceedings*, A.S.T.M., Vol. XX, Pt. II, 1920, p. 451.

Although certain writers[2,8,9] have stressed heretofore the necessity of restricting pore space, little heed has been given to this essential phase of construction. As a consequence, numerous roadbeds fail even where the Modified Proctor standard of compaction has been followed.

Charles H. Lee,[9] M. Am. Soc. C. E., sets a tentative limiting value for air at 5% by volume or 3.5% expressed as equivalent water in terms of dry weight. This limit appears to be practicable, provided the limit of total pore space is adequately restricted.

CHANGE OF STATE

Many substances have definite melting and freezing points. Furthermore, the strength of metals is greatly affected by heat and the presence of carbon and certain other elements. As bituminous pavements are weakened by heat or the presence of solvents such as naptha, so are road surfaces composed of mixtures of aggregates and clay or clay alone weakened by the solvent action of water. As long as these materials remain rigid, they are strong; but, when they are overcome by solvents, a plastic and therefore weak condition prevails. The knowledge of these facts led Bennett H. Levenson,[10] in the fall of 1926, to make an investigation of clays and other sediments to determine the exact manner in which they are affected by absorbed water. He wished to determine, by experimental methods, whether sediments soften gradually by the absorption of water or whether the change from the rigid to the plastic state occurs suddenly.

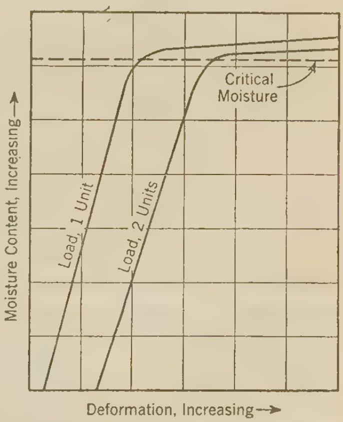

FIG. 2.—GENERALIZED CURVES SHOWING THE EFFECT OF CRITICAL MOISTURE ON LOAD AND DEFORMATION

To begin, forty-two samples of roadbed materials were obtained from various parts of the United States. These were selected so as to yield a wide range of plasticity and strength and all were tested in duplicate to determine their lower plastic and lower liquid limits. The effect of moisture content on uniformly prepared specimens was also determined in duplicate under various loads, all being measured at a given deformation.

After preliminary tests had indicated that the curves would be of the general form of the two shown in Fig. 2, the procedure was modified to include only two pairs of test values at moisture contents above and also below what seemed to be the critical moisture. This procedure was planned to test the validity of an indication that the lower limit of plasticity might be determined by the stress-strain method as truly as by the well-known Atterberg method.

[a] In Table (*a*) "lower plastic limits," and in Table (*b*) "lower liquid limits."

entire end of the cylinder. Confined tests had the walls of the cylinders supported by tight-fitting brass cups, but to allow bulging at the upper surface the bearing block did not cover the entire end of the cylinder.

Thus, the unconfined cylinders under load were free to deform by bulging at the circumference, but in the confined cylinders deformation took the form of a bulge at the top end of the cylinder in the open area around the bearing block. That freedom to deform or to bulge was equal in both types of cylinder is indicated by the close agreement of critical moistures under different loads shown in Table 1(*a*).

Table 1(*a*) also shows that, whether the load was doubled or increased as much as sixfold, the change in the moisture content at which slip occurs is little affected. This was found to be true also in the confined series of tests. Detailed examination discloses that the ratio of mean critical moisture (moisture at which critical slip occurs) to Atterberg's lower plastic limit averages 0.924 with a maximum deviation of 0.266.

A comparison of average critical moistures for the several loads as compared to the mean lower plastic limit is rated as shown in Table 2(*a*). Although the numerical differences in the average critical moistures at the several loads are not large, the tendency of the percentage to be decreased under increasing load is apparent. However, since clays and other earthy sediments are known to undergo certain changes of state due to the absorption of water, the facts disclosed by Table 1(*a*) are to expected. One important fact, however, must be kept in mind: The change from the plastic to the rigid state is always marked by rupture. It matters not whether the force producing rupture is the weight of the hand, as by rolling out under the Atterberg method, or the force exerted by the largest testing machine; the principle involved remains identical. However, the speed of rolling out like the speed of a testing machine must have an influence on the results obtained.

TABLE 2.—COMPARISON OF AVERAGE CRITICAL MOISTURE

Description	(*a*) With Mean Lower Plastic Limit					(*b*) With Average Lower Liquid Limit				
	Plastic limit	5.6-lb load	12-lb load	16-lb load	32-lb load	Liquid limit	5.6-lb load	12-lb load	16-lb load	32-lb load
Percentage.........	25.8	24.2	23.8	21.5	20.6	27.1	20.2	19.1	19.5	19.8
Ratio..............	1.000	0.938	0.922	0.833	0.798	1.000	0.746	0.705	0.720	0.730

The second series of tests by Mr. Levenson is represented by twenty incoherent or nonplastic sediments obtained and tested in a manner similar to that described. However, owing to the nature of these sediments, obviously no lower plastic limit could be determined; hence, the lower liquid limit as defined by the Atterberg method was substituted as the reference point. In all other respects, determinations were made in accordance with the method followed in the plastic group.

The results obtained from this group are shown in Table 1(*b*). The mean critical moisture or the moisture at which slip was started, under conditions indicated, is expressed in Col. 7, Table 1(*b*), as a ratio of the lower liquid limit.

Although only one set of tests (Table 1(*b*), line 16) in both confined and unconfined conditions is shown, the critical moisture content is identical under all loads. However, additional tests are needed.

For unconfined loads of 5.6 and 12.0 lb, Table 1(*b*) shows average critical moistures of 20.2% and 19.1%, respectively, and for confined loads of 16 lb and 32 lb average critical moistures of 19.5% and 19.1%, respectively. The maximum difference in critical moistures obtained in confined tests is 6% with no other differences greater than 0.5%. The maximum difference obtained in the confined tests is 1.0%. Col. 7 shows the ratio of mean critical moisture to the lower liquid limit as 0.734 with a maximum deviation of 0.289.

A comparison of average critical moistures obtained under the several loads is shown in Table 2. Although the effect of load on lowering critical moisture is not always shown in individual cases, this tendency is indicated. For example, the average critical moisture in the plastic sediments tested under a 32-lb load was found to be 0.798 of the plastic limit and that in the nonplastic sediments 0.730 of the lower liquid limit. Thus, it will be seen that slip or plastic flow is affected by both fluids and loads.

Inasmuch as Col. 7, Table 1, shows variations between the critical moisture as measured by the Atterberg method and that of stress and strain, the need of a factor of safety is apparent. Moreover, if pore space is reduced to 70% of that required for a critical moisture (lower plastic sediments or 75% of the lower liquid limit in nonplastic sediments) as recommended by the writer[2] in another paper, roadbed failure is avoided.

The occurrence of slip at a definite water content has been observed by H. Thiemecke,[11] and also by Fred Burggraf,[12] who emphasizes the importance of keeping the moisture content in coherent or plastic types of roadbeds below that of their respective lower plastic limits.

TABLE 3.—EFFECT OF POROSITY-MOISTURE CONDITIONS ON STABILITY STRESS IN ROADBEDS

Sample	DENSITY		Pore space (%)	MOISTURE		Lower plastic limit (%)	Pore saturation (%)	Ratio, Col. 6/Col. 7	Stability index	Stability stress (lb per sq in.)
	Absolute	Bulk		Content (%)	Capacity (%)

[11] "Plastic Flow of a Nearly Dry Clay Body," by H. Thiemecke, *Journal*, Am. Ceramic Soc., Vol. 19, No. 3, 1936, p. 67.

[12] "Field Tests and Their Application to the Design of Stabilized Soil Roads," by Fred Burggraf, *Bulletin No. 50*, Am. Road Builders Assn., 1940.

In another paper, Mr. Burggraf[13] shows the adverse effect of water in excess of the lower plastic limit on the stability of roadbeds and corroborates his and other conclusions relative to the abrupt loss of bearing capacity of clays containing water equivalent to the lower plastic limit. The basic values obtained by him have been arranged by the writer in Table 3, where, for convenience, the original bulk density values given in pounds per cubic foot have been converted into grams per cubic centimeter.

Samples B-2 and A, Table 3, show stability stresses of 20 lb per sq in. and 14 lb per sq in. corresponding to moisture contents of 62% and 90%, respectively, of the lower plastic limit with pore saturations of 61% and 80%, respectively. A comparison of values in Cols. 10 and 11, Table 3, shows that when the stability index is high, so is the stability stress; and, in a similar manner, the values in Col. 9 indicate the downward trend of stability to be expected when the pore space becomes saturated. (The "stability index" is the ratio of the lower plastic limit to the moisture content.)

TABLE 4.—EFFECT OF WATER CONTENT ON BEARING CAPACITY

Sample No.	Lower plastic limit	MOISTURE CONTENT AT TIME OF TEST (%)		Actual moisture difference at test (%)	BEARING CAPACITY[a] CORRESPONDING TO MOISTURES I AND II		Bearing capacity increase (%)
		Test I	Test II		I	II	
1	30.7	33.0	30.0	3.0	400	700	75

[a] Pounds per square foot.

Additional data tending to show that the bearing capacity of earthy sediments becomes critical at or near the lower plastic limit are shown in Table 4. Data in this table are from the work[14] of K. B. Woods and R. R. Litehiser, Members, Am. Soc. C. E. (Instead of showing all the values given by Messrs. Woods and Litehiser, under the heading, "Summary of Test Averages for 467 Ohio Soil Samples,"[15] the writer shows only the moisture and bearing capacity relation of their data.)

Attention is called to the increase of 75% in bearing capacity due to a 3% decrease in moisture of sample 1, Table 4. Test II shows the moisture to be only 0.7% less than that of the lower plastic limit and that of test I, 2.3% more than this limit. In sample 2, test I is 0.4% wetter than the lower plastic limit; and test II, 1.5% drier with a consequent increase of 68% in bearing capacity.

---

[13] "Field Tests on Shearing Resistance," by Fred Burggraf, *Proceedings*, Highway Research Board, December, 1939, pp. 484–490.

[14] "Soil Mechanics Applied to Highway Engineering in Ohio," by K. B. Woods and R. R. Litehiser, *Bulletin No. 99*, Ohio State Eng. Experiment Station, 1938.

[15] *Ibid.*, p. 62.

In samples 3 to 10, Table 4, all moistures are less than the lower plastic limit and the increase in bearing capacity due to decrease in moisture content ranges from 7% to 57%. In none of the latter tests is the break near the lower plastic limit as sharp as is found in the Levenson tests. However, when test values are measured above and also below the lower plastic limit, the change is marked. Moreover, inasmuch as the bearing capacity apparently was measured by means of the Proctor needle, an instrument which does not permit a steady rate of application of load, very sharp breaks or knees should not be expected. This belief is corroborated by many needle resistance curves shown as a part of the report by Messrs. Woods and Litehiser[14] and also by others, all of which are of the characteristic shape of the curves in Fig. 1.

Examination of many published data shows that the so-called optimum moisture (A.S.T.M. D698–42T) is commonly near that of the lower plastic limit and it is not unusual for the two moistures to differ as little as 1% to 5%. Furthermore, the record of density-moisture-penetration resistance values indicates that Fig. 1 is typical of many. Point B, Fig. 1, occurs entirely too close to the maximum density obtained to provide adequate bearing capacity. The plastic or near plastic condition of the mass at the maximum density obtained (not necessarily the ultimate density obtainable) is shown not only by the change beginning in the vicinity of point B, but this condition has been observed also many times on earthwork construction jobs where rolling operation showed a plastic condition, although the moisture content of the material was at "the optimum" as indicated by the laboratory test mentioned.

Evaluation of Roadbeds.—Table 5, based on data by Messrs. Woods and Litehiser,[14] is offered to demonstrate how the structural properties of roadbeds may be evaluated correctly. The average of maximum and minimum density values determined by these writers corresponding to "good," "fair," "poor," "very poor," or "unsatisfactory" roads is shown in Cols. 1 and 9. Data in Cols. 2, 3, 4, 7, and 8 were computed from basic data observed by Messrs.

TABLE 5.—COMPARISON OF MODIFIED PROCTOR STANDARD AS USED IN OHIO WITH CRITICAL MOISTURE STANDARD

PROCTOR MAXIMUM DENSITY		Pore space (%)	Moisture capacity of pores (%)	Water content of pores (%)	Lower plastic limit (%)	METHOD OF CLASSIFICATION

85.0	1.36	48.7	35.8	30.0	30.7	1.16	21.5	Poor[b]

[a] Pore capacity reduced to 70% of the lower plastic limit. [b] Unsatisfactory or exceptionally poor.

Woods and Litehiser, with an assumed absolute density or apparent specific gravity of 2.65.

A comparison of Cols. 7 and 9, Table 5, shows that the order of numerical values is in agreement with the values assigned by Messrs. Woods and Litehiser. Table 3 shows a similar agreement with work by Mr. Burggraf.[13] Moreover, if pore capacity can be reduced to 70% of the lower plastic limit as shown in Col. 8, Table 5, all the materials represented can be rendered satisfactory for use in roadbeds, provided they are compressed to the densities required.

In further support of the writer's claim that roadbed stability under given moisture conditions is predictable by the ratio of moisture content to the lower plastic limit, reference is made to Table 3, Cols. 10 and 11; but, for the most adverse moisture conditions to be expected, Col. 9, Table 3, should be used instead of Col. 10. Without a single exception, Cols. 9 and 10 are in accord with the stability stresses obtained.

Whether the reader is willing to accept the factor of safety proposed is of minor consequence; but, with a knowledge of the well-known properties of the three constituents—air, water, and solids—of roadbeds, it would seem that all must agree that the mixing of fluids with solids must be controlled rigidly if stability is to be developed. As fluids weaken the structure of rocks and other less consolidated masses of matter only by entering pore spaces, the necessity of restricting the volume of the spaces is obvious. Although air is less detrimental to the structural properties of hydrous materials than water, it is indeed essential that the air content be restricted also if adequate support is to be attained. Moreover, if the air content is not restricted, a part of it is likely to be replaced by water during rainy seasons, resulting in a weakened roadbed.

Since water weakens roadbeds in a greater measure than air, it seems desirable that pore space be restricted so that if it does become entirely filled with water the roadbed will not be critically soft. Obviously the percentage of water required to produce critical softening must be determined before the plans are made. Also, a suitable factor of safety must be set and maintained during construction. Of course, the water content of the roadbed material during construction must not be in excess of the capacity of the designed pore space; but for facilitating consolidation it should be 80% to 90% of the pore capacity, a value close to that proposed by Mr. Lee[9] as 5% by volume of the pores.

Much effort has been given to the determination of the measure of consolidation required to produce stable roadbeds. The methods in general use consist of applying compactive force to laboratory samples by means of static or impact loads of given magnitude and applying this as a standard for roadbed compaction or consolidation. A report by James H. Stratton,[16] M. Am. Soc. C. E., giving the experience of the U. S. Corps of Engineers on the usefulness of these standards (A.S.T.M. D698–42T) seems to indicate that they have not been entirely satisfactory.

Inasmuch as work cannot be measured in terms of energy applied to different materials, the findings of the Corps of Engineers are to be expected. For example, a well-graded mixture of sand and clay, such as that used for sand-clay road surfaces, can be consolidated to a density of, say, 2.15 to 2.25 without great effort, although a much greater amount of energy is required to compact a gumbo clay to a density of, say, 2.00. Indeed, certain materials cannot be consolidated by ordinary mechanical processes. Of such materials, one carrying an abundance of flake mica is an example. The elasticity of the flakes causes the mass to expand or recover upon removal of the pressure. Therefore, the mere application of a compacting force cannot be utilized successfully as an index of consolidation of roadbed materials; if this were not true, tooled steel could be machined to the same shape as soft steel in an equal period of time.

[16] "Military Airfields": A Symposium, *Transactions*, Am. Soc. C. E., Vol. 110 (1945), pp. 670–696.

Consolidated Roadbeds.—In the case of two approach fills made of black gumbo clay, the following contrast found at the time of paving between rains in the month of December is recited: The east approach, graded and water jetted for compaction several years previously, had been subjected to traffic until the time of paving. The west end was graded and consolidated a few weeks previous to the time of being paved so that the pore space was less than that required for water equivalent to the lower plastic limit. The east end had to be "planked" throughout for the paving operations but the west end did not rut at all. Although the subgrade was quite slippery on the west end, a few shovelfuls of sand applied to wheel tracks eliminated this slipperiness. Weather conditions were considered nearly identical during the time that both approaches were paved.

On another black gumbo clay road, a section of brick pavement had to be removed for an overhead bridge approach. The bricks were laid on a thin layer of sand and the surface of the pavement was reasonably smooth. The gumbo clay under the pavement was found to be moist but firm. The manner of consolidation is not known; but, whatever the method used, it appeared from the smoothness of the old brick pavement to be adequate for heavy loads such as those needed on truck-line highways in a region engaged in the production of mineral oil.

A concrete pavement built in 1917 in California between Patterson and Newman by Lloyd Aldrich,[17] M. Am. Soc. C. E., then county engineer of Stanislaus County, California, was found three years later to be in fine condition over all types of soil (including Yolo adobe) except at the extreme north end through a village where the pavement had been laid on a roadbed not prepared by Mr. Aldrich. In contrast to other roads, no shrinkage beneath the road slab was observed.

The method followed by Mr. Aldrich in constructing the roadbed requires light lifts of pulverized and moistened material compacted by means of heavy rollers. Before laying the pavement the subgrade is allowed to dry five or more days, during which time shrinkage cracks do not develop. The failure of shrinkage cracks to develop is a positive indication of the use of a very limited amount of water and of a high measure of compaction of the roadbed—two conditions essential to the longevity and smoothness of all types of pavement.

The Pittsburg, Calif., test highway[18] also built under the supervision of Mr.

[17] "Report on California State Highways," by J. B. Lippincott, Waller C. Howe, C. Derleth, Jr., and H. J. Brunnier, copyrighted 1921 by Automobile Club of Southern California, Los Angeles, Calif., and Calif. State Automobile Assn., San Francisco, Calif., pp. 112–114.

[18] "Report of Highway Research at Pittsburg, California, 1921 and 1922," by Lloyd Aldrich and John B. Leonard, California State Printing Office, Sacramento, Calif., 1923.

Aldrich (1921) was constructed in a manner similar to that of the Patterson-Newman road; and, of the seven conclusions following the tests, the first one is significant. It reads: "The method of constructing the subgrade on adobe soil, as described, so reduced the objectional features of this material that a reliable foundation for the pavement resulted."

Numerous other instances of the stability of naturally occurring or artificially produced beds of consolidated clay or sand-clay could be recited. Frost action on these consolidated beds has been studied by the writer in regions where the ground freezes to depths of 6 ft and not a single instance is recalled where freezing appeared to be detrimental. The reason for this is simple—pore space being limited, little water finds its way into these masses of material and enough air space is left to allow for the expansion of freezing water.

Unconsolidated Roadbeds.—The sight of a curb in a southern city is recalled where plastic movement had distorted a curve horizontally and vertically, all in a length of 100 ft. The material in which the curb was placed was a silty clay.

Following the inundation of the Omaha (Nebr.) Municipal Airport by the Missouri River in April, 1942, W. H. Campen, Assoc. M. Am. Soc. C. E., and J. R. Smith[19] made a survey to determine the effect of water on the density and water content of the compacted earth subbase and also the gravel-clay base of the airport runways. The inundation covered the airport grounds to depths of from 3 ft to 7 ft for a period of from 10 to 17 days. The depth of water and the duration of the inundation created conditions for saturating the runways which were unusually favorable. The compacted earth subbase was from 6 in. to 12 in. thick and the gravel-clay base approximately 6 in. thick.

The survey revealed at least one fact that is almost always overlooked. It is the effect of pore capacity on the maximum water content, the uniformity of saturation to be expected for given types of materials, and their measures of compaction. The values given by Messrs. Campen and Smith indicate skill and careful work. In only a few cases is the computed pore capacity less than the actual water content, a condition probably due to the writer's use of an erroneous value of specific gravity of fine solid particles—hence, the confidence that is warranted in the values given in Table 6. The table justifies the conclusion that water content can be controlled by the restriction of pore capacity. This evidence and numerous other data further confirm the writer's belief expressed elsewhere[2] that the pore spaces are rarely completely filled with water even after long periods of inundation. In only two cases did the tests show complete saturation of the compacted earth subbase and only one case of saturation as low as 76%. In the base, 99% saturation was found at two points and at only one point was saturation found as low as 63%.

The data on bases indicate a much lower percentage of saturation than do the data on compacted subbases. This tendency has been observed often by the writer when comparing highly compacted bodies with less compact ones. A case is recalled in which a very stable federal-aid sand-clay road surface in the State of Nebraska showed an average saturation of only 31% at the time of a spring thaw following a winter of considerable snow.[20] Such projects demonstrate the value of density and water resistance of minute pore spaces.

---

[19] "The Behavior of Densified Soil-Water Mixtures Under Very Adverse Water Conditions," by W. H. Campen and J. R. Smith, *Proceedings*, Highway Research Board, Vol. 23, 1943, pp. 450–458.

The writer's tentative conclusion is that, as pore spaces are restricted, the penetration of water and the escape of air become increasingly difficult, thus accounting for the greater abundance of air in the minute and sealed pore spaces. On the other hand, it appears that deposits of silt nearly free from clay are more susceptible to high or complete saturation, due probably to the ease with which these fluids enter and escape from sediments low in cementing or claylike matter. This condition has been observed many times in eastern Iowa.

[a] These item numbers correspond with the table numbers in the work by W. H. Campen and J. R. Smith (*Proceedings*, Highway Research Board, Vol. 23, 1943, pp. 450–458).

Many instances of "flow ridges" or "cat-step" topography are recalled in the "Great Plains" of the United States and in belts along the Ohio River. In these areas landslides are common. Investigations show that these sediments are very porous and hence become so filled with water that they tend to slip downhill. Often the slip is so pronounced that trees become bent in an effort to right themselves. These areas contain many "soft spots" and in regions of intense freezing "frost boils" are numerous.

Characteristics of certain beds of material in their natural states, and also in compact states, were presented by the writer in 1938.[20]

In contrast to the statement made relative to the stability of consolidated deposits of sediment, the following statement concerning unconsolidated sediments can be made: In an area extending from the Canadian border to the Gulf of Mexico and from the Atlantic Ocean to the Rocky Mountains, the writer has found roadbed failures only in unconsolidated sediments. Many failures of "stabilized bases" and bituminous mats have been observed, laid on roadbeds that had not been compacted to extents that precluded the entrance of water into the pore spaces in amounts equal to or in excess of that of critical moisture. Numerous failures have been observed also when the roadbed foundations have been compacted to so-called "maximum density at optimum moisture content." Frequently these "compacted roadbeds" have become so saturated with water from windrows of wet aggregate on the roadway that mixing and laying of bituminous mats or other surfacing material had to be delayed to allow "soft spots" to dry. Although the soft spots may have been allowed to dry before stabilized surface courses or bituminous mats were laid, many observations of later failures on these areas furnish clues that future failures are to be expected. Pore spaces for absorbing water being present, only water and loads are needed to complete the ever-recurring cycle of wetting, instability, failing, and drying. Truly it may be said that the patterns of the soft spots of today are to be those of failure tomorrow.

---

[20] "Principles Applying to Highway Road-Beds," by Ira B. Mullis, *Transactions*, Am. Soc. C. E., Vol. 104 (1939), Table 1, p. 1393.

Adequate Consolidation.—What constitutes adequate consolidations? Ideally two types of material are essential—a hard durable aggregate, well-graded from coarse to fine, and a glue-like material such as bitumen or a high-strength clay to coat the aggregate and bind it into a dense and highly resistant mass. The proportion of binder to aggregate must be such that the load will be carried only by the aggregate. Hence, the volume of the binder must be slightly less than that of the voids. The fluidity of the binder at the time of mixing should be such that all solids are evenly though thinly coated. This is a condition to be sought when applying any binder, whether it be bitumen or clay. However, if the volume of the binder plus the volume of its solvent is in excess of the volume of voids, the solvent must be allowed to volatilize until the binder and solvent can be contained in the voids as designed; otherwise, a plastic and porous mass will be obtained.

In case the binder is clay, consolidation must be such that water cannot find room to enter in a quantity sufficient to cause critical softening of the mass. However, since small quantities of water are essential to toughen or temper the clay binder, the presence of limited amounts of both air and water is essential, as these work in harmony under properly guarded conditions to preserve the stability of the structure.

Since it has been proved that clays and other fine-grain sediments show yield values at definite moisture contents, it seems obvious that the moisture content at which slip or yield starts, even under light loads, should furnish a sound basis for the design of roadbeds. The points at which materials yield under high loads or high temperatures and the laws that attend these critical changes must not be violated. Engineers recognize with profit the action of solvents on paint, wax, etc., and they must also recognize the weakening effect of water on clay.

Water does not weaken any form of rock matter until it penetrates the pores. Moreover, rock matter is weakened in direct proportion to the water absorbed into the pore spaces until the critical point is reached. At this point, the additional loss of strength far exceeds the final increase in water content.

Two methods—the Atterberg method and the so-called stress-strain method—have been mentioned. The Atterberg method can be used only on fine-grain sediments, but the stress-strain method can be applied to all coherent bodies.

Following the practice of designing with reference to the yield point of structural materials, the engineer must learn to follow a similar procedure in designing roadbeds. As with other engineering materials, a factor of safety is essential. To determine such a factor, the writer[2] proposed in 1938 that the capacity of the pore space be restricted to 70% of the water content at the lower plastic limit. This means that a material with a lower plastic limit of, say, 20 must be consolidated so that its pore space could contain only 14% of water, the equivalent to a density of 1.93. For such consolidation, 11.5% to 12.5% of water and a heavy sheepsfoot roller or some other equally efficient means would be required.

However, the recommendation that pore space be restricted to a water capacity of not more than 70% of the lower plastic limit is not to be regarded as all that is desired. Whenever economically possible to do so, the reduction to smaller percentages will result in greater safety against water softening and also will increase the bearing capacity. Moreover, in incoherent materials, such as sand and silt, the mixing of clay is necessary to consolidation and its attendant stability.

Inasmuch as roadbeds are designed to resist both traffic and weather, it would seem that a measure of resistance to impact and a measure of resistance to the disintegrating effect of water should be of value. For this reason the plasticity index was compared to the corresponding cementation and slaking values.

Cementation or resistance to impact was measured by means of the well-known Page machine, once used as a standard measure of cementing value of rock dust used in macadam construction. The earth specimens to be tested were molded in the standard manner, dried to constant weight and cooled. The number of blows required for breaking a standard briquet represents its bond strength. The bond strength of individual specimens was plotted against its plasticity index. Fig. 3 shows the relationship of the values obtained.

Time of slaking was determined on specimens molded in the same manner and at the time that briquets were molded for the cementation tests. The slaking value obtained for each specimen was plotted against its plasticity index value as shown in Fig. 4.

The results obtained from the two series of tests show values of the scatter chart type without apparent relationship. From these values one may compute the mean average number of occurrences for the several plasticity indexes and thereby derive a statistical relationship similar to that found in life expectancy tables used by life insurance companies. Of course, the average death rate and expectation of life are quite accurate for large groups but for a

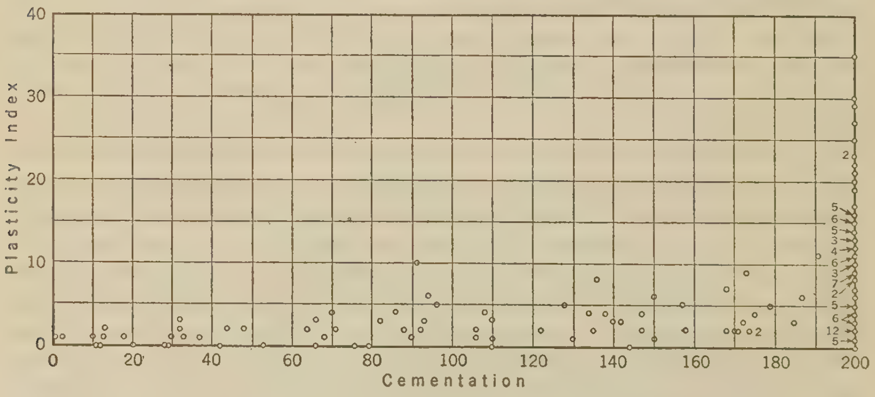

Fig. 3.—Relation Between Plasticity Index and Cementation

single person the data do not apply. For example, a large group of persons twenty-one years of age are expected to die at the rate of 7.85 per 1,000 and have an expectation of life of 41.53 years, although any one of a group may not live another day. Although age does have a definite effect on death rate and expectation of life, there are too many chance causes, such as disease and accident, to permit tables of mortality to be of any value whatsoever in predicting the duration of life of a particular person. Similar relationship is found in many engineering data and to be safe one should consider the probability of occurrence of the least favorable condition in applying such data. It would seem, therefore, that the average plasticity index curve is not only worthless for individual applications, but that it may be dangerous to apply. Numerous road failures on projects constructed on the basis of plasticity indexes support this statement.

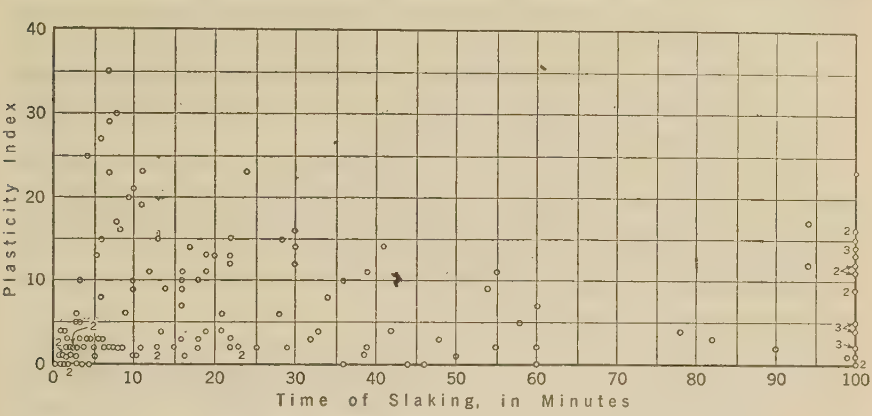

FIG. 4.—RELATION BETWEEN PLASTICITY INDEX AND TIME OF SLAKING

Once a roadbed is consolidated as described herein, it must be protected against weather by a weather-resistant and traffic-resistant surface such as sand-clay, bitumen, etc.; otherwise, these forces tend to destroy the stability of the crust thus obtained. The principles discussed in this paper are well known. Some must have been apparent to prehistoric man and others are as old as the science of physics itself. Geologists have observed them many years and have recognized their effects on resistance to topographic change. Applied to highway work, these principles are equally indicative of roadbed stability. Indeed, it would seem that, since it is known that hydrous materials require certain proportions of water to produce critical softening, the necessity of restricting pore space to prevent it should be a self-evident conclusion.

SUMMARY

The writer invites a full and free discussion of this method of design and construction in comparison with other methods now in use for the purpose of obtaining roadbeds of higher measures of stability for postwar roads. Entirely too many roadbed failures are occurring, even on projects built under the supervision of those following approved methods; hence it would seem that a thorough review of basic principles is imperative.

At least fourteen topics are offered as a guide to such discussion:

1. Three essentials—air, water, and solids—constitute all roadbeds. Each constituent has its own function but the volume of fluids must be restricted rigidly.

2. The presence of excessive volumes of fluid produces a change of state that destroys roadbed stability. This change of state is a critical point.

3. The change of state in roadbeds, as discussed in this paper, is characterized by the loss of rigidity, and failure under load occurs through plastic distortion rather than through planes of rupture.

4. High resistance to loads and the penetration of water can be developed best when pore spaces are caused to be minute and of the isolate type. In this condition the movement of water into or out of pore spaces is restricted by molecular forces of considerable magnitude. Moreover, pore spaces must be so restricted that the presence of either air or water will not be sufficient to destroy the rigidity of the roadbed.

5. Although high-strength clays are difficult to shape and consolidate, they offer great resistance to loads and weather when consolidated at moisture contents that preclude cracking upon loss of water. More thought and experimentation on clays of the gumbo type are urgently needed.

6. The use of tenacious clays is recommended for the bonding of aggregates. These clays can be best ground in water and applied to aggregates in the form of a slurry. The elimination of air by puddling is important but consolidation must be delayed for adequate drying.

7. Clays of the kaolin type are shaped easily, require little water for compaction, but are too weak to offer much resistance to traffic and weather.

8. Consolidation of tenacious clays should be attempted only by means of sheepsfoot rollers exerting pressures of from 300 lb per sq in. to 675 lb per sq in. or more. The water content should be the optimum for the force or pressure utilized.

9. The shrinkage of clays is not an inherent property of the solid matter but a measure of water lost. Therefore, clays should be consolidated under high pressures with water contents equaling from 80% to 90% of the designed pore space.

10. The use of stabilizing materials such as gravel, slag, and stone aggregates may be profitable, but not until local material has been utilized and compacted to its economic limit.

11. As applied energy is not equivalent to work required, standards of compaction or consolidation cannot be measured successfully in terms of static or impact loads applied as compactive effort.

12. The standard of consolidation proposed for roadbeds is based on critical moisture with an adequate factor of safety. Obviously, the higher the factor of safety, the more resistant the roadbed will be to traffic and weather.

13. Measurement of resistance to loads and weather should be made by means of stress-strain methods on laboratory specimens or on roadbeds artificially saturated with water.

14. For further protection against traffic and weather, fine-grain sediments must be surfaced with protective coatings, such as sand-clay, bitumen, etc.

DISCUSSION

Charles W. Britzius,[21] Assoc. M. Am. Soc. C. E.—The paper seems somewhat academic. Admittedly, to provide a stable subgrade, it is necessary to keep the moisture content low, and this can be done best by compacting the subgrade soil to a low void content. It is impracticable, however, to compact the heavier soils to such a density and low void content that the critical moisture content would not be exceeded. A compacted soil mass does not absorb water in its air-void spaces without expanding, and thus increasing in volume.

TABLE 7.—Factors that Reduce Expansion and Water Absorption

[a] Modified Proctor density, in pounds per cubic foot. [b] Moisture content when voids are filled.

The factors that will reduce the amount of expansion and water absorption are the weight of the overlying soil, the moisture available, and the moisture content and density at the time of compaction. The writer wishes to present some data on the latter factor. Consider three soils, a sandy loam, a clay loam, and a clay. Their properties are as given in Cols. 1 to 9, Table 7.

A reasonable, practical, and workable requirement for compaction of these soils is 95% of the Modified Proctor maximum density. At this density the air voids in the soil mass will be as shown in Cols. 10 to 13, Table 7. The air-void values, for these soils, do not conform to the suggested requirement that the pore space be restricted to such a value that, when the space is filled, the moisture content does not exceed 70% of the plastic limit. Because extreme densification is not practicable, thicker and more carefully graded base courses must be used to carry the loads.

Compacted soil masses swell and absorb water to some extent after compaction, until a so-called equilibrium is reached. Soils compacted drier than the optimum swell and absorb water to such a great extent that they finally reach a high moisture content—the same condition that would have resulted if the soils had been compacted beyond the optimum originally. The new residual density curve for sandy and silty soils lies just below the Proctor moisture density curve; but, as the soil becomes heavier, the top of the curve moves to a higher moisture content. The practical implication is that a soil should be compacted to the specified density at such a moisture content that the lowest final moisture content and greatest density will exist. For most soils this moisture content is just greater than the Proctor optimum, and for expansive and gumbo clays it may be considerably greater.

---

[21] Twin City Testing & Eng. Laboratory, Inc., St. Paul, Minn.

In field soil compaction, many times it is expedient to compact soils drier than the optimum. To prevent greater swell and moisture absorption than would have occurred if the compaction had been done at the optimum, a greater density should be required.

The observation made by Mr. Mullis (see heading, "Change of State: Consolidated Roadbeds") to the effect that soils compacted to low air voids are resistant to frost action is misleading. Soils are adversely affected by frost action not because of any change in the soil, water, and air constituents of a unit soil mass due to freezing, but because of an increase in moisture content due to the movement of water toward the source of the freezing. If the soil is silty and thus of a type that has a favorable porosity and capillarity, the heaving due to moisture accumulation will be as much as 1 ft. When the frost heave has melted, a frost boil remains.

J. T. L. McNew,[22] M. Am. Soc. C. E.—One solution to the problem involved in the design of stable earthwork is proposed by the author. Although not specifically identified as such, the author has upheld vigorously the fundamental engineering principle that diagnosis must be thorough and complete before any proposed solution may have better than an average opportunity for success.

Design of earthwork structures involves, from the very beginning, a frank and straightforward admission that soils are materials far different from steel, concrete, and stone. These latter materials are almost always such that they may be assigned certain average characteristics, and the designs resulting therefrom may be expected to have average behaviors. On the other hand, soils are subject to almost all the "peculiar" behaviors and are influenced in their permanent behavior by many more natural occurrences than is steel.

Probably the most serious oversight now common in the design of soil structures is the failure to modify a "theory" as dependent upon the variation between the climate at the site of the structure and the "climate" of the laboratory. Certainly the roadbed that is successful in arid regions of the southwestern United States might not be successful in the Gulf Coast section, nor in regions subject to hard freezes and thaws. The addition of water beyond a small proportion weakens plastic soils so far as load-carrying ability is concerned, and the water that enters a dry, compacted soil first enters through pore space. Just what happens after pore space in a soil is filled with water is quite another matter. Unless such things are considered before construction is started, and unless provisions are made for them, new failures may, and often do, result.

As a principle of design to be adopted, the author's concept, that consolidation should be such as to attain a chosen percentage of pore space in terms of the lower plastic limit, is unquestionably sound. Such a procedure may provide the best design for a given soil; and, as the author states, such densities may not be attainable with reasonable construction effort. The requirement of high density may properly lead to the use of the author's suggested procedure in the selection of better raw materials, or even to the use of other expedients to exclude water from the irreducible pore spaces. Perhaps the soil structure may be planned for a locality where the intrusion of water seldom occurs.

---

[22] Vice-Pres. for Eng., Agri. and Mech. College of Texas, College Station, Tex.

There seems to be no substitute yet for competent and careful engineering diagnosis of soil characteristics and for an accurate evaluation of the "loads" to be carried, both as a result of climate and traffic, in the engineering design of roadbeds. "Rules of thumb" probably do not exist that will replace the engineer's work in a diagnosis of all the problems prior to the prescription of a remedial treatment or cure. It is stimulating, therefore, that Mr. Mullis has insisted that the fundamental behaviors of soils be studied thoroughly before a soil structure is erected. There are reasons for the inability of a soil to do some things; there are ways in which almost all types of soil can do certain jobs; and there are many ways that these types of soil can be misused. Therefore, the engineer must discover these ways with the aid of his "on the job" investigations of the fundamental soil behaviors and, in the light of these findings, propose the design most likely to succeed. Truly, as the author states (see "Introduction"): "The method of approach is a rational one, the principles of which have been long understood, although habitually overlooked."

Gustavo Pérez Guerra,[23] Jun. Am. Soc. C. E.—Considerable difficulty has been encountered, in several cases, in attempting to compact soils that were at their optimum moisture content. In most such cases the difficulty is attributed to imperfect control of embankment operations. Disregarding that simple explanation, many engineers have thought that there was a missing link in the practical application of the compaction principle.

The method of design proposed by the author is founded on well-established facts and sound reasoning; it should be considered with interest by soil engineers. To the writer it seems that the case presented is so clear and evident that this paper should lead to a complete revision of compaction standards.

When it was developed in 1933, the Proctor method was a valuable scientific tool which eliminated rule-of-thumb methods. It was later standardized and the mechanics of its routine application obscured several well-known and important factors.

It is a known fact that, more often than otherwise, the optimum moisture content for standard compaction is only a few points below the lower plastic limit. It also is known that there is a "slip" when that optimum content is exceeded. The basic process of compaction was not misunderstood, only that the standard compaction was the best that could be obtained using roller pressures of about 200 lb per sq in., as was the case in the early thirties, while at present it is common to use pressures as high as 290 lb per sq in. for regular work and much higher pressures for special compaction problems. Several manufacturers list, as standard, rollers producing a ground pressure of 390 lb per sq in. The tendency for rolling to create higher ground pressures has emphasized the deficiencies of the standard method and at the same time has made possible the development of the new method of design proposed by the author.

---

[23] Civ. Engr., Parsons, Brinckerhoff, Hogan & MacDonald, Caracas, Venezuela.

In general, the writer agrees with the conclusions of the paper and draws the following practical conclusions:

(1) The curves of moisture-density relation obtained by the use of different compacting forces can be considered as theoretically tangent to the zero air-voids curve with the ascending maxima located on a curve roughly parallel to that curve. The standard curve determined with a specified number of blows is one of the lowest of the range and thus this test furnishes a minimum of compacted density with a safety factor equal to or slightly greater than unity. It is obvious that the designer should try to avoid that minimum.

(2) Rollers of different sizes are available in the market, and their indiscriminate use in conjunction with the standard compaction test defeats the advantage gained by the use of higher pressures.

(3) Extensive correlated laboratory-field tests are urgently needed to set up new compaction standards. There appears to be no need to discard the popular standard apparatus for routine determinations, provided enough correlation is secured. Nevertheless, the basic determinations of critical moisture for the new approach, and the need for load and weather tests, require the use of the stress-strain method and the testing of full-size sections.

Jacob Feld,[24] M. Am. Soc. C. E.—The paper analyzes the stability of the soil as a mixture of gas (air), liquid (water), and soil solids (rock fragments), and attempts to fix limiting percentages of each state of matter as a criterion for the absence of undesired physical characteristics. Actually, the argument presented is applicable to all soil stability problems, not only to roadbeds.

Complete logical solutions of the problem can be expected only when all the factors are considered. A soil is not merely a mixture of solid rock fragments, liquid water, and gaseous air. The air fraction may be partly gas, partly liquid, and even partly solid (occluded gas held as solid constituents by certain minerals and metals). The water in the soil may be (and usually is) partly gas, partly liquid, and partly solid. The rock fragments are sometimes entirely solid (clean granular soils), but also sometimes entirely liquid, and even partly gaseous (dust storm and soot additions). The state in which the soil constituents occur depends largely upon the absence or presence of colloid admixtures or impurities. The colloids may result from the mechanical or chemical disintegration of the rock fragments, or from animal and vegetable refuse leachings. Minute colloid admixtures, if chemically and electrostatically correct, have major control of the physical action of soil mixtures.

When the influence of colloids is fully appreciated, and when a soil can be properly identified and analyzed for all its physical and chemical constituents, not only can the physical behavior of the soil be prophesied, but the desired physical characteristics can be produced by the addition of colloidal admixtures.

---

[24] Cons. Engr., New York, N. Y.

In the 1921, 1922, and 1923 progress reports of the Special Committee to Codify Present Practice on the Bearing Value of Soils for Foundations,[25] there is included an exhaustive treatment of the colloidal properties of clay as a soil constituent. In a discussion of these reports, the writer extended that treatment to include the other colloids often found in soils—silicic acid, silicates, aluminum and iron hydroxides, humus acid, as well as colloidal clays of various types.[26] The effect of various colloids on different soil types is there described not only on the physical property but also on the fertility of soil. Much useful information on this subject can be found in the reports of soil studies by the agronomists.

That air, water, and rock fragments are not always gas, liquid, and solid, respectively, at normal temperatures and pressures, is not a new idea. For instance, Galileo, in 1640, understood that there was a difference between liquid water and pore water. He states that the smallest parts into which water can be divided must be smaller than the smallest consistency of water; for, no matter how small or finely a powder is divided, the particles can still be wetted. That water is different from the smallest divisible quantities of liquid water.[27]

In 1920, Karl Terzaghi, M. Am. Soc. C. E., stated that water films less than two millionths of an inch in thickness are semisolid in action. Such water does not boil or freeze at normal temperatures. C. A. Hogentogler,[28] Assoc. M. Am. Soc. C. E., has shown that, although the division between the solid state and the plastic state depends on the percentage of moisture, the percentage decreases as the soil is put under pressure; and the pressure can be applied either externally or internally, the latter by reduction of the water film thicknesses. H. F. Winterkorn,[29] Assoc. M. Am. Soc. C. E., has added, to this study, the proof that the entire relation between moisture percentage and plastic state can be changed by adding chemicals to the water.

When it is kept in mind that, as W. D. Bancroft[30] states, all solids tend to adsorb or condense upon their surfaces any gases or liquids with which they come into contact, the importance of colloid-sized particles must be evident; for colloidal particles have very great ratios of surface area to weight.

Many practical applications of soil control by colloids and of clay soil control by chemicals can be found in recent reports. One application developed by experience, and not as a result of laboratory or analytical study, may be of interest. Seneca County, in New York State, is almost entirely covered by soft shale and extremely fine clay. When the surface is disturbed, there are only two conditions—dust clouds when dry and a slick slippery surface when wet. Nevertheless, local farmers have used a layer of crushed local shale rock, taken from the exposures where thin limestone seams occur, to build the secondary roads. The rock, in pieces up to 50 lb in size, are spread along the desired location, and preferably they are spread directly upon the ground surface. Traffic and weather form a fairly smooth road surface in a few months. These surfaces, locally known as "shuck roads," cannot be made from shale that lacks the requisite limestone content.

[30] "Colloid Chemistry," by W. D. Bancroft, McGraw-Hill Book Co., Inc., New York, N. Y., 1932.

When the writer was required to produce large areas of serviceable parking fields and bus terminal pavements, with a minimum of labor and no outside materials, as part of the construction facilities for a war project in Seneca County, he applied the "shuck road" idea, with very good results. A local fine sand deposit was found to contain a large limestone content, from the leaching of limestone bedrock. The sand was unfit for construction purposes. By disking about 1 in. of this sand into the clay surface, adding a slight quantity of water, and rolling with a 10-ton roller, a hard impervious surface was obtained. The top crust, about 4 in. thick, hardened in a few days and was used as a parking field, with practically no maintenance, for a year. A sprinkling of limestone chips was applied in the bus terminal areas, and these were used for three years with little maintenance.

The paper by Mr. Mullis is of great value in pointing to a logical approach to soil compaction studies. The method can be made of far greater value by adding the necessary factors of colloid action.

Jasper L. Stuckey,[31] Esq.—Strong arguments are presented by Mr. Mullis for the rigid control of liquids and solids in the development of stable roadbeds; also excellent reasons are offered for a better knowledge of geological materials and the fundamentals of geology on the part of the highway engineer. A better appreciation of both of these should be helpful to all highway engineers, and especially to those concerned with the problem of constructing permanent roadbeds for modern traffic conditions.

Long before the development of modern roadbeds it was known that too much water on the roadway caused softness and ruts. As a result, roads generally followed the ridges and divides in order to take advantage of natural drainage. It is but natural that, with changed demands for roads and highly specialized facilities for research, methods should be developed for producing permanent roadbeds where they are needed. Mr. Mullis should be especially commended for the contribution he is making to this end.

It is interesting to note that of fourteen topics offered as a guide to any discussion of the paper, seven deal with the physical properties of the geological materials necessary in roadbed construction. It is also interesting that these materials are properly designated and not erroneously called "soil" as is so often done.

Since most of the materials used in roadbed construction are obtained along the line of the road or from local sources of supply, the engineer should consider two factors: (1) The geological conditions that may affect the permanence and stability of the roadbed; and (2) the kind, character, and proper utilization of the materials available for construction. Failure to do this has caused, and is causing, entirely too many roadbeds to prove unsatisfactory.

---

[31] Prof. of Geology, Univ. of North Carolina, Raleigh, N. C.

Dense rocks such as granites, quartzites, and many limestones, in undisturbed masses, might be considered ideal materials for roadbed foundations. They have low porosity and are known to be highly resistant under most conditions. In the majority of cases, however, fresh, unaltered rock of any type is seldom found in adequate quantities at or near the surface. In many areas, weathering and rock decay have produced a mantle, of variable thickness, of decayed rock material which overlies the hard and fresh rock and grades gradually into it. If, as in the Atlantic Coastal Plain, sediments which are not deeply weathered are found at or near the surface, they are often of variable character and poorly consolidated. Since this is true, the highway engineer is forced in most cases to use materials that have high porosity and low resistance and require special treatment to be made into a stable mass such as is required in a modern roadbed.

Building stone usually is tested dry because its strength often decreases when wet. T. L. Watson, F. B. Laney, and G. P. Merrill[32] have shown that sandstone, with an absorption of 3.71% and 4.2%, tested only slightly more than one half as strong when saturated as when dry. This evidence strongly supports the argument for the controlled mixing of fluids with solids if roadbeds are to be stabilized.

The crushed stone, gravel, and sand used in the production of concrete for road paving and the preparation of the concrete have been standardized and closely controlled for many years. This paper definitely indicates the need for higher standards and better controls in the building of roadbeds.

Delbert L. Lacey,[33] Esq.—Among highway engineers there are two schools of thought regarding the proper density to which soils in roadbeds should be compacted. One group contends that an extremely high soil density with a resultant low void space is necessary to provide adequate permanent support for traffic loads. The other group contends that each soil has some "natural" density or range of "natural" density, and although placed outside the density range, either above or below it, when exposed to cycles of freezing and thawing and moisture changes, the soil will, return to its "natural" density state. Therefore, it is the contention of the second group that it is useless and a waste of effort to compact fine-grained plastic soils to a density greater than the "natural" density as such soils will eventually return to that density.

The contention of the second group of engineers is largely based on observations made on plastic soils that were compacted at low moisture contents and fairly high densities. Pavements placed on such soils become distorted as the soil beneath the edges of the pavement and beneath expansion joints absorbs moisture from the surface—causing the soil to undergo a considerable volume increase and to exert sufficient force to lift sections of the pavement above the original position. Since not all the subgrade soil has access to this moisture increase, the part of the soil under the center of the pavement and for some distance back of the joints does not undergo any volume change, and the remaining pavement stays in its original position. The result is a very disagreeable riding surface.

[32] *Bulletin No. 2*, N. C. Geological Survey, 1906, pp. 235–236.

[33] Field Soils Engr., State Highway Comm. of Kansas, Topeka, Kans.

However, laboratory research conducted by the Kansas Highway Department[34] to determine the expansive properties of soils indicates that the moisture content at which a soil is compacted has more influence on volume increase (while the soil absorbs moisture) than does the density to which it was compacted. During this research, specimens of a soil were compacted at a number of different moisture contents and to various degrees of compaction. A load equivalent to the weight of a concrete pavement was placed on each specimen, and each specimen was permitted to absorb water until all vertical movement of the soil ceased. The vertical movement was measured and the volume increase of the specimen, based on original volume, was calculated. The results of a series of these tests conducted on a silty clay loam soil to determine percentage of volume increase are shown in Table 8. The volume change of a soil definitely decreases as the initial moisture content at which the soil was compacted is increased. At any given moisture content, on the other hand, there is very little decrease in the soil swell if the density to which the soil was compacted is increased.

TABLE 8.—THE PERCENTAGE INCREASE IN THE VOLUME OF SOIL AS AFFECTED BY THE COMPACTED DENSITY AND THE PERCENTAGE MOISTURE CONTENT AT WHICH THE SOIL WAS COMPACTED

Compacted density (lb per cu ft)	PERCENTAGE MOISTURE WHEN COMPACTED				
	10	12	14	16	18
94	1.0	3.2	2.6	1.6	....
100	5.5	3.6	2.6	1.8	1.2
106	5.7	4.4	2.6	1.6	0.7
112	5.6	4.1	2.5	1.4	0.0
115	5.5	3.6	1.5	0.8	....

Therefore, had the plastic soils that caused pavement distortion been compacted to the same high densities, but at higher moisture contents, the volume change would not have been large enough to cause any appreciable change in the pavement elevation. This conclusion is logical when it is considered that, under an impervious surface that retards evaporation, soils tend to absorb moisture until their void space is nearly filled. Therefore, if sufficient moisture is present in the soil during compaction nearly to fill the void space and to satisfy the colloidal requirements, there will not be space for enough additional moisture to cause detrimental soil swell. In the light of the foregoing information and line of reasoning, there seems to be very little danger of overcompacting a soil if it contains sufficient moisture to fill the voids when compaction is completed.

In further support of the author's contention that high soil densities are essential to a durable roadbed, it should be emphasized that the deflection of the surface of a soil caused by a given wheel load is directly dependent upon the existing density of the soil. Thus, a loose, poorly compacted soil might deflect enough under a wheel load to rupture the wearing surface. This deflection would be due to an increase in the soil density; whereas if the soil had been compacted to a high density before the surface was constructed, this surface deflection due to density change would have been eliminated and all deflection would have been due to the plastic flow of the soil. Since resistance to plastic flow is largely dependent upon friction between the soil particles and since these particles are in more intimate contact when the soil exists at a high density, the resistance of the soil to plastic flow is increased, and consequently a stronger roadbed results.

---

[34] "The Results of Tests to Determine the Expansive Properties of Soils," by Harold Allen and A. W. Johnson, *Proceedings*, Highway Research Board, National Research Council, 1936, p. 220.

Additional evidence to substantiate the author's contention that a high state of compaction provides additional soil strength or bearing power is presented in Table 9. These data are the results of triaxial shear tests conducted on a number of soils, largely from the central and western semiarid areas of Kansas. The values in Cols. 9 and 12, Table 9, are the moduli of deformation of the soil tested, for a depth below the point of load application equal to the thickness of flexible surface required. Thus, a soil having a high modulus would require a thinner base course to support a given load than would a soil having a low modulus.

TABLE 9.—Subgrade Modulus for Soils Tested at Various Densities (Triaxial Shear Tests)

Sample No.	Class	Plastic index	Sand (%)	Clay (%)	Specific gravity	Test 1, Density Lower			Test 2, Density Higher

[a] Initial density (before saturation) in pounds per cubic foot. [b] Initial moisture content (before saturation), expressed as percentage of dry weight. [c] Modulus of deformation, in pounds per square inch, for a depth below the point of load application equal to the thickness of the flexible surface required. [d] The four samples indicated in Col. 1 were remolded in the laboratory. The remaining sixteen were obtained in an undisturbed condition from the existing roadbed.

The results of triaxial shear tests conducted on two types of samples are summarized in Table 9. One type is obtained by cutting out an undisturbed section of an existing roadbed and trimming it to proper size for testing, with a minimum of particle disturbance. The second type of sample is prepared for testing by compacting loose, moist soil into a mold of proper size. After the samples are either cut or molded to proper size, they are saturated by admitting a supply of water to the lower part of the sample and applying a vacuum to the upper part until free water is drawn through. Therefore, the two specimens prepared from each sample were treated in the same manner, the only difference being that one specimen existed at a lower density prior to saturation than the other. In each case, regardless of whether undisturbed or molded samples were tested, an increase in density resulted in an appreciable increase in the subgrade modulus value.

One specimen of each undisturbed sample was obtained from the extreme upper section of the roadway, representing a high-density stratum condition developed by the action of traffic. The density of such a sample is usually higher than standard density for the soil, and is always considerably higher than the density of the material below that stratum. Some of these crust-density values were so high that it was not possible to duplicate them in the laboratory using a large static load applied by a hydraulic compression machine.

A large proportion of the undisturbed samples was obtained from beneath flexible bituminous wearing surfaces that had been in place for several years. However, the high density condition in the crust, developed by traffic before the surface was constructed, still existed. Thus, soils similar to those in Table 9 do not undergo any appreciable loss of density with the passage of time if they have reasonable protection from surface moisture.

The data presented by Mr. Mullis and the limited quantity of data included in this discussion indicate definitely that high compaction of roadbeds is essential if the best possible use is to be made of materials that exist within the right-of-way limits. Although most of the data presented in this discussion have been within the present working range of densities (that is, those commonly obtained during construction), they indicate the need for research to determine the increase in durability and bearing power obtained by compacting soils to much greater densities than can be obtained with present compaction equipment. Such a research program might show that it would be more economical to spend more effort and money during construction to compact the soils that comprise the upper section of the road structure to an extremely high density than to spend the same amount of effort and money on expensive road surfaces.

René S. Pulido y Morales,[35] Esq.—Soil is the most important of the infinite varieties of material in a roadbed. For this reason and may others, engineers are developing the new science of soil mechanics and pedology in order to explore the properties of the different constituents of soils. Mr. Mullis' work is another valuable contribution to the science of pedology.

In the middle of the nineteenth century research investigators, in the fields of physics and chemistry, first approached a study, and thus gained an understanding, of the properties of gases and liquids in the soil, and of their influence on mechanical structures. In 1930, N. F. Lebedeff stated[36] that water occurs in soil as:

---

[35] Civ. Engr., Havana, Cuba.

[36] "Soil Water," by N. F. Lebedeff, Moscow, 1930.

(1) Vapor water in the voids, fissures, underground channels, and cavities;

(2) Hygroscopic water absorbed by soil particles from the vapor of the air (according to R. Rodewald[37] this water forms a monomolecular film on the particles;

(3) Film water, that covers the soil particles and is retained by gravitational molecular forces (this process is a continuation of the hygroscopic absorption in item 2);

(4) Gravity water, further subdivided as—

  (*a*) Capillary water that ascends from the phreatic water,
  (*b*) Suspended water that fills the pores of the soil but without communication with the phreatic water, and
  (*c*) Gravity water or free water that flows downward by gravity force;

(5) Solid water;
(6) Crystallized water; and
(7) Water containing chemicals.
